Paper No. 1239

THE SIXTH AVENUE SUBWAY OF THE HUDSON AND MANHATTAN RAILROAD.*

By H. G. Burrowes, M. Am. Soc. C. E.

With Discussion by Messrs. T. B. Whitney, Jr., William J. Boucher, Lazarus White, H. L. Oestreich, and H. G. Burrowes.

Introductory.

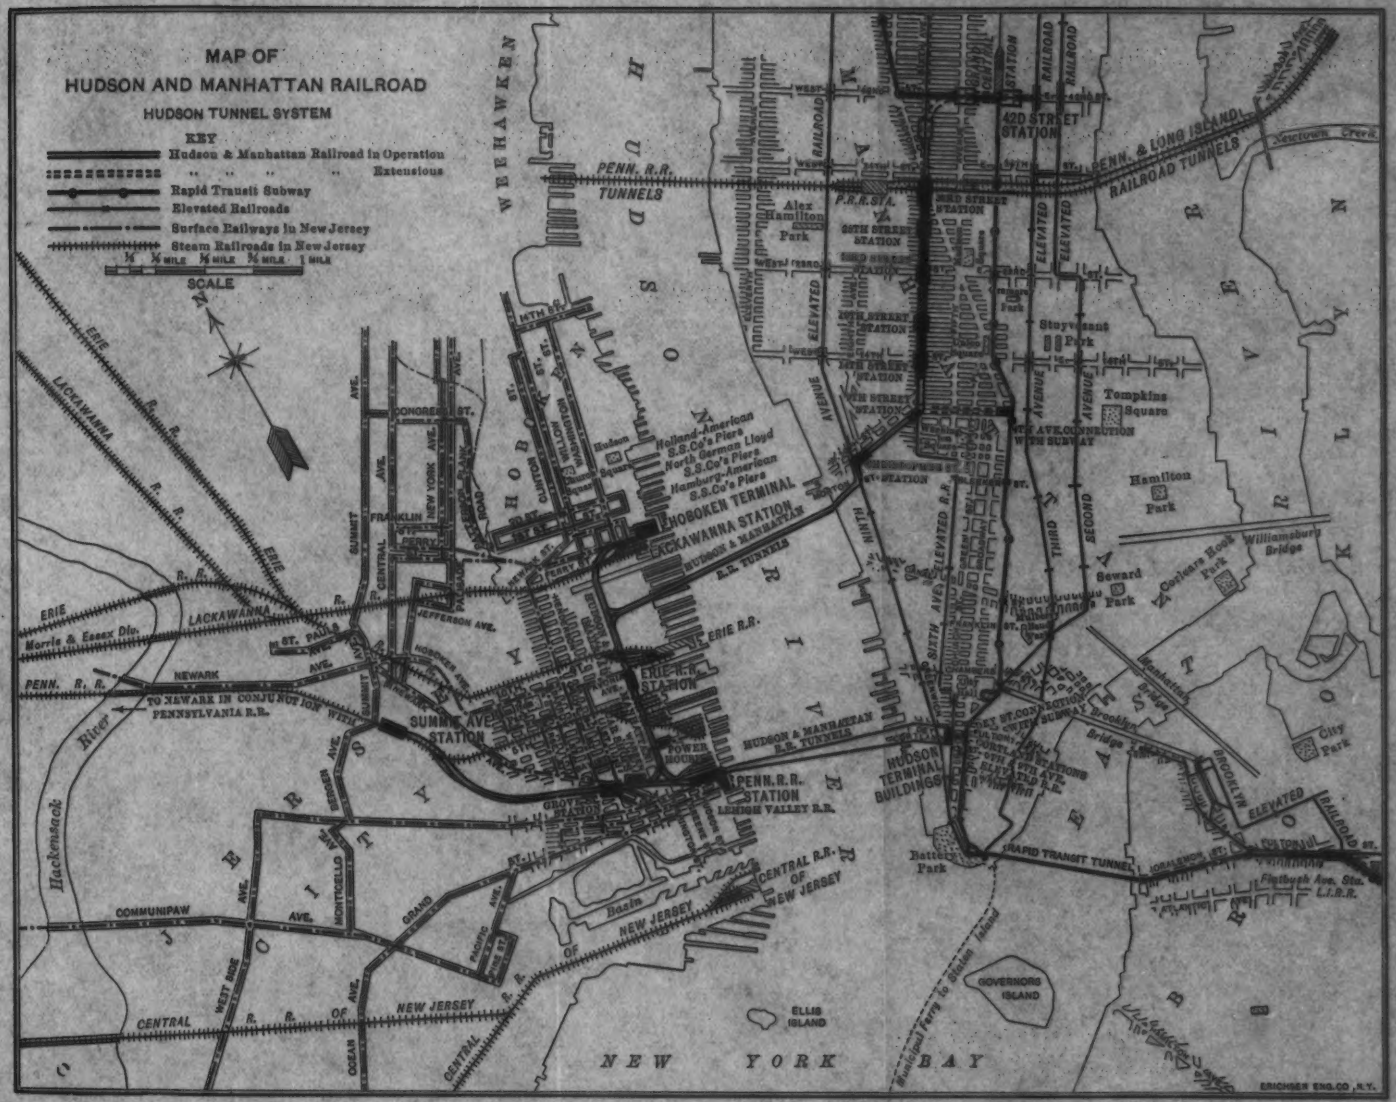
The Hudson and Manhattan Railroad work described in this paper is that portion built under Sixth Avenue between 12th and 33d Streets, New York City, as shown on Plate I. The general plan consists of a two-track, reinforced concrete subway in the center of Sixth Avenue from the end of the iron-lined tunnels at 12th Street north to and including a three-track station at 33d Street. The extension northward from this Station to the Grand Central Station was authorized by a later franchise, and is not considered in this paper.

There are five stations. Those at 14th, 19th, 23d, and 28th Streets are similar to one another in type and practically the same in detail, with the exception of the entrances. The 33d Street Station is more comprehensive in all its details, and the structure and its general arrangements and equipment call for particular attention, it being of a new type compared with the usual stations on New York City tunnels.

In prosecuting this work, it was necessary to support temporarily the entire elevated railway, the entire surface railway, and also all

* Presented at the meeting of October 2d, 1912.

the pipes and electric cable properties between 12th and 33d Streets. Before making the excavation, it was necessary to construct temporary channels for all existing sewers and then build new sewers, one on each side of the structure; support all vaults within the limits of the work; remove and replace all vaults, and support all buildings between 31st and 32d Streets, carrying their foundations down to sub-grade; replace the elevated and surface railways on permanent concrete and brick foundations resting on the roof of the structure; relay all pipes and electric subways in the street, supporting them on timber bents; replace the electric cables in new ducts; restore the water, gas, and electric services; back-fill over the subway; and relay the asphalt pavement.



Under the conditions of the franchise, the street surface had to be maintained for the unobstructed use of traffic. This made it necessary to bridge over the entire surface and maintain the planking in first-class condition. The franchise also required that no openings be made in the street planking other than those absolutely necessary for the economic prosecution of the work.

The subway and stations throughout are of reinforced concrete, and the columns in the stations are of steel or cast iron.

Standard Tunnel Section.—The standard tunnel section, shown on Plate II, was used between the stations and in the work between 27th and 33d Streets, but, between 12th and 27th Streets, the walls are 4 in. thicker. At the track cross-over enlargement, between the 19th and 23d Street Stations, the section was modified by the elimination of the center wall and by changing the roof from an arch to an I-beam, concrete construction, supported on the side-walls alone. There was also a modification between 12th and 13th Streets due to the widening of each tunnel in order to provide for the reverse curve in the tracks made necessary by the difference in track centers in the standard subway and in the iron-lined tunnel below 12th Street, the distance between the tracks being 13 ft. 3 in. in the standard subways and 17 ft. 6 in. in the iron-lined tunnels.

Standard Stations.—As shown on Plates II and III, the standard stations differ little in detail except in the entrances. These are built under the stairways of the elevated railway, with the exception of the east entrance of the 23d Street Station, which is through the store on the southeast corner; the east entrance of the 19th Street Station, which is through the store on the southeast corner; the west

PLATE I.

SIXTH AVENUE SUBWAY,
H. & M. R. R.

entrance of the 19th Street Station, which is through the store on the northwest corner; and the east entrance of the 14th Street Station, which is through the store on the southeast corner. Where entrances were made through stores, or private property, an agreement was entered into with the owners granting a right of way through the building. This was considered to be of advantage to the owners, as many patrons of the subway would pass through the stores, with consequent increase in their trade. At the points where such entrances were established it was necessary to make alterations in the interiors of the buildings.

The platforms of the stations rest on the foundations of the columns, on the side-walls, and on a brick wall under the overhang of the platform. At the 28th Street Station, however, a concrete girder was built, replacing the brick wall.

The roof of each station is of groined arches resting on the side-walls, the center-wall, and cast-iron columns.

Toilets are provided on each platform, and are drained by an automatic ejector operated by air power, which discharges into the sewers alongside the stations, with the exception of the 19th Street Station, where the sewer is below the level of the platform and the connection is made directly into it.

Floor drains were provided in the platforms and station entrances in the 14th and 19th Street Stations, but subsequent use has shown that they become clogged because so little water is passed through them in washing the platforms, and the dirt and sweepings remain in the drain heads. In the 23d and 28th Street Stations the platforms are sloped toward and drained to the track.

The cast-iron columns of the stations are 15 in. in diameter, 2 in. thick, and rest on bases having a bearing area of 2 304 sq. in. The area of the caps for the support of the concrete roof is 1 521 sq. in. The reinforcing rods are shown on Plate II, and need no description.

The Thirty-Third Street Station.—This is a three-track "through" station, as shown on Plate IV, and, for convenience in this description, will be taken to include the enlargement at the south end. Two enlargements were planned, one at each end of the station, to provide room for the track arrangements necessary to change from two tracks in the subway to three tracks in the station.

The station is built on rock foundation, and in general consists of

framed steel columns resting on concrete foundations, with side-walls and groined arch roofs and concourse floor. The roofs and the concourse floor are supported on the side-walls and on steel brackets riveted to the steel columns.

The columns of the elevated railway, excepting the two in the center of 32d Street, are supported on concrete piers based on steel grillages which span over, and distribute each column load on, four of the station columns. Each station column is in one piece, and passes through the concrete of the roof and the concourse floor. The elevated railway columns in the center of 32d Street are supported on steel towers made up of the extended columns of the station.

Over the enlargement, the elevated railway column foundations or piers rest directly on the roof, and under them extra girders are embedded in the roof for their support. These girders are supported by the side-walls and by steel columns in the center-walls.

The floor or invert of the station, between the foundations of the columns and the side-walls, is simply a concrete floor resting on the rock bed to carry the tracks, etc., and was planned to be 12 in. thick; but, owing to the unevenness of the rock surface as blasted out, it varies, sometimes reaching 3 ft.

All the station columns are 13 ft. 10 in. from center to center, and the groined arches, therefore, are in square panels and of the same radius, 8 ft. 3 in., in both directions.

The roof arches of the station are of reinforced concrete, 12 in. thick at the crown over the concourse, where the depth of fill was 10 ft., and 24 in. thick at the crown in the south end of the station, where the depth of fill varied from 18 to 20 ft.

There are five entrances to this station, as shown on Plate IV: three under the stairways of the elevated railway station at Sixth Avenue and 33d Street, covered with metal kiosks; one through the department store between 32d and 33d Streets, and one under Greeley Park, covered with an ornamental kiosk of artificial stone. In addition to these entrances which lead directly to the street, there are three stairways leading up to the street floor of the store between 32d and 33d Streets. There are, therefore, eight entrances, all leading to the concourse floor of the station.

The station is 387 ft. long on the train platforms, providing for the unloading of 8-car trains, and, throughout its entire length,

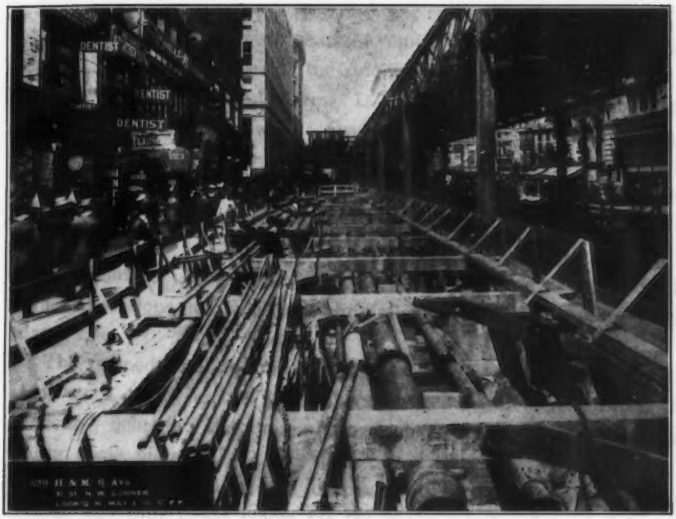

FIG. 1.—GENERAL VIEW OF STREET CONDITIONS WHILE RELAYING PIPES ON SIXTH AVENUE.

FIG. 2.—ROCK EXCAVATION IN ONE OF THE LARGE PITS.

occupies the full width of Sixth Avenue, being 94 ft. 10 in. wide between the interior faces of the side-walls.

There are two side platforms, 15 ft. 1½ in. wide, and two center platforms, 18 ft. 5 in. wide. Over the northern half of the train platform, between 32d and 33d Streets, there is a concourse, the full width of the station and 152 ft. long. Leading to this concourse there are twelve reinforced concrete stairways, three to each of the four platforms.

The roof is of groined arches of the same type as used in the standard stations, and the walls throughout are lined with ornamental glazed tile.

The framed steel columns of the station are encased in artificial stone slabs, made on the work, and the twelve stairways between the concourse floor and the train platforms have railings and balustrades of the same material.

At the north end of the concourse there are toilets, telephone booths, and four ticket offices for the various railroads served by the tunnel trains. At the south end there are two porter's rooms and a fan-room for the exhaust fan which discharges the foul air from the subway.

A signal tower and a battery-room are at the south ends of the two center platforms for the operation of the mechanism of the cross-over, etc., of the track in the enlargement. The same provision for tower and battery-room will be made at the north end of the station when the extension is built.

Under the Sixth Avenue front of the department store between 32d and 33d Streets on the west side of Sixth Avenue, and at the level of the platform, there is a large baggage and storage-room, 194 ft. long and 69 ft. wide, with access to the west platform, for the handling of baggage. This baggage-room has a large baggage chute and an escalator for raising and lowering parcels, etc., between it and the street level at 33d Street. On the 33d Street side of the same store building there is an entrance and handling-room, at the heads of the chute and escalator, so that baggage by truck, etc., may be received from and delivered at the street level.

Over the north end of this baggage-room and at the level of the concourse floor, there is a parcel check-room which is connected with

the large baggage-room below by a small chute and dumb-waiter for small parcels.

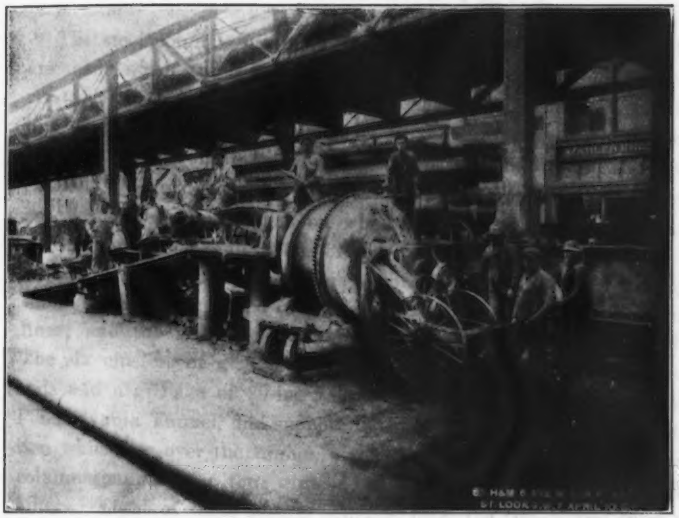
This station has four electrically-operated fans, two at the south end of the concourse, for the discharge of foul air from the subway, and two at the south end of the large baggage-room, for the supply of fresh air to the station. The exhaust fan draws the foul air through a reinforced concrete duct laid on the roof of the station and subway from a point north of the end of the 28th Street Station, which is the high point in the grade of the east or up-town tube. The fresh-air fan supplies the air through a concrete duct laid below the foundation of the station, at right angles to the track. This duct has openings under the platforms with louvers through which fresh air is supplied. The foul air is discharged through an opening in Greeley Park; the fresh air is taken in through an opening beside the department store at 32d Street.

Two automatic ejectors, one in the middle of the station, under the west center platform, and one at the north end of the same platform, are operated by compressed air. They are set in sumps which collect the drainage of the subway and station at this point. The ejector at the north end of the platform also collects and discharges the drainage of the toilets. These ejectors lift the drainage 30 ft., and discharge it directly into the sewers.

The concourse floor is of the same type as the roofs, the thickness being 6 in. at the crown of the arches.

The platforms are of 8-in. reinforced concrete slabs resting on 13-in. reinforced girders, the ends of which are carried on the concrete jackets around the bases of the steel columns and on the side-walls. These concrete girders and slabs were built in one operation. The tops of the platform and entrance floors are finished with a 1-in. coating of granolithic pavement which was laid as soon as the concrete had set sufficiently.

Structural Steel.—At 32d Street, where the station crosses the Pennsylvania Tunnel, the track level or grade line passes through the arch of the roof of that tunnel. It was necessary, therefore, to remove the reinforced concrete arch of the tunnel and replace it with heavy girders resting on the tunnel walls. The columns of the station and the track and platforms rest on these girders.



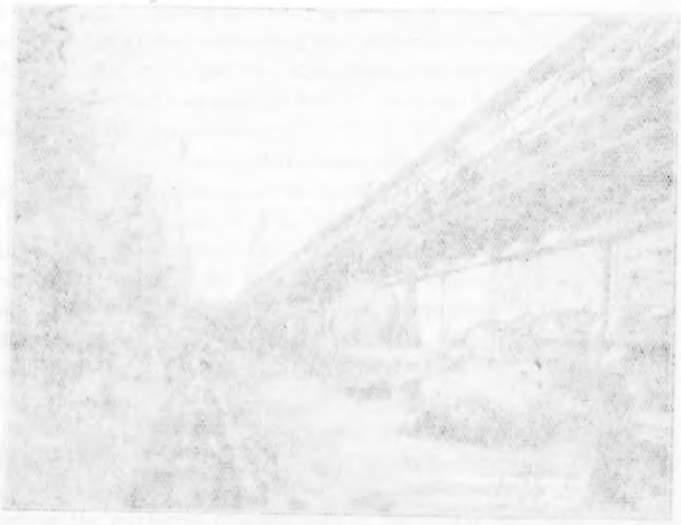


FIG. 3.—CONCRETE MIXER AND GANG.

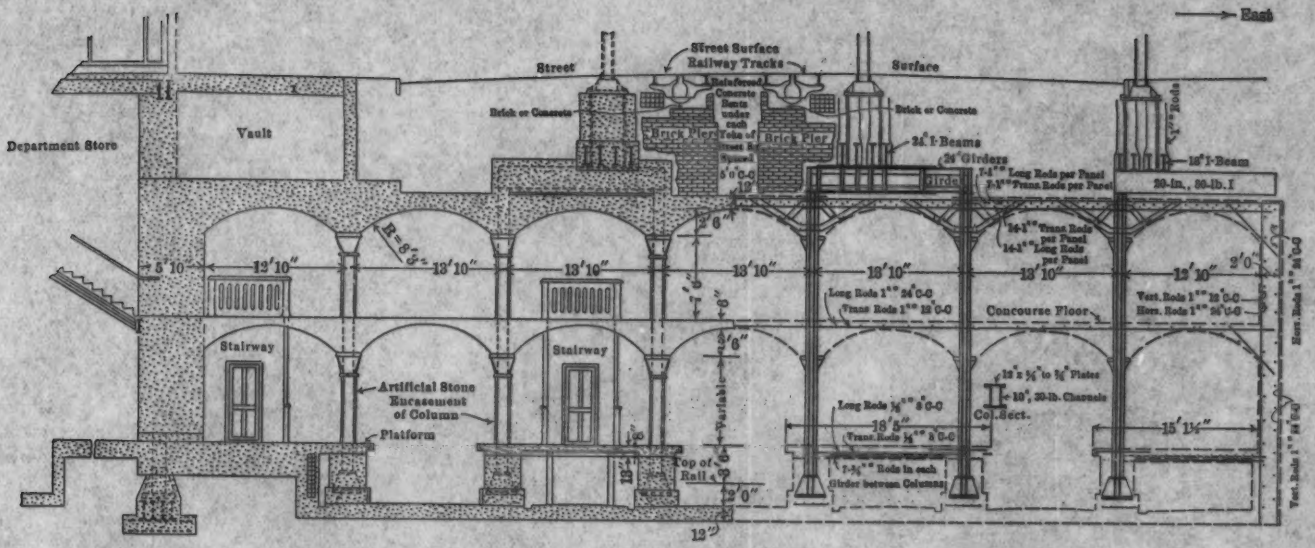
FIG. 4.—CABLEWAY ON SIXTH AVENUE.

The steel columns of the station, as shown on Plates II and IV, are made up of two $\frac{5}{8}$ to $\frac{3}{4}$-in. plates and two 10-in., 30-lb. channels riveted to form box columns, and these have brackets at the springing line of the arches for their support. The bearing areas of the base castings vary from 961 to 1296 sq. in., depending on the loads carried. The grillages on top of the station columns consist of three and sometimes four girders on which rest the four 24-in. I-beams which support the foundations of the elevated railway columns.

The twenty-four heavy girders spanning the walls of the Pennsylvania Tunnel are grouped in clusters of four under the station column lines; and the four I-beams are in two pairs near the side-walls. The six clusters of girders rest on steel billets placed between their ends and a grillage of 20-in. I-beams embedded in the walls of the Pennsylvania Tunnel, and support the twenty-four columns of the station which are over the tunnel, a steel billet being placed under each column spanning the four girders. The columns are anchored to the billets. Eight of these station columns form the two towers supporting the two elevated railway columns in the center of 32d Street. These eight columns pass through the concrete roof of the station.

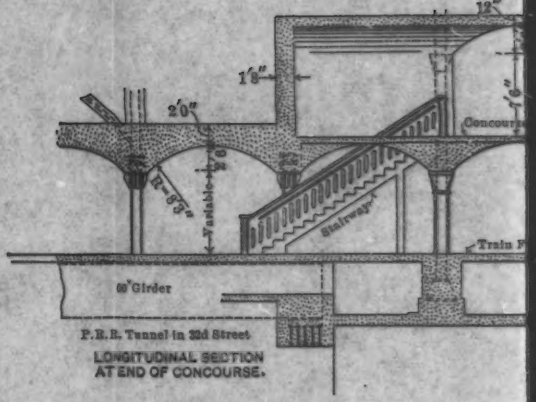
The track is carried across the Pennsylvania Tunnel on a steel trough flooring resting on angle steps fastened to the webs of the outer girders of each group. The ties of the track are laid in this trough floor, as shown on Plate II.

Steel Reinforcing Rods.—In each panel of the roof over the concourse there are two sets or grids of rods laid so that the nearest rod is 2 in. below the top face of the concrete and 2 in. above the crown of the arch. The upper set of rods in each panel is composed of seven 1-in. square rods laid each way, transversely and longitudinally. The lower set is composed of fourteen 1-in. square rods laid each way in each panel. In each panel of the roof over the south end of the station, where the load is greater, the upper set of rods is 6 in. below the top surface of the concrete and consists of seven 1-in. square longitudinal and fourteen 1-in. square transverse rods per panel. The lower set is 2 in. above the crown of the arch and of the same number per panel both ways as in the upper set. In the concourse floor there is only one set of rods, and these are 2 in. above the crown of the arch, there being fourteen transverse and seven longitudinal rods per panel, and all are 1 in. square. Around the steel columns (where



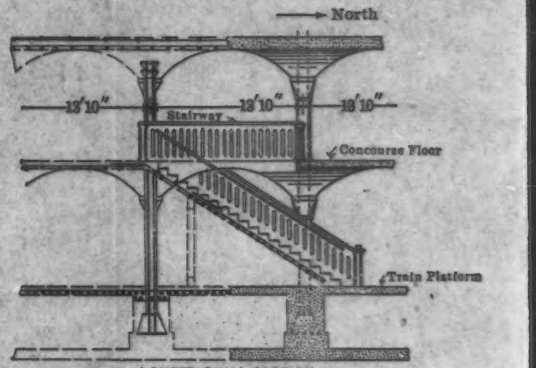
they pass through the roof) there are additional special bent rods as shown on Plate II, in the form of a basket cluster. The reinforcing rods in the side-walls are 1 in. square, and 2 in. from the faces of the walls. The vertical inside rods are 12 in. from center to center and the horizontal rods 24 in. from center to center. The vertical outside rods are 9 in. from center to center and the horizontal rods 24 in. from center to center. The rods in the platform girders and slabs are 2 in. from the lower sides. There are seven ¾-in. square rods in the bottoms of each girder and ½-in. square rods 8 in. apart each way in each slab or panel formed between the columns of the station.

There are 1-in. square rods 2 in. from the outside faces of the 5 by 5-ft. elevated railway column piers, and 11 in. from center to center, to reinforce the piers, because it was impossible to increase the areas of the bottoms of the piers, owing to the position of the steel grillages supporting them. This reinforcement in the column piers was placed where the depth exceeded 6 ft.



Station Finish and Decoration.—After the completion of the station walls, floors, roofs, and platforms, the interiors were finished and decorated. The floors and platforms are finished with a granolithic top. The side-walls are tiled throughout, from the floors to the springing lines of the roof arches, with 6 by 6-in. white tile with green trim, laid in a mortar bed. All the stairways are equipped with wooden hand-rails, and the steps with iron safety treads embedded in the granolithic top finish. The ceilings and the faces of the center walls are finished with a wash of white cement and white sand or marble dust, applied with a brush. In the stations at 14th, 19th, and 23d Streets, the ceilings were first plastered to give a smooth appearance, but this was not done in the 28th and 33d Street Stations because it was decided that the form marks, or visible lines left by the lagging, were not detrimental to the appearance, as they conformed to the lines of the arches.

The iron railings at the ticket booths and the cast-iron columns are painted with an enamel green, conforming to the station color. The woodwork of the ticket booths, etc., is painted or varnished to conform to the color of the station.



The steel columns of the 33d Street Station are encased in moulded slabs made of white cement and marble dust, and the railings and

balustrades of the stairways between the train and concourse floor, are of the same material. All this artificial stone was made on the work.

Enlargement.—The enlargement south of the 33d Street Station is on rock foundation, and in general consists of one or two center-walls, excepting at the track cross-over, and two side-walls, all resting on rock. These walls support a flat roof made up of steel girders embedded in concrete on which rest the elevated railway, the surface railway, the street, etc. This enlargement is 280 ft. long, between the standard tunnel and the 33d Street Station, 27 ft. 3 in. wide at the south end and 92 ft. 4 in. wide at the north end. The thickness of the side-walls is 18 in. at the south end and 24 in. at the north end. The center wall is 15 in. thick, embedding the steel columns supporting the roof girders.

Street Surface Car Tracks.—The surface car tracks, shown on Plates II, V, and VI, are supported by brick piers and reinforced concrete bents under each yoke of the car track, 5 ft. from center to center. Over the concourse, and where the depth between the yokes of the street car tracks and the top of the roof is less than 7 ft., the piers are of brick and rest on the roof of the tunnel and stations. These piers are built transversely across the street car tracks. Over the south half of the 33d Street Station and over the enlargement and tunnel, where the depth between the car track yokes and the top of roof is from 7 to 17 ft., there are reinforced concrete bents. Two plain concrete girders, 24 in. wide and 4 ft. deep, are set longitudinally in order to distribute the loads of the reinforced concrete bents. These bents were cheaper than brick piers for depths exceeding 7 ft. The legs of these bents rest on the plain concrete girder built on the roof.

Buildings.—The architects of the store building on the west side of Sixth Avenue between 32d and 33d Streets, having the construction of the subway in mind, carried the column foundations of that building down to the sub-grade of the tunnel, so that it was not necessary to underpin this building. Between 31st and 32d Streets on both sides of Sixth Avenue it was necessary to support the buildings temporarily and carry their foundations down to rock or to sub-grade.

Drainage.—In addition to the two sumps in the 33d Street Station, there are two others to provide for the drainage of the subways.

These are equipped with automatic ejectors which discharge into the sewers.

Air Line.—An air line in each tube supplies compressed air for operating the signals, pumps, or ejectors, and for the use of air tools and in making necessary track repairs. These air lines are of wrought-iron pipe, and are reduced in diameter from 8 in. at 12th Street to 3 in. at 33d Street.

Subway Ducts.—There is a duct bank in each tube between 12th Street and the 33d Street Station. There are splicing chambers at each end of each station in both tubes, and also between stations, where necessary to shorten the length of cable haul.

Water-Proofing.—The subway and stations between 12th and 27th Streets are water-proofed with the regular burlap and pitch, and between 27th and 33d Streets with a compound or powder mixed with the concrete.

General Methods.

From 12th to 27th Streets.—The first step, as shown on Plate V, was to excavate pits between the columns of the elevated railway to or near sub-grade, and, in them, build up the timber bents to carry the girders which supported the elevated railway columns.

Between 12th and 18th Streets (excepting at 14th Street and because of wet foundation), pits were dug to within 8 or 12 ft. of sub-grade, between the elevated railway bents to be supported in the first operation, then timber piles were driven in the bottoms to hardpan or rock, and timber bents were built and framed on the piles to support the girders. These bents were carried above the street surface, and carried the I-beams or girders supporting the elevated railway columns.

Between 18th and 20th Streets, the pits between the elevated railway bents were carried down to sub-grade, the subsoil being dry. Between 20th and 27th Streets, the pits were carried down to rock, and on it the timber bents were built.

After the elevated railway columns were underpinned in the first step, the cores of excavation, between the pits and under the columns, were removed, as shown at *A*, and the piece or length of subway or station under each column supported was built. The column was then set on its final foundation on the roof of the subway or station, as shown at *B*. Then the timber bents between *A* and *B* were removed,

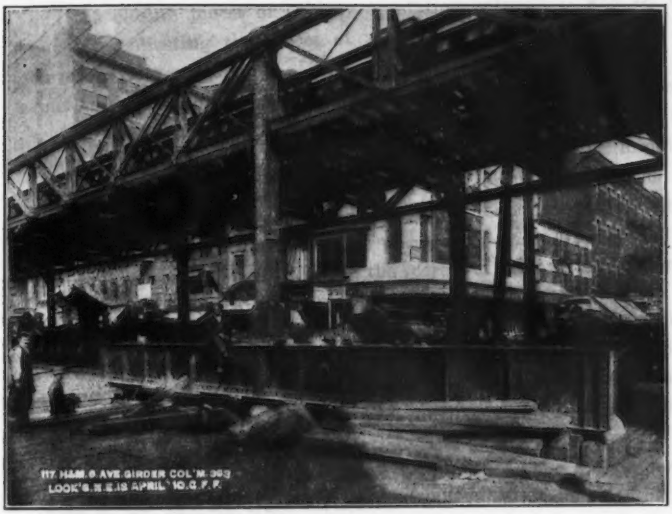

FIG. 5.—COLUMNS OF ELEVATED RAILROAD SUPPORTED ON 36-INCH GIRDERS.

FIG. 6.—ELEVATED RAILROAD SUPPORTED BY OVERHEAD TRUSSES.

and the closure pieces of subway or station between *C* and *D*, were put in, connecting the pieces of subway or station built under the elevated railway columns. The condition after this step was that four of the elevated railway bents, or eight columns, in any one block rested on their final foundations on the roof, and the only remaining columns were those at the street intersections and in the middle of the blocks, which were still on their original brick foundations. The next step, therefore, was to support these remaining two bents or four columns on the other legs of the timber bents already built in the first operation, and remove the cores of excavation under the columns. The pieces of tunnel or station under these columns were then built and the columns were set on their final foundations on the subway roof. The girders and timber bents which last supported these columns were removed and then the closure pieces of subway or station were built. Meanwhile, during the completion of the closure pieces of subway or station, the brick piers for the final foundation of the surface car tracks were built on the roof under each yoke of the surface track structure. The duct benches of the track structure were built on a dry rock packing wall laid up between the brick piers and resting on the roof of the tunnel or station, as shown at *D*.

The sewers were built as the work progressed, and the spaces behind the walls and over the subway or stations were back-filled and puddled to within 7 ft. of the street surface.

Timber bents were built every 6 ft. on each side of the subway on firm foundations of earth or rock, as the case might be, to support the gas and water pipes and electric duct lines, and prevent settlement with the fill.

The gas and water pipes and electric duct lines were then relaid, and the street was back-filled and puddled, up to the surface. A temporary block pavement was laid on the fill at the level of the street surface; this was left in place until the fill had settled sufficiently, and then the asphalt pavement was put down, completing the work.

From 27th to 31st Streets.—The methods and progressive steps in this section were similar to those in the blocks between 12th and 27th Streets, the only essential difference being in the first operation, which was to underpin temporarily the columns of the elevated railway, and, after the removal of the earth excavation, to build

temporary concrete foundations under these columns from the top of the rock, so that they rested thereon and were in safe condition for the excavation of the earth and rock under those adjoining. The foundations of the columns in the center of the cross streets and in the middle of the blocks were carried down to rock temporarily, and then the succeeding operations were similar to those in the work between 12th and 27th Streets.

From 31st to 33d Streets.—The 33d Street Station.—The methods in this section, as shown on Plate VI, differed from those in the work between 12th and 31st Streets, owing to the following conditions: The station occupied the full width of Sixth Avenue, 100 ft.; the station roof was to be of the groined-arch type; and the positions of the elevated railway columns were eccentric with reference to the station columns. For these reasons, it was necessary to build larger pieces of station under the columns in order to provide a safe foundation for them while excavating the adjoining cores. It was found necessary to support the elevated railway columns in such a manner that there would be sufficient space between the temporary column supports in which to build these larger pieces of station under the columns.

The first step was to underpin temporarily the alternate columns and carry their foundations down to rock by temporary foundations of concrete. This, of course, made these columns safe while the intermediate cores of rock were being excavated. Large overhead trusses, resting on the temporary concrete foundations of the alternate columns, were then erected to support the intermediate columns. Then light steel trusses were placed under the street surface planking, spanning the space required for the section of station to be built, and the street surface and all pipes and other properties in the street were supported on them. This left the entire space between the bearings of the light trusses free from encumbrances such as timber or other supports of the street. The rock under the columns supported on trusses was then excavated, and sections of station were built up under them. Then these columns were placed on their final foundations, supported by the steel columns of the station. After this operation, the trusses were removed and the columns, which had been first underpinned temporarily, were again underpinned and the temporary foundations and rock cores were removed from under them. The closing sections

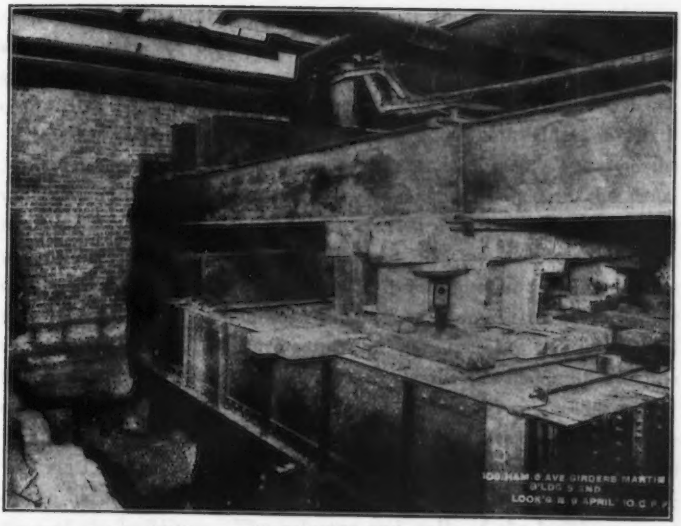

FIG. 7.—STEEL UNDERPINNING OF A COLUMN OF THE MARTIN BUILDING.

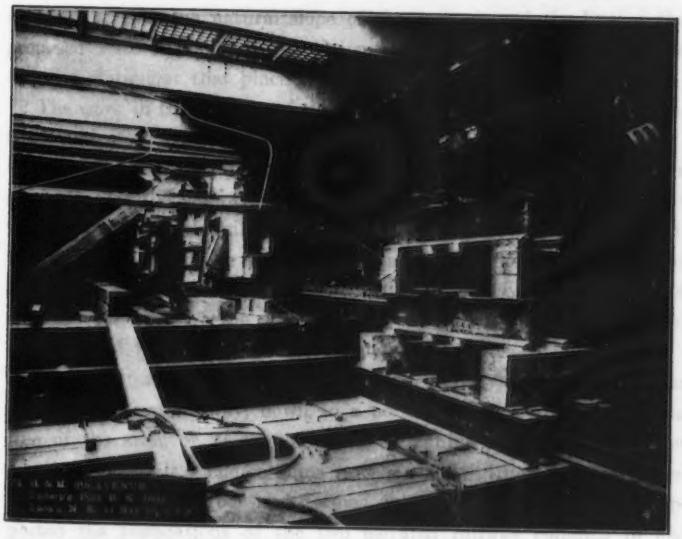

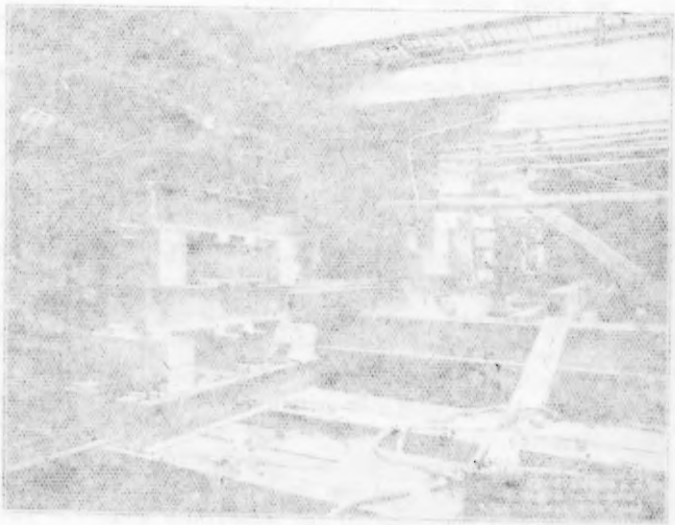

FIG. 8.—STEEL UNDERPINNING OF A COLUMN OF THE BROWNING-KING BUILDING.

or lengths of the station were built under these remaining columns and they were set on their final foundations carried on the steel grillages supported by the steel columns of the tunnel station, thus completing the gaps between the pieces of station first built.

During these operations, the buildings on both sides of Sixth Avenue between 31st and 32d Streets were underpinned. Those on the west side (from four to six stories) were underpinned in the usual manner, and their foundations were carried down to solid rock. The underpinning of the buildings on the east side, was a different matter, as the slope of the rock required that it be removed from under the faces of the buildings and to a distance of from 15 to 20 ft. inside the building line. To insure safety, it was necessary to excavate all the rock to the stratum the toe of which cleared the inside lines of the new foundation walls of the buildings at the tunnel sub-grade.

In underpinning these buildings, the rock excavation for the subway station was carried east as far as the point at which the top of the natural slope of the strata safely cleared the original foundations of the buildings. The columns and walls of the buildings were then underpinned, as shown on Plate VI, and the rock prism was removed so that the natural slope of the rock cleared the line of the proposed wall. Then the foundation was carried down to sub-grade and the station at that place was completed.

The work in the interior of the station was then prosecuted, and the track and other details were completed.

The Crossing of the Pennsylvania Tunnel at 32d Street.—The grade line of the subway passed 5 ft. 6 in. below the top of the roof arch of the Pennsylvania Tunnel. This required that this arch, 5 ft. thick at the crown, be removed and a steel girder construction be built, as shown on Plate II. The elevated railway columns resting on the roof arch of the Pennsylvania Tunnel were supported temporarily and the tunnel arch was removed.

The reinforced concrete arch of the Pennsylvania Tunnel was drilled and blasted away, down to a point 10 ft. above the springing line of the arch, or 2½ ft. above the mezzanine floor, and the girder crossing was built. The columns resting on the girder crossing passed through the station roof and formed the towers on which were supported the foundations of the two elevated railway columns in 32d

Street. The four platforms of the station were supported by these girders and I-beams.

Underpinning the Elevated Railway.

From 12th to 31st Streets.—It will be readily seen that the existence of the Sixth Avenue Elevated Railway structure over the proposed location of the tunnels was the controlling factor in determining the method of prosecuting the work. With the exception of about ten of the lighter columns (those supporting the station platforms beyond the lines of the excavation), the entire elevated railway structure was supported temporarily and placed on new foundations on the roof or walls of the subway.

It was specified by the Interborough Rapid Transit Company that the maximum number of main structure columns removed from their original foundations at any time and supported temporarily should be four bents of two column each, out of the six bents in any block of Sixth Avenue. Between 12th and 31st Streets it was decided to adopt a system of underpinning four bents and leaving two bents on their original foundations for the anchorage of the structure while carrying on the work. In any block, therefore, the usual plan was to leave the columns at the street intersections and in the middle of the blocks on their original foundations and to underpin the other four bents, and, after setting these four bents on their final foundations on the roof of the tunnel or stations, to underpin the first two bents and set the four columns on their final foundations. At some points, such as at 14th, 18th, 23d, and 28th Streets, this system was modified, but, in general, it was followed.

The loading on each elevated railway column was 45 tons on those between the stations and from 45 to 80 tons on those at the stations.

It will be readily seen that, as the elevated railway is a pin-connected structure, it was possible to support it only at the columns.

To support these columns, brackets, with the same spacing of rivet holes as the columns, were made, having from twelve to twenty-four 1-in. holes in each. Rivets were knocked out of the columns of the elevated railway structure at the places where brackets were to be fastened, and the brackets were riveted to the columns through the rivet holes of the columns. The number of rivets in the brackets and the sizes of the brackets depended on the loading of the columns. The

FIG. 9.—STEEL PLUGS AND LATERAL BRACING OF COLUMNS USED IN UNDERPINNING THE BROWNING-KING BUILDING.

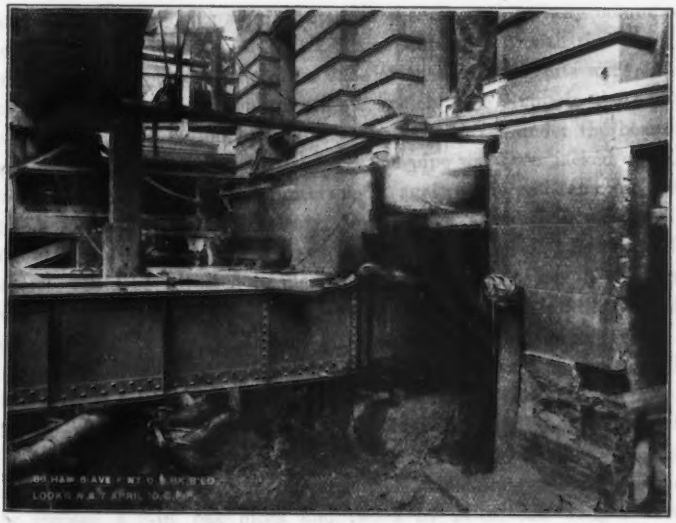

FIG. 10.—GIRDER NEEDLES USED IN SUPPORTING THE BANK BUILDING.

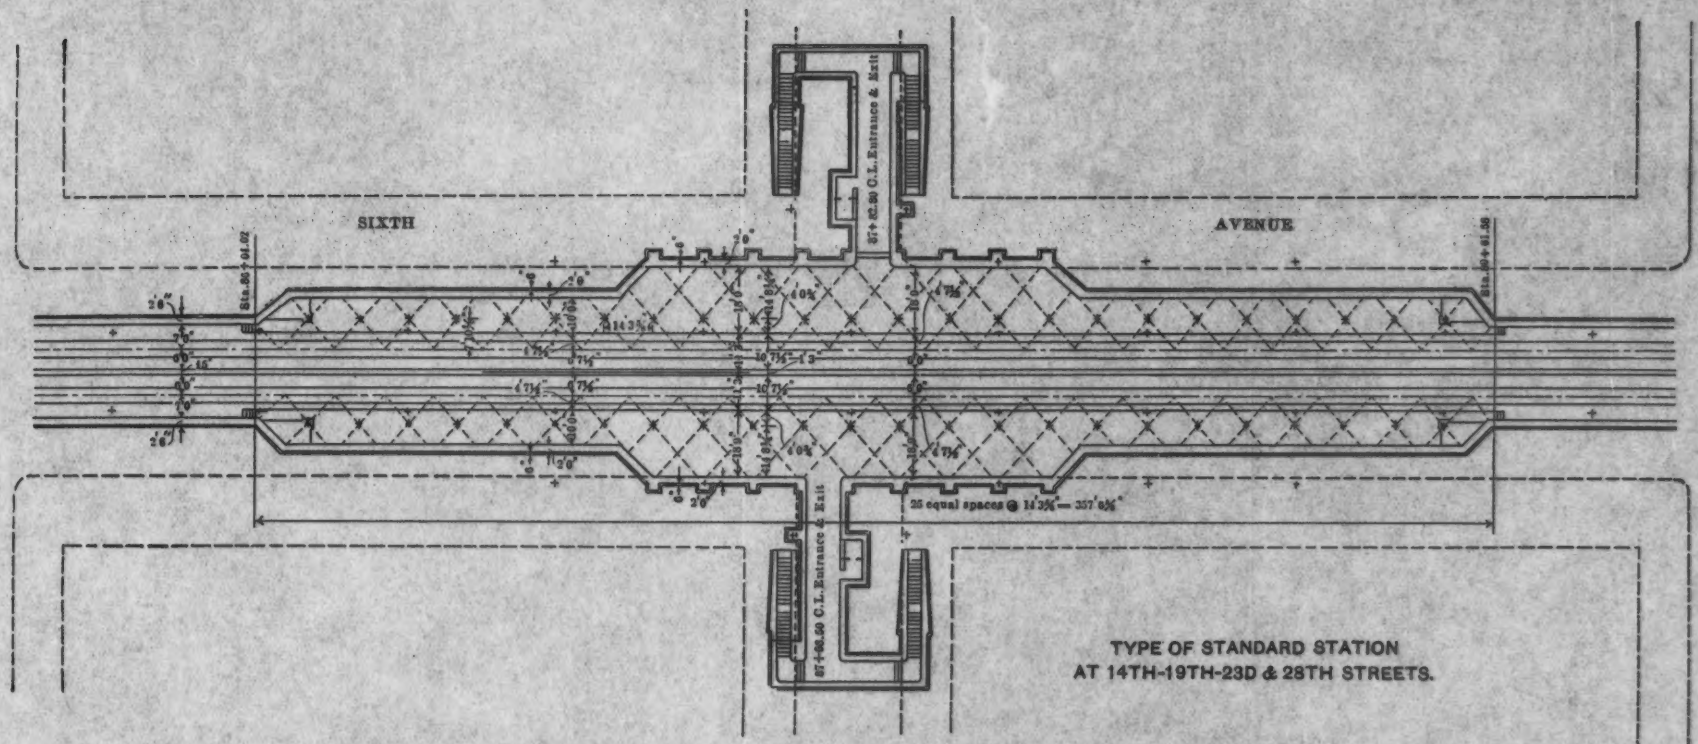
underpinning or framing for the temporary support of each column of the elevated railway was made up of two timber bents supporting the two 24-in. I-beams, 26 ft. long (or 36-in. girders, 39 ft. long), on which rested the column brackets already described. These timber bents were made up of two 12 by 12-in. legs, a 12 by 12-in. cap, and a 12 by 12-in. sill which rested on the concrete floor or on piles in the bottom of the pits dug to receive the underpinning timbers. When wet soil was encountered in the pits at or near the sub-grade of the tunnel, timber piles were driven in the pits down to hardpan or rock, and the timber bents were framed on them. Four timber piles were driven for each timber bent, or eight for each elevated railway column. These piles were driven with an ordinary steam pile-driver running in the leads of a common pile-driver frame provided with drop leads to allow the steam hammer to be lowered below the surface of the street.

Between 17th and 18th Streets, which was one of the localities where the foundation was wet, the station of the elevated railway prevented the use of the pile-driver, because there was not clearance enough for the frame, and here pipe piles were driven with the aid of jacks and a water jet. These pipe piles were driven in the following manner: Two brackets were riveted to the elevated railway columns to be supported, and two 24-in. I-beams were placed with their ends under the brackets. At the other ends of the I-beams, pits were dug to receive the pig-iron counterweights, which were slung to the ends of the beams. A 60-ton hydraulic jack was then set under the beams and on top of the pipe to be driven. The pipe was then jacked down, using the two beams as a counterweight against the resistance of the pile. The columns, if necessary, would have afforded a weight of 60 tons, at one end of the beam, and the weight of pig iron, of course, could be adjusted to meet any weight equal to it. The pipes were driven in small lengths, which were screwed on, one after the other, as each pipe was driven.

As shown on Plates V and VI, the timber bents were braced transversely and longitudinally with 6 by 12-in. timbers, and steel knee-braces were placed between the timber legs and the bottoms of the beams or girders. These braces were made up of two 4 by 3 by ⅞-in. angles. Between the brackets on the columns and the beams or girders, a 2-in. oak block and two 2 by 24-in. oak wedges were inserted, by which the column was raised in cases of small settlement.

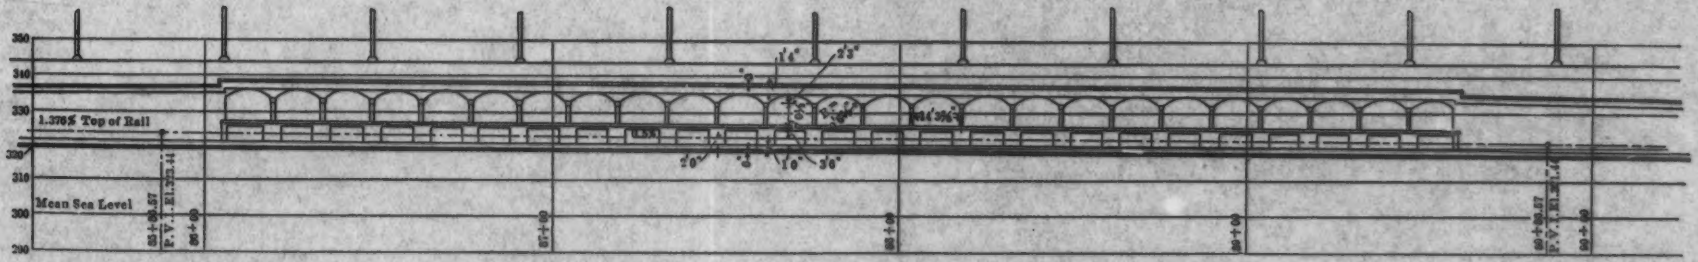
The columns of the elevated railway were maintained at all times within 1½ in. of their original elevations.

At the commencement of the work each column of the elevated railway was supported on two 24-in. 100-lb. I-beams, 26 ft. long, which rested on the timber bents, but this required the digging of two pits between the columns, or two pits for each column. This process was so slow, so expensive in excavation, and reduced so much the sizes of the pieces or lengths of subway to be built under each column in the first operation, that the span of the underpinning beams was increased by substituting for the I-beams two 36-in. girders, 39 ft. long.



It is evident that this improvement in framing the temporary underpinning greatly facilitated the work of building the subway, and effected a large saving in time and money. The digging of one pit 14 ft. wide, north and south, for each column, instead of two pits 8 ft. wide per column, greatly reduced the cost of the excavation of the subway, as it was practically as cheap to dig the 14-ft. pit and erect the timber tower in it as it was to dig one 8-ft. pit and erect the single bent in it with the framing. This was especially noticeable in wet ground.

When the 39-ft. girders were adopted, two timber bents were placed under the ends of the girders, 6 ft. from center to center, and framed together in the form of towers in the pits. This massing of the timber bents and framing removed much of the obstruction to the concrete work of the subway.



At the stations of the elevated railway, the columns had greater loadings. Where there were the heaviest loads, 42-in. girders were used, with the same spans as the 36-in. girders, or the span of the latter was decreased. The 36-in. girders were made up of $\frac{5}{16}$-in. webs, four 6 by 4 by $\frac{9}{16}$-in. base angles, and thirty-two 5 by 3 by $\frac{5}{16}$-in. and $\frac{7}{16}$-in. angle braces or stiffeners. The 42-in. girders were made up of $\frac{3}{8}$-in. webs, four 6 by 4 by $\frac{5}{8}$-in. base angles and thirty-two 3 by 3 by $\frac{5}{16}$-in. and $\frac{7}{16}$-in. angle braces or stiffeners.

From 31st to 33d Streets.—After every alternate column of the elevated railway had been temporarily underpinned, a temporary concrete foundation was built up under it from the rock, so that the columns would be carried safely on the rock while the excavation was being done under the intermediate ones. These temporary concrete

TYPE OF STANDARD STATION
AT 14TH-19TH-23D & 28TH STREETS.

foundations were made large enough to support the ends of the large trusses, as shown on Plate VI. The steel trusses were then erected on the temporary foundations, and had a span of 75½ ft. The top chords of the trusses were bolted to the elevated railway columns, through the rivet holes of the columns (from which the rivets had been removed), and a bracket was riveted to the outside faces of the columns above the outside girders of the trusses. An oak block and oak wedges were inserted between the outside girders and the bracket and between the inside girders and the transverse floor-beams of the elevated railway structure at the columns, to give additional bearing on the trusses. Each truss at each column was made up of two girders, 62 ft. long, supported by two box posts, or legs, framed into the ends of the girders with a bottom chord composed of two 8-in. channels attached to the bottoms of the legs by a pin connection. The pins connected the legs and a cast shoe which rested on a grillage of three 8-in. I-beams, the latter being embedded in the temporary concrete foundations. The girders were made up of ⅜-in. webs, four 6 by 6 by ¾-in. base angles, sixteen 6 by 6 by ¾-in. angle braces, or stiffeners, and six 1-in. cover-plates, three at the top and three at the bottom. The posts or legs were made up of two ⅜-in. plates and two 15-in., 35-lb. channels.

On the completion of the lengths of station under the elevated railway columns which were supported by the trusses, the columns were set on their final foundations, supported by the steel columns of the tunnel station, and then the trusses were removed. The elevated railway columns which were on temporary concrete foundations were again underpinned on girders in the same manner as used in the general underpinning between 12th and 31st Streets.

The columns of the elevated railway at the curb lines, which were not main structure columns, were underpinned either in the same manner as between 12th and 31st Streets or were supported on the street surface itself, where it was simply necessary to carry their foundations down to the rock or to the sub-grade of the subway.

Underpinning Buildings.

All the buildings on Sixth Avenue between 31st and 32d Streets, except those on the northeast and northwest corners of 31st Street, which are only 20 ft. front, were supported temporarily while their

foundations were being carried down to rock or to sub-grade. Before the work was started, arrangements were made with the tenants for underpinning and restoring the buildings. On the west side the buildings were of brick, from four to six stories in height. They were underpinned in the usual manner, and before the excavation was well under way in this block, 24-in. I-beams being set under the walls and supported on timber blocking inside the buildings and outside in the excavation for the tunnel. A trench was then excavated to the rock and a 3-ft. concrete wall was built from 2 to 3 ft. below the original foundations, and with its outside face at the building line of Sixth Avenue. The brick walls of the buildings were built on this concrete wall and then the I-beams were removed. The excavation of the rock below the bottom of the concrete wall was done in the usual manner by "line-holing" the rock to make a straight and even break, as the station extended the full width of Sixth Avenue and to within 7 in. of each building. The reason for carrying the foundations of the buildings on the west side of Sixth Avenue to the rock only, and not to sub-grade, was the fact that the strata dipped northeast, and thus aided in making the excavation of rock in front of the building safe.

The four buildings underpinned on the east side were: A 20-ft. front, four-story brick, between two large buildings; a 59-ft. front, eleven-story, steel frame building, designated as the "Martin Building," which was shored at all points, with the exception of the south wall; a 59-ft. front, eight-story, steel frame building, with cast-iron columns, designated as the "Browning-King Building"; and a 40-ft. front, five-story, granite and marble-faced building, without steel framing, designated as the "Bank Building." These buildings are shown on Plate VI.

The rock was removed as close to the existing foundations as safety allowed, the buildings were shored up, the rock was removed from under their fronts, and then their foundations were carried down to sub-grade.

The Martin Building.—The front of this building was carried on four framed steel columns, the two end ones being embedded in the side-walls. It was necessary to shore up the north wall and column and the two center columns. The south wall and column rested on rock, and, being at a safe distance from the excavation, required no

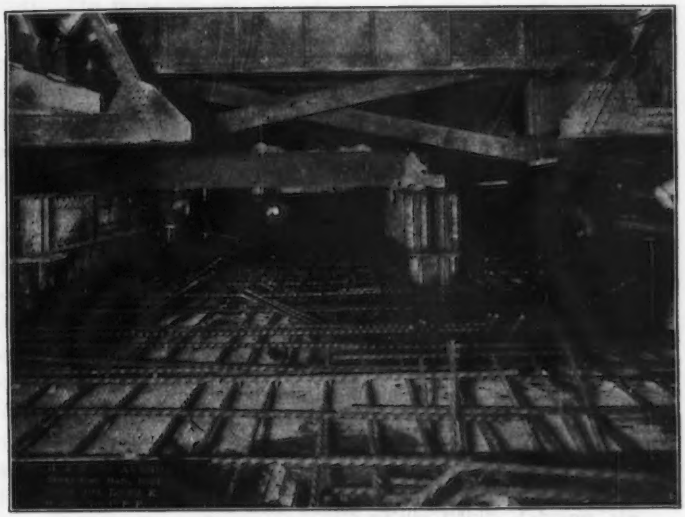

FIG. 11.—REINFORCING RODS, GROINED ARCH FORMS, AND STEEL GRILLAGES FOR FOUNDATIONS OF ELEVATED RAILROAD COLUMNS.

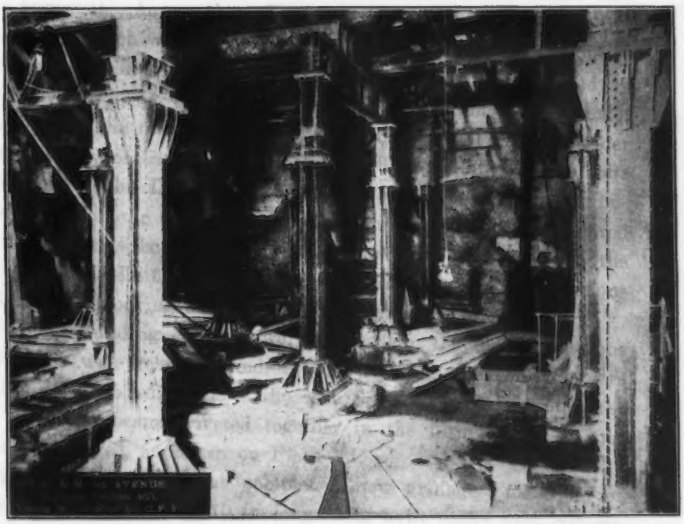

FIG. 12.—COLUMNS, WITH GRILLAGES, FOR SUPPORTING COLUMNS OF ELEVATED RAILROAD.

support. The three columns shored up were of a steel box, riveted type, 16 by 14 in. Rivets were removed from each column, and four steel brackets, aggregating 106 ¾-in. rivets per column, were riveted to them. Seven 36-in. girders, 39 ft. long, similar to those used in underpinning the elevated railway between 12th and 31st Streets, were placed on each side of each column. These girders, fourteen under each column, were supported at the outer ends by a pair of heavy 12 by 12-in. timber bents, parallel to the building front, in the excavation already made and 20 ft. from the building columns. At the inner ends they were supported by a reinforced concrete beam or girder, built on the rock, as close as possible to the second line of building columns and parallel to the building front. These 39-ft. girders had a span of 34 ft. between the center of the bearings on the concrete girder and the center of the timber bent. Across each of the fourteen girder clusters there were laid four 24-in., 100-lb. I-beams, two on each side of the column, on which rested the lower two brackets fastened to the building column. Above these I-beams, and parallel to the girders, there were twelve 24-in., 100-lb. I-beams, six on each side of each column, which were supported by the girders through timber blocking. These beams also supported the front wall of the basement. Across these I-beams there were laid four 24-in., 100-lb. I-beams, on which rested the upper two brackets of the building column. An additional support of the columns was afforded by using twelve suspender bolts (four 2-in. round and eight 1½-in. round), which held up the five 15-in. I-beams of the original grillage under the base casting of each building column. The top nuts of the bolts took bearing on the I-beams of the steel above. The proper distribution of the load over the parts of the steel underpinning was secured with wedges and the suspender bolts supporting the bases of the columns. The building columns were kept at their proper elevations with jacks and blocking under the ends of the girders.

After the building columns were picked up, the old foundations and the rock were removed, and, in this building, the columns were extended down to sub-grade with steel columns made up of three 24-in., 100-lb. I-beams, riveted together in the form of an I, and latticed and braced, as shown on Plate VI.

After the excavation was completed, new grillages, made up of five 20-in., 80-lb. I-beams, 10 ft. long, were built under each column

at sub-grade and embedded in concrete; the extension columns were set in place, anchored to the new grillages, and bolted to the grillages of the old foundations. Then a concrete wall was laid with its outside face at the building line, filling the entire space of the excavation over the slope of rock. This wall extended up to the old foundations, which were then grouted on it, and, after the concrete had set, the shoring was removed and the subway station work at this point was prosecuted to completion.

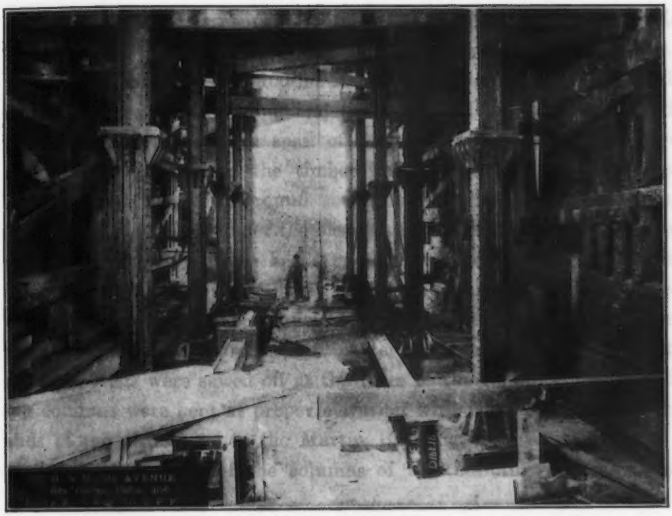
The load on each of the columns of this building was calculated to be 400 tons. Of course, the loading on the wall columns was partly taken up by the brickwork of the north wall of the building, part of which was supported on the steel underpinning and part remained on the original foundation resting on rock.

The Browning-King Building.—The entire front of this building was supported by four cast-iron columns, 11 in. in diameter and 2 in. thick, two in the center and two embedded in the side-walls. The method of shoring this building was similar to that used in the Martin Building (concrete girder and timber bents), except that the details of the steel were different and the columns were not extended to sub-grade.

A similar concrete wall, filling the entire space of the excavation back of the building line, was built, the columns were grouted on top of this wall, and then the steel underpinning was removed.

The method of picking up the columns was as follows: As shown on Plate VI, six holes were drilled completely through each cast-iron column, and then enlarged so as to pass 6 by 1¼-in. steel plugs. These plugs were 24 in. long, and were placed in the holes on edge, 18 in. apart, vertically.

At each end of each steel plug, two 6 by 4 by ⅝-in. angles were bolted to give greater bearing on the I-beams supporting them. There was one 15-in., 60-lb. I-beam on each side of each column, supporting the steel plugs at each end, arranged in the form of towers. An equal bearing was maintained on these beams with blocking and steel wedges, so that the steel towers might be considered as one mass fastened to each column. The load was transferred through the 15-in. I-beams and blocking down to 36-in. girders similar to those used in the Martin Building. Ten girders, five on each side of the column, supported each of the two center columns; five girders and seven



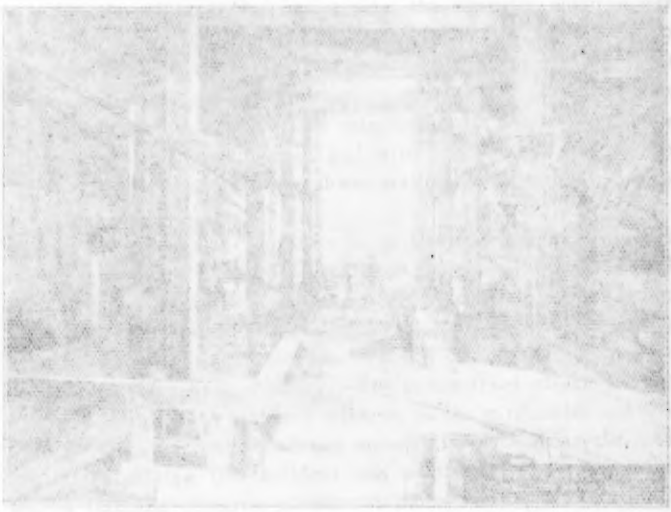


FIG. 13.—CLOSURE SECTION OF THIRTY-THIRD STREET STATION. STEEL COLUMNS SET UP.

FIG. 14.—CONCRETE FLOOR AND ROCK CORE BETWEEN SECTIONS OF THIRTY-THIRD STREET STATION.

24-in., 100-lb. I-beams supported the south wall and columns of this building and the north wall of the four-story building; and four girders and eight 24-in., 100-lb. I-beams supported the north wall and columns of this building and the south wall of the Bank Building. These girders had a span of 34 ft. between their bearings on the concrete girder and the timber bents. Additional support was obtained with four 2-in. round suspender bolts supporting six 9-in., 30-lb. I-beams placed under the base castings of the building columns, taking bearing at the bolt heads on the lower set of I-beams of the steel tower. These 9-in. grillages under the column bases were placed after the columns had been picked up on the steel towers, and were simply an additional precaution. After the removal of the shoring, the steel plugs were sawed off at the faces of the columns. The building columns were kept at proper elevation with jacks placed under the ends of the girders, as in the Martin Building.

The load on each of the columns of this building was calculated as between 240 and 260 tons.

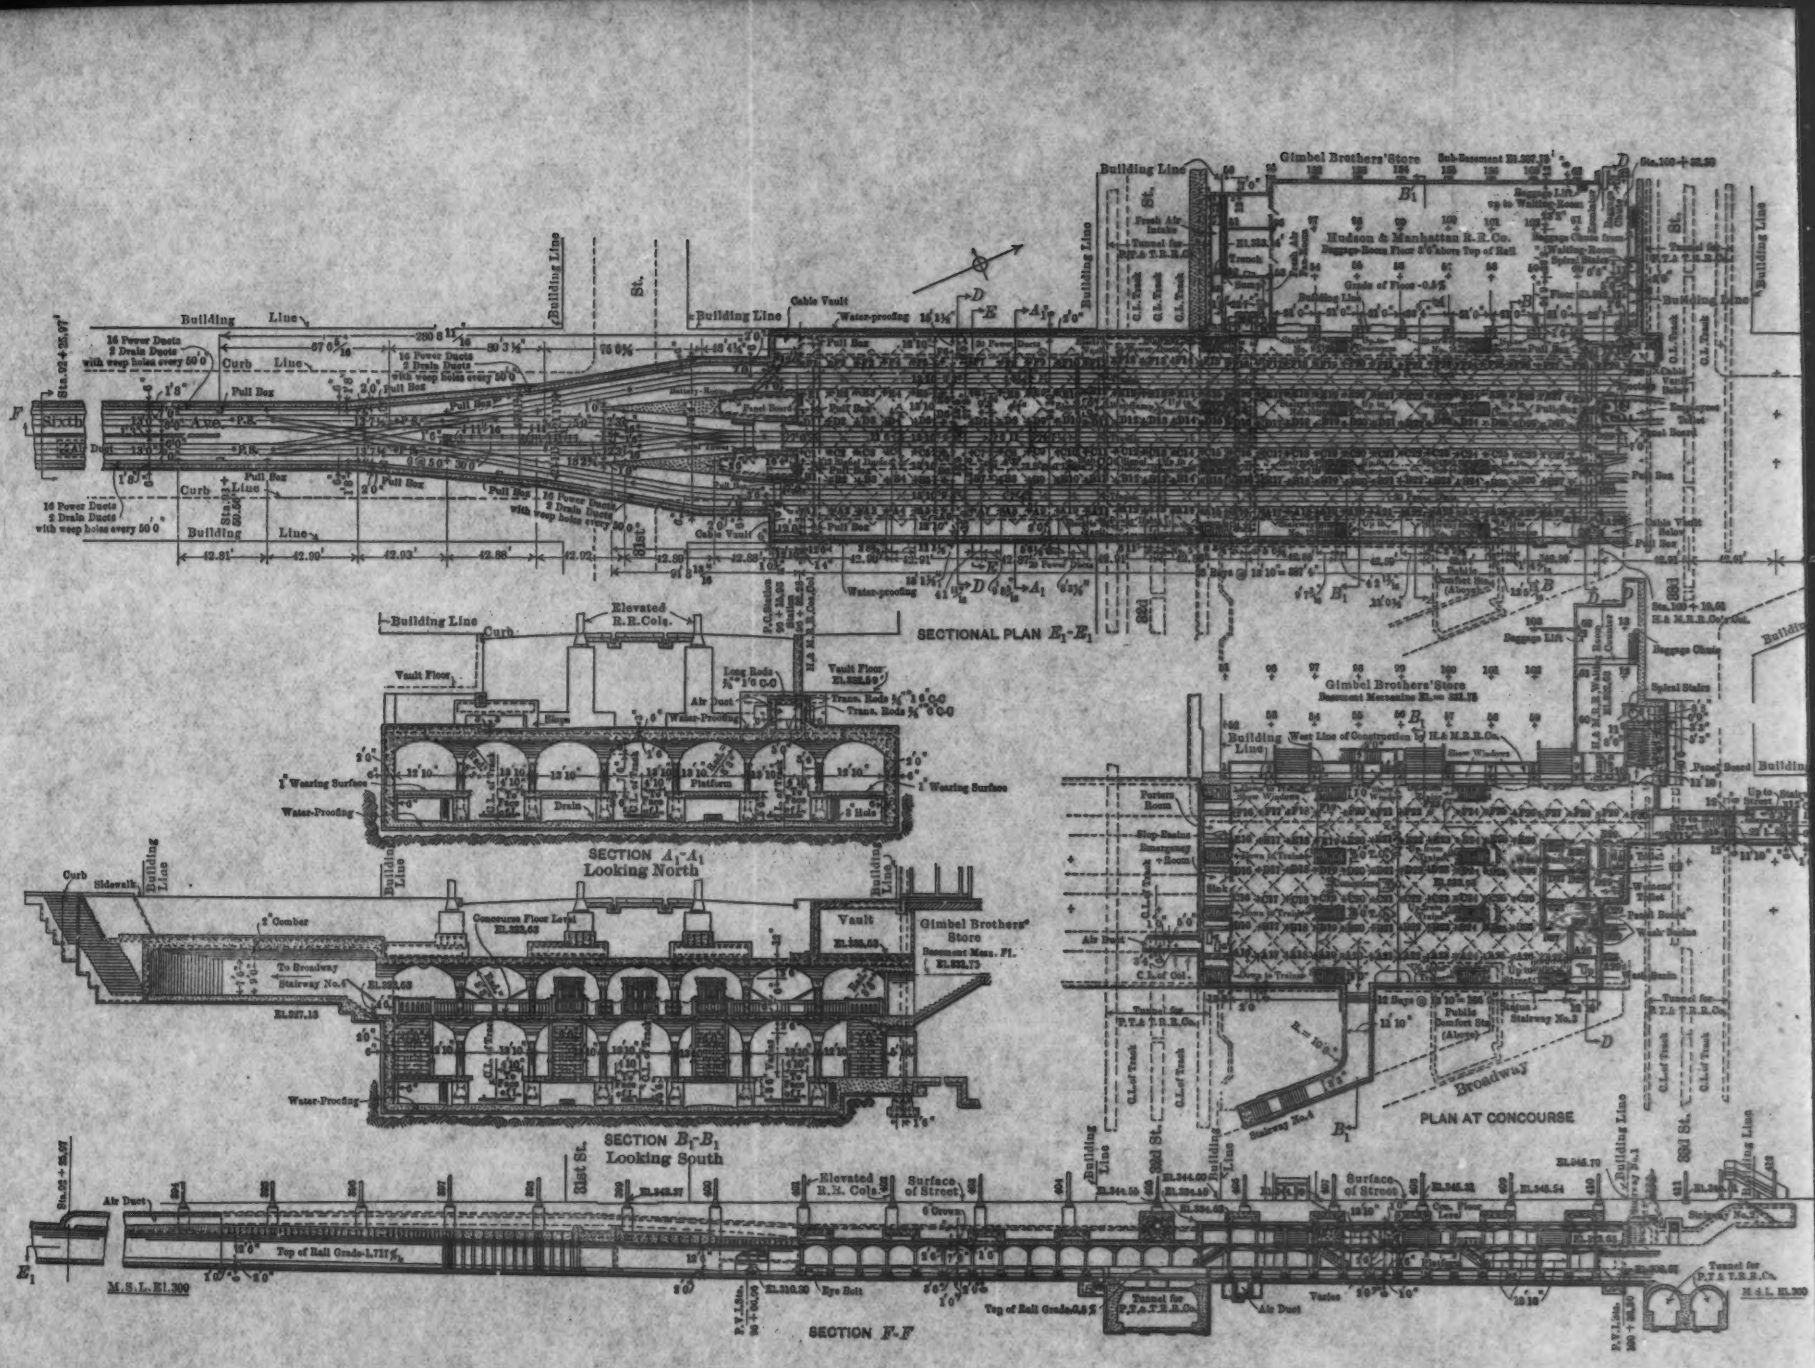
The Bank Building.—As this building had no steel framing, a different method of support was necessary. The underpinning cared for the entire front of the building and a short length east of the corner. The foundation was composed of four piers or columns of granite-faced brick masonry. The front was carefully tied together with wire rope fitted with turnbuckles.

Owing to the condition of the excavation and the order of building the different pieces of station, it was found that the excavation in front of the bank could not be completed soon enough to allow sufficient time for the underpinning of the building and the subsequent construction of the piece of station opposite it. If the underpinning had been left until the excavation had been made in front of the building, the completion of the station and the opening of the tunnel for traffic would have been delayed. Owing to these conditions, two reinforced concrete girders were built on top of the rock, and the steel girders used in underpinning the building were supported on them. One of the girders was built inside the building and the other outside, and both were parallel to the building front. A concrete wall was then built in the trench excavated under the building front, up to within 2 ft. of the bottom of the steel girders supporting the build-

ing, and the foundations were carried down with brick masonry to the top of the wall, with the gradual removal of the girders.

At the outside edges of the piers of the foundation, recesses or steps were cut deep enough to allow the placing of one girder on each side of each pier. The remainder of each pier was then gradually removed, substituting the girders for the brickwork, until the piers were supported entirely on the girders. Eighteen steel girders were used in supporting this building, with the aid of the eight 24-in. I-beams and four girders used for the north wall of the Browning-King Building and the south wall of the Bank Building. The rock trench was line-holed along the inside face of the building and the face of the outside concrete girder, in order to provide an even break near the concrete girders, and the rock faces of the trench were braced with timber to prevent the rock from slipping.

Owing to the removal of the steam-heating plant of this building, which was originally under the sidewalk, it was necessary to erect a 50-h.p. boiler on the street to supply heat during the winter and until a new heating plant had been installed in the basement.



The four-story brick building between the Browning-King and Martin Buildings was supported on the underpinning used for the walls of the adjoining buildings.

A factor of safety of four was used in calculating the strength of the steel underpinning systems. The buildings were maintained to within ¼ in. of their original elevations by the jacks. The girders and I-beams were used several times, as the buildings were not all underpinned at the same time. There were no cracks or other damages due to settlement, and the interiors of the buildings were restored to the satisfaction of the owners.

Excavation.

The excavation was started in a series of pits to contain the elevated railway supports. These were usually 8 ft. wide, extended across the street the full width of the work, and were carried down to sub-grade in cases of dry soil, and to within from 8 to 12 ft. of sub-grade in cases of wet soil, where piles were required to support the elevated railway.

The excavation of the cores of earth or rock under each pair of bents of the elevated railway were generally from 100 to 110 ft. long,

33D STREET STATION
GENERAL PLAN & PROFILE

from north to south, depending on the depth, and were of the full width required for building the subway and including the sewers. When these large pits were finished to sub-grade, the lengths of subway were built in them, and the elevated railway columns were set in their final position on the roof. The intermediate cores of excavation between these large pits were then removed to sub-grade, thus completing the excavation.

The timbering is shown on Plates V and VI. There were two or three lifts in the sheeting of the cuts, depending on the depth of the excavation and the elevation of the sewers alongside the subways. Where the soil was wet the lower lift was made up of 3-in. tongued and grooved, yellow pine sheeting. The sheeting for dry soil was of 2-in. yellow pine.

The bracing of the cut, as shown on Plate V, was designed so as to interfere as little as possible with the laying of the subway concrete, but the braces were left in place and allowed to pass through the concrete roof where there was any advantage in the saving of time or cost. The bents or timber sections were made up of 10 by 10-in. rangers and 12 by 12-in. braces and posts, and were generally placed 10 ft. apart. The details of the timbering are shown on Plate V, and need no special description.

The temporary planking of the street surface was laid on 10 by 10-in. and 12 by 12-in. stringers or deck pieces running longitudinally with the work, and on them was placed 4- and 5-in. planking laid transversely across the stringers. This deck or planking was supported by the posts of the cut bracing. As this planking was necessarily in service a long time, and subjected to the wear of the street traffic, it was necessary to watch it constantly and renew it in order to avoid accident.

When the 39-ft. girders were used in underpinning the elevated railway columns, as shown on Plate V, the timbering of the cuts was greatly simplified during the rock excavation between stations by using six 24-in., 80-lb. I-beams, 35 ft. long, in three pairs, each pair supported by one 12 by 12-in. post under the ends, resting on the rock. These I-beams supported the street surface and permitted the elimination of the posts necessary to support it. The bracing of the sheeting was carried across the cuts as usual, but required very few posts.

The materials through which the excavation was made were generally dry sand and loam, but between 12th and 13th Streets a fine sand with water was encountered at sub-grade, below tide level, and it was necessary to lay a 10-in. timber floor in the bottom of the cut on which was laid a 3-in. planking to furnish a proper foundation on which to build the tunnel. It was also necessary to provide temporary drains to carry off the water while laying the concrete in this part. Between 15th and 18th Streets a wet sand was encountered at sub-grade, but in this case it was simply necessary to put in a floor of 3-in. planking on which to lay the concrete floor. A small outcrop of rock was removed at sub-grade at 14th Street, but the rock excavation really commenced at 20th Street and continued north throughout the work to 33d Street. The rock varied in depth from 6 ft. above sub-grade at 20th Street to 35 ft. above sub-grade at 33d Street, and was very uneven, at times running just below sub-grade, and requiring a deeper excavation at these points.

Rock Excavation.—The rock formation was the usual mica schist, the general slope of the strata being about N. 30° W.; the inclination was between 15° and 20° east of vertical.

The bench rock was drilled with 2½- and 3-in. drills, and the boulders and large pieces with "Little Wonder" drills. It was blasted and broken into small pieces suitable for dumping into the trucks. The drill holes in the bench rock were generally 14 ft. deep. Where the temporary foundations of the elevated railway columns were on the rock, the excavation between these columns was carried as close to them as safety allowed, and lines of holes were drilled and blasted transversely across the cuts so as to make an even break and give as much space as possible in the excavated pits for building the pieces of tunnel or station. The rock excavation was carried toward the east on account of the slope of the strata.

From 31st to 33d Streets.—The 33d Street Station.—In this section the methods of excavation were similar to those described for the work between 12th and 31st Streets, excepting that, on account of the larger pieces or lengths of station required to be built in the first operation, as described in "Underpinning the Elevated Railway," the method of underpinning the elevated railway made the pits of shorter length from north to south.

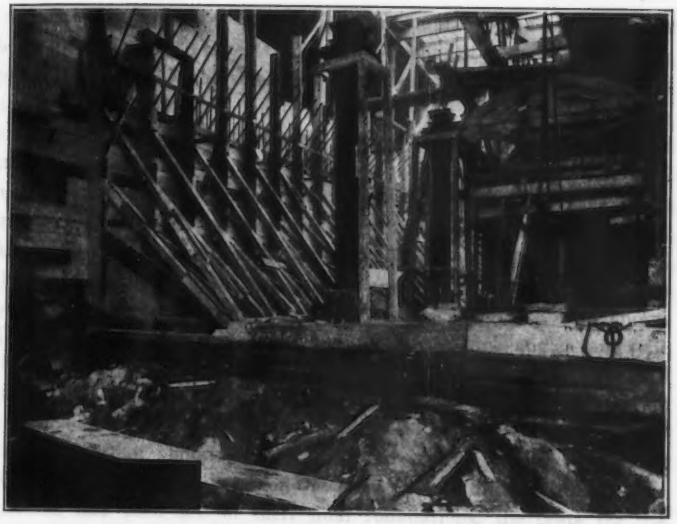

FIG. 15.—WALL AND ROOF FORMS, THIRTY-THIRD STREET STATION.

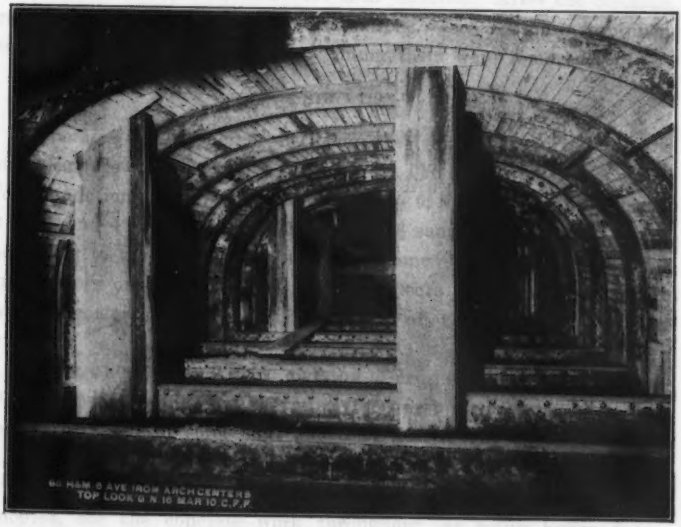

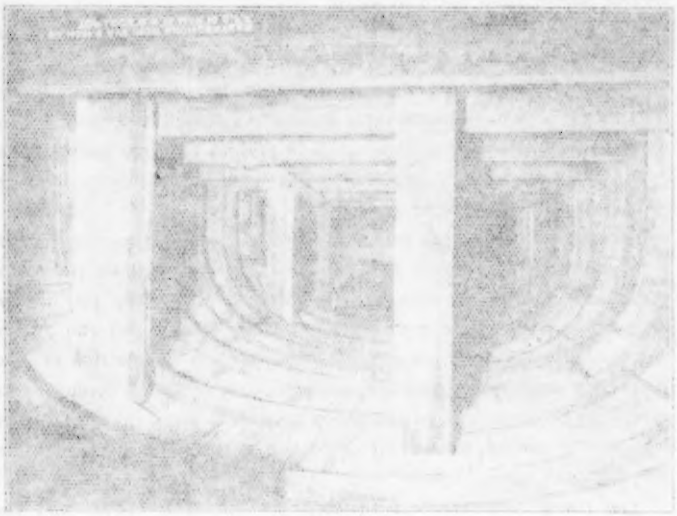

FIG. 16.—STEEL RIBS AND LAGGING OF FORMS IN STANDARD SUBWAY SECTION.

As shown on Plate V, the timbering and support of the street between 31st and 33d Streets differed from that of the work from 12th to 31st Streets. Light steel lattice trusses, 8 ft. deep, were erected under the street planking, and the surface car tracks, pipes, electric properties, and the street surface planking were all supported on these trusses. This eliminated all the obstructions caused by the usual method of bracing the cuts with timber, and furnished a clear space in which to build the subway or pieces of station under the columns. As shown on Plate VI, each lattice truss was made up of a bottom chord, two 8 by 8 by $\frac{11}{16}$-in. angles and one 7 by $\frac{9}{16}$-in. web-plate between the $\frac{9}{16}$-in. gusset-plates connecting the diagonals to the chord. The top chord consisted of two 8 by 8 by $\frac{1}{2}$-in. angles and one 16 by $\frac{9}{16}$-in. web-plate. The bracing or diagonals were made up of two angles, 6 by 4-in. and 4 by 3-in., from $\frac{3}{8}$ to $\frac{3}{4}$ in. thick. These trusses were made up in small pieces in order to facilitate their erection under the street planking. When the lengths of subway or sections of station had been built under these trusses, and the elevated railway columns had been set on their final foundations, the posts for the street pipes, street surface, etc., were carried down to the roof of the completed work. The trusses were then removed. After the columns, resting on temporary concrete foundations, were again underpinned, the foundations and cores of rock under them were removed.

Construction.

Concrete.—The concrete used on the work was mixed on the street surface in Ransome, $\frac{3}{4}$-yd. mixers. The proportions of concrete for foundations, walls, and roofs was 1 to 6, varying from 1 cement, 2 sand, and 4 broken stone to 1 cement, $2\frac{1}{2}$ sand, and $3\frac{1}{2}$ broken stone, according to the voids in the sand and stone. The concrete used for track floors on bed-rock, and for other floors or places where there was little strain or load, was composed of 1 cement, 3 sand, and 5 stone.

The stone was $\frac{3}{4}$ and 1-in. and run-of-crusher Hudson River limestone. It was found that the $\frac{3}{4}$-in. stone first used contained such a large percentage of screenings and dust that it was advisable to get 1-in. stone, ranging from $1\frac{1}{4}$ to $\frac{1}{2}$ in., with a small percentage of screenings and a very small percentage of dust. This stone was adopted, for the concrete work throughout, as being better for a

1 to 6 mixture, under the conditions of the work. The stone and sand were delivered alongside the dock and stored at the yards. The stone used in the street restoration, being required in small quantities, was delivered directly on the work.

The sand was obtained mostly from Hempstead Harbor, Long Island; it was of a good coarse quality and contained from 2 to 3% of loam. The maximum quantity of loam allowed was 2%, and, during the first two years of the work, it was very hard to obtain sand of this quality, but there was no difficulty during the last three years.

"Giant" cement was used throughout the work. It was tested at the company's laboratory in Jersey City, and delivered at the yard in trucks.

The cement was tested according to the Am. Soc. C. E. standard. It was uniform in quality, and there was no difficulty in obtaining a reliable set or proper age.

The water for the concrete was obtained from the city mains through metered connections at convenient points along the work. The mixers were run with compressed air obtained from the contractor's power plant at the 42d Street yard. The mixing gangs consisted of from 14 to 18 men, as follows:

One mechanic running the mixer,

One skilled laborer dumping the cement and handling the water,

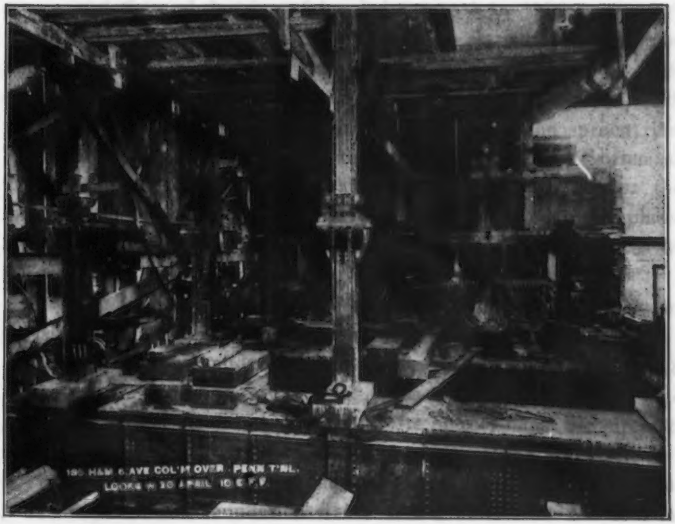
From 6 to 8 men loading wheel-barrows, and feeding sand and stone to the mixer,

From 6 to 8 laborers delivering concrete from the mixer at the point of laying.

The sand and stone were measured and delivered to the mixer in wheel-barrows. The concrete was carried from the mixers to the points of laying in "Ransome" concrete carts, and dumped into chutes at the street surface.

The sizes of the gangs placing the concrete varied considerably with the number of mixers supplying concrete and with the size of the piece laid, the difficulties in placing, and the length of haul between the mixer and point of laying. All the concrete was mixed "wet" and of such consistency that it would flow readily through the chutes and be handled easily. The length of haul of the concrete

FIG. 17.—PLACING STEEL GRILLAGES FOR SUPPORT OF GIRDERS OVER PENNSYLVANIA RAILROAD TUNNEL.



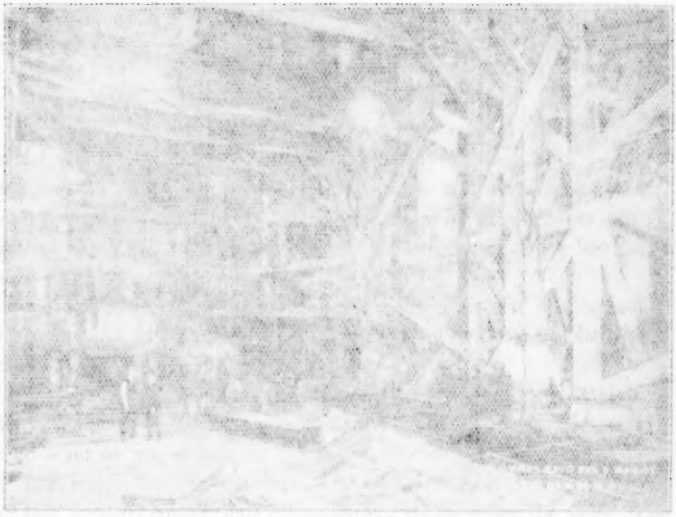


FIG. 18.—STEEL CROSSING OF PENNSYLVANIA RAILROAD TUNNEL.

was from one to two blocks, or from 260 to 520 ft. There was little delay in delivering the concrete from the mixer to the points of laying, because the men could wheel the carts over almost any portion of the street surface.

Owing to the great number of rods in the reinforcement, it was difficult to handle the concrete in the forms for the roofs and walls, and great care had to be exercised not to displace the rods or crowd them against the forms.

All the concrete of the subway was laid under the street planking, and great care was necessary to prevent dirt or chips from being dropped into the forms. No face mixture was used; the concrete was simply rammed or "quaked" by the use of long 2 by 4-in. timbers in the wall work and rammers in the floor and roof work. The faces of the walls and roofs showed very few voids or dry spots after the removal of the forms. The form centers in the standard tunnel section were composed of steel ribs made up of two 5 by 3-in. steel angles. These ribs extended from the toes of the center- and side-walls up to and including the arches. The inside face planking of the walls and the arch lagging were fastened to them with wire staples. The inside wall face forms were of 2 by 10-in., tongued and grooved spruce, and the arch lagging of beveled spruce 3 in. thick.

In building the groined arch forms of the station roofs, the ribs were placed under the groin lines of the arches and were of 2-in. spruce supported by 4 by 4-in. spruce posts. The lagging was beveled, planed spruce, with butt joints, and was nailed to the spruce ribs. The face planking and lagging were used over again as often as their condition allowed, but no attempt was made to redress the forms, as there was little economy in it, there being plenty of places where the rough forms were good enough in the exposed faces of the work.

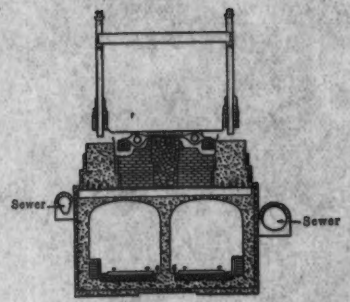
It is a feature of this concrete work that the forms failed or slipped only four times during the entire work.

The concrete was under the most favorable conditions for setting, as it was under the street planking, thus avoiding sun drying and quick setting and being aided by the drafts of cool moist air circulating through the cuts and finished pieces of tunnel.

The concrete of the subway and stations was laid up in three lifts: first, the floors and foundations; second, the walls from the founda-

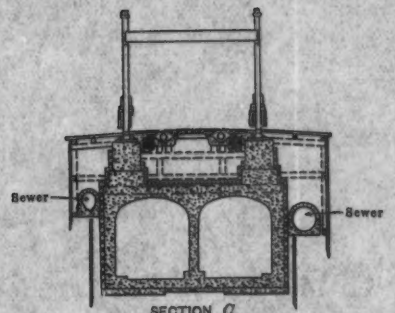
tions to 1 ft. below the springing lines of the arches; and third, the roofs.

Concrete was not laid when the temperature was lower than 25° Fahr., and in all cold weather the concrete was covered with salt hay to prevent freezing. Salt was not used in mixing the concrete. The temperature in the pits was very seldom lower than 30° Fahr.



The forms were dressed with soap or paraffin oil in all the work, excepting the arches of the 28th and 33d Street Stations, where the dressing with oil or soap was abandoned in order to obtain a better bond between the white cement finish and the concrete in whitewashing the interiors of the stations.

The steel and cast-iron columns of the stations were filled with 1:3 mortar grout poured in from the tops; this was done in two operations in order to permit the first batch to settle.



The spaces between the girders spanning the Pennsylvania Tunnel at 32d Street were grouted with neat cement. Mortar could not be used in this grouting because the spaces between the angle stiffeners were so small that mortar was too thick to form a certain enough grout. In this work the cement grout was poured into a 2-in. pipe at the street surface, which gave a head of 35 ft. for the pressure required to fill completely the spaces between the girders.

Reinforcing Rods and Expanded Metal.—The reinforcing rods were 1-in. and ¾-in. square Ransome twisted steel for the walls, roof, and foundations, and ⅝ and ½ in. for the platforms and thin walls. All the rods were delivered alongside the company's dock in lengths ranging from 10 to 30 ft. Rods were bent to special shapes in the yard, by using a bender made on the work and having a hydraulic jack. The rods requiring a bend up to about 45° from the straight were bent by hand. All the lengths and shapes represented certain positions in the walls, roofs, etc. The plans showed continuous rods around the shell of the subways and stations, and longitudinally, so that it was necessary to break the rods at points where it would do the least harm, and bond the breaks by an overlap of 40 diameters of the rods. The rods of the walls, roof, etc., were held 2 in. from the forms by using small mortar blocks laid between them and the forms. The rods in the roof were supported by the forms and by wire hangers fastened to timbers above. The weight of rods per cubic yard of concrete in the station roofs was very high, and the weight of the

PROGRESSIVE STEPS & METHODS
12TH TO 31ST STREETS.

concrete and rods combined required that the forms of the roofs be well supported by the 4-in. posts. The average spaces between the rods through which the concrete was poured was 12 by 12 in., and particular attention was given to spacing the rods properly so that the concrete could be placed in the most economical way. The clusters of rods (in the form of baskets) over the station columns were especially difficult to place and keep in position, because the concrete dumped into the haunches of the arches tended to shift the entire cluster so that the rods were displaced or forced against the forms.

Expanded metal or wire cloth was laid under the roof beams of all the flat arches to bond the concrete cover of the beams to the concrete between them.

Brickwork.—The bricks used in underpinning buildings, in the foundations of the surface railway, and in the stations, were the usual standard house brick, and were laid in 1:3 mortar. The partition walls of the stations, booths, ticket offices, etc., were built of 3-in. and 4-in. hollow tile.

Water-Proofing.—The entire work between 12th and 27th Streets was water-proofed with "Siastex," a burlap and asphaltum process. A strong and durable burlap, of more practical value than the usual felt, was used because of the necessity of handling the reinforcement rods over it on the floors and walls. The normal thickness of the water-proofing was 2-ply with felt "plus ply." This was increased to 3- and 4-ply where water pressure and flow were met. A single ply of felt "plus ply" was first laid under all the water-proofing where the concrete surfaces were wet, and over this were laid the burlap and tar. On the roof of the 23d Street Station and under the floor of the enlargement at 12th Street, where there was a flow of water and very wet conditions, a brick and mastic was used. This consisted of a tarred felt "plus ply," on which was laid hot bricks which were grouted with pitch. In all the water-proofing in which the burlap was used, an armor course of 3-in. hollow tile or 4-in. brick was laid to protect it. In the floors, a 6-in. concrete floor was laid, on which the water-proofing was placed. Between 27th and 33d Streets, a new process of water-proofing was tried. The great cost of the membrane water-proofing called attention to the possibility of using a compound to be mixed with the concrete with a great saving in cost. Therefore a powder compound was mixed with the concrete in this section.

It was anticipated that the shrinkage of the concrete in drying would open up cracks which would require caulking, but the saving over the cost of the previous method was calculated to pay for this and still effect considerable economy.

Tunnel Ducts.—The ducts in the subway for the cables of the power and light services were laid on the toes of the side-walls and under the platforms of the stations. These ducts were laid after the completion of the shells of the subway and stations, and call for little description, as no difficulties were met.

All the ducts were of vitrified clay, usually of 4-hole pieces, 30 in. long, with the addition of 2-hole pieces in certain places. The joints were wrapped with canvas, and two dowel pins were placed in each duct joint. The joints were made with 1:3 mortar. Bond straps of $\frac{1}{8}$ by $1\frac{1}{2}$-in. iron were laid between the ducts to bond the concrete faces to the ducts. Manholes were built in each subway tube, between stations, and at each end of the stations for pulling and splicing purposes. The duct banks were covered with a concrete jacket to protect them from injury, and the faces of this jacket were reinforced with expanded metal or wire cloth.

Sewers.—Previous to the commencement of the subway work, a main outlet sewer, 5 500 ft. long, was built in 18th Street from Sixth Avenue to the North River, commencing at Sixth Avenue as a concrete and brick structure 5 ft. 9 in. in diameter. At Eleventh Avenue it is a box-shaped section, of reinforced concrete, and is finished at the river end with two barrel sewers supported on the timbers of the steamship pier at West 18th Street.

The original sewers in Sixth Avenue were in the center of the street, and, as they were below the level of the roofs of the subway and stations, the entire system, from 12th to 33d Streets, had to be rebuilt. The old sewers were broken away as the work progressed, and the flow of sewage was maintained through temporary 12 to 20-in. spiral riveted pipes. In rebuilding, it was necessary to provide a sewer on each side of the subway, and to connect those in the side streets.

The new system in Sixth Avenue consists of a trunk sewer on the east side, flowing north from 14th Street to the sewer junction under the subway at 18th Street, 3 ft. 6 in. in diameter at 14th Street, and 4 ft. in diameter at the junction; and a trunk sewer from 31st

FIG. 20.—ENLARGEMENT OF SUBWAY SOUTH OF THIRTY-THIRD STREET STATION.

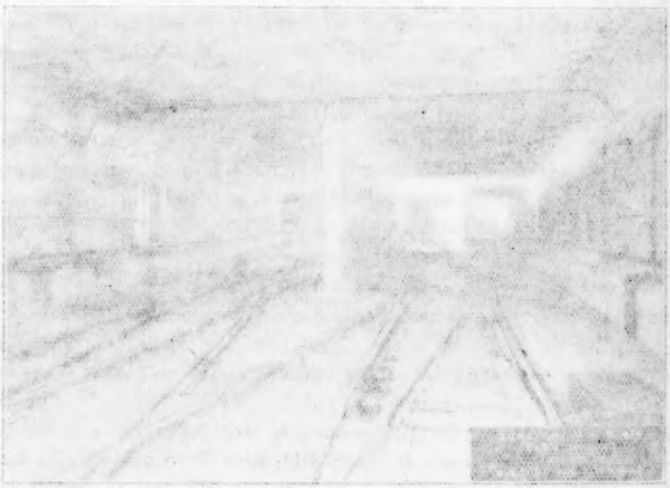

FIG. 21.—STANDARD STATION BEFORE PLATFORM WAS BUILT.

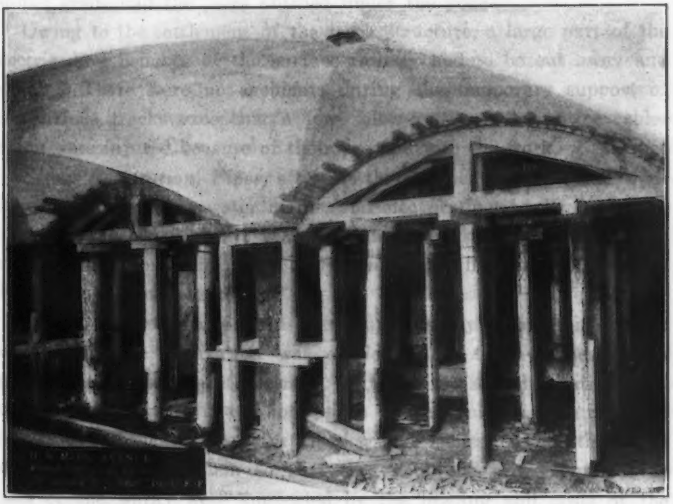

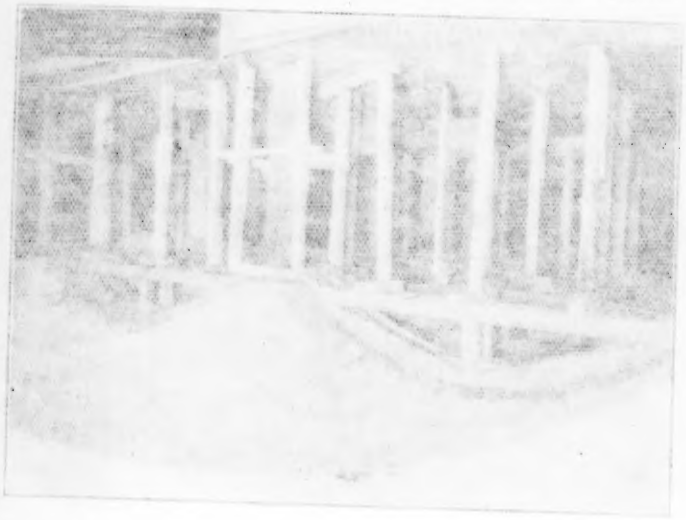

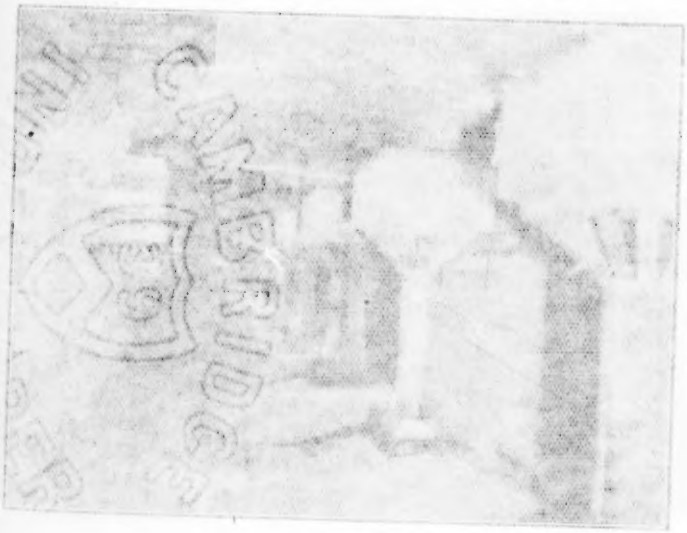

FIG. 22.—FORMS FOR GROINED ARCHES OF ROOF, THIRTY-THIRD STREET STATION.

Street south to the junction at 18th Street, 3 ft. 6 in. in diameter at 31st Street and enlarging to 4 ft. 9 in. at the junction, running down the east side from 31st Street to 21st Street, passing under the 28th and 23d Street Stations and crossing under the subway south of 21st Street to the west side where it turns south to the junction at 18th Street. Smaller laterals, ranging from 12-in. vitrified pipe to 3 ft. 6-in. by 2 ft. 4-in. egg-shaped sewer, were built on both sides of Sixth Avenue at the points not served by the trunk sewers.

The pipe sewers were laid on a concrete invert or foundation 8 in. thick; all the other sewers were built with 8 to 12-in. concrete inverts and 8-in. brick crowns. The forms for the concrete invert were of pine ribs with 1-in. lagging, or were collapsible steel centers. The house connections were of vitrified or cast-iron pipe, and each sewer connection was made with a cast-iron spur.

Surface Railway.—The surface railway track structure was supported on the bracing and posts of the excavation during construction, and brick piers for heights up to 7 ft., or reinforced concrete bents for greater heights, were built up from the subway and station roofs every 5 ft. under each yoke. The tracks were then jacked up to proper grade and the piers finished under the yokes.

Owing to the settlement of the track structure, a large part of the electric duct benches of the surface railway had to be cut away and rebuilt. There were no accidents during the temporary support of the surface tracks excepting a few "blow-outs" of the power cables which were injured because of their proximity to the work.

Street Restoration, Pipes, etc.—At the commencement of the work there were gas mains, water mains, and electric duct banks, including those for the street railway, and all these had to be relaid. There were also additions laid under agreements with the owners, for which the work was compensated.

All the water and gas mains were supported by 10 by 10-in. timber bents where the excavation was carried under them. These bents were erected on solid earth or rock, or on the roofs of the stations, and were built every 6 ft. on both sides of the subway. During the subway work these pipes, duct banks, and cables (where the ducts were stripped from them so that they could be raised outside the lines of the work) were supported by the bracing and posts of the excavation. Before the general excavation was started, 6, 8, and 16-in.

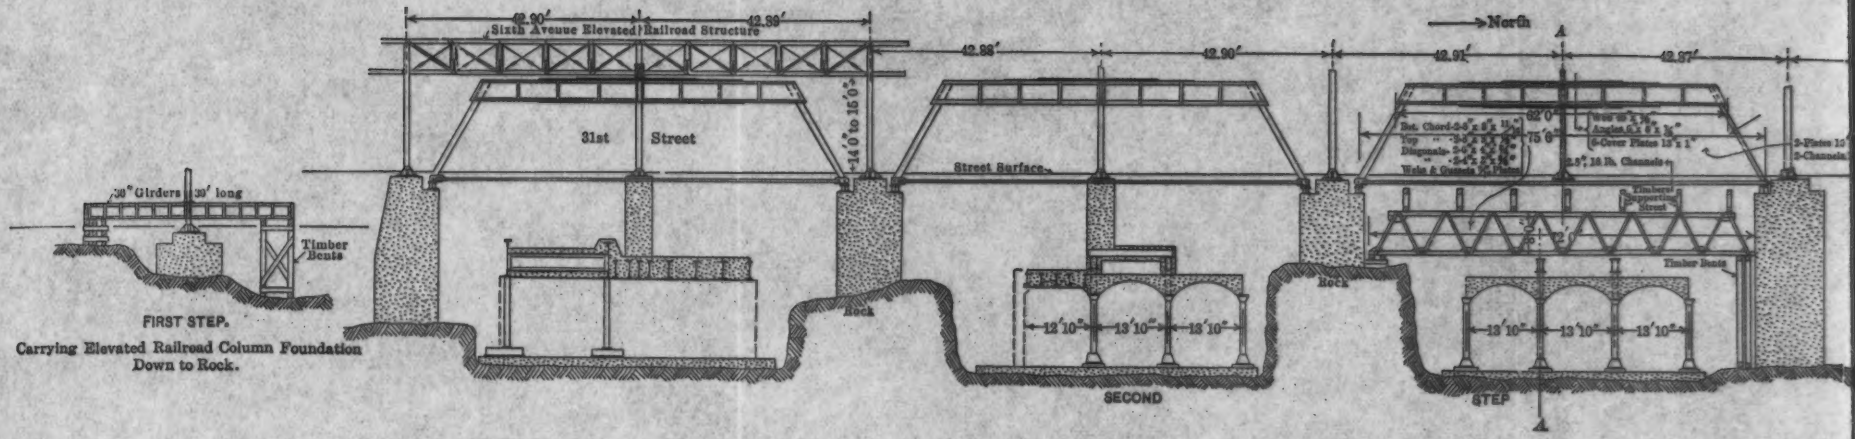
wrought-iron pipe by-passes were laid at the curb lines for the temporary supply of gas, and then the gas was removed from the mains. The empty mains were slung to the timbers and left until they were relaid in their new positions in the street, at which time the house connections were replaced on the mains and the temporary by-passes were removed. The traffic required that only one side of the street be opened at a time in any block.

The pipes were laid on the timber bents, and the duct benches on the rammed fill, excepting those of the surface railway which were laid on the brick or concrete piers and the dry packing laid between the piers.

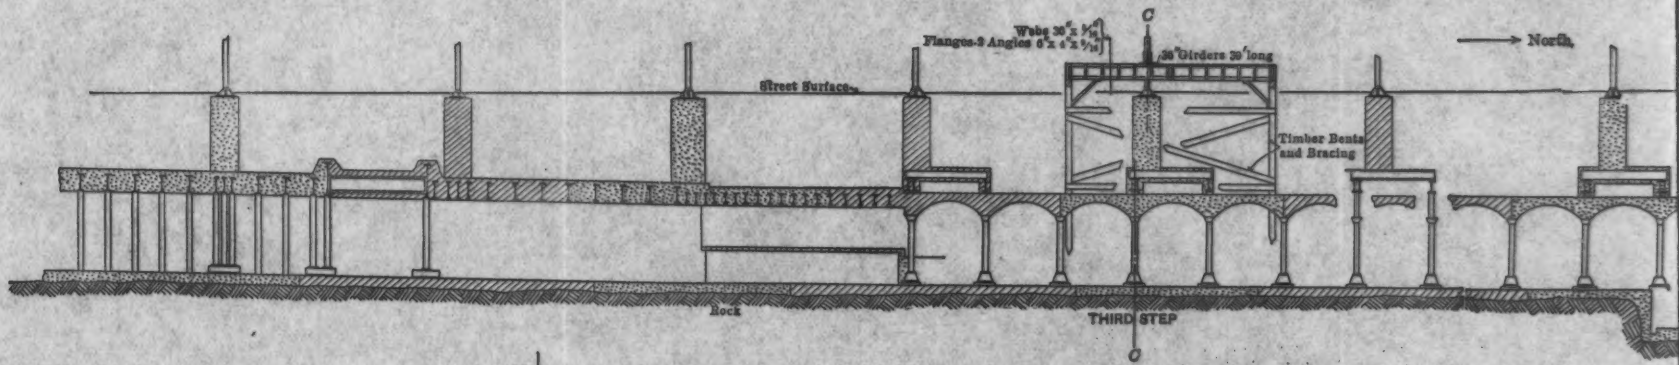
When the gas and water services were replaced in the mains, the street was back-filled and the temporary pavement laid and maintained until the fill had settled sufficiently for the laying of the final asphalt pavement.

This temporary pavement was of granite blocks which had been removed from the street when the work was commenced.

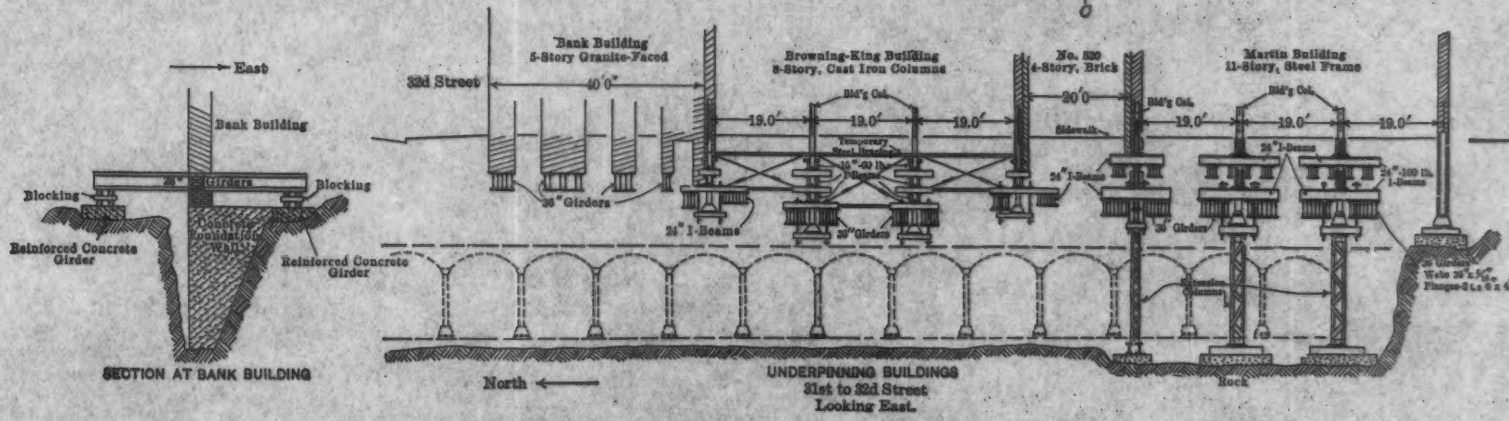
Storage Yards.



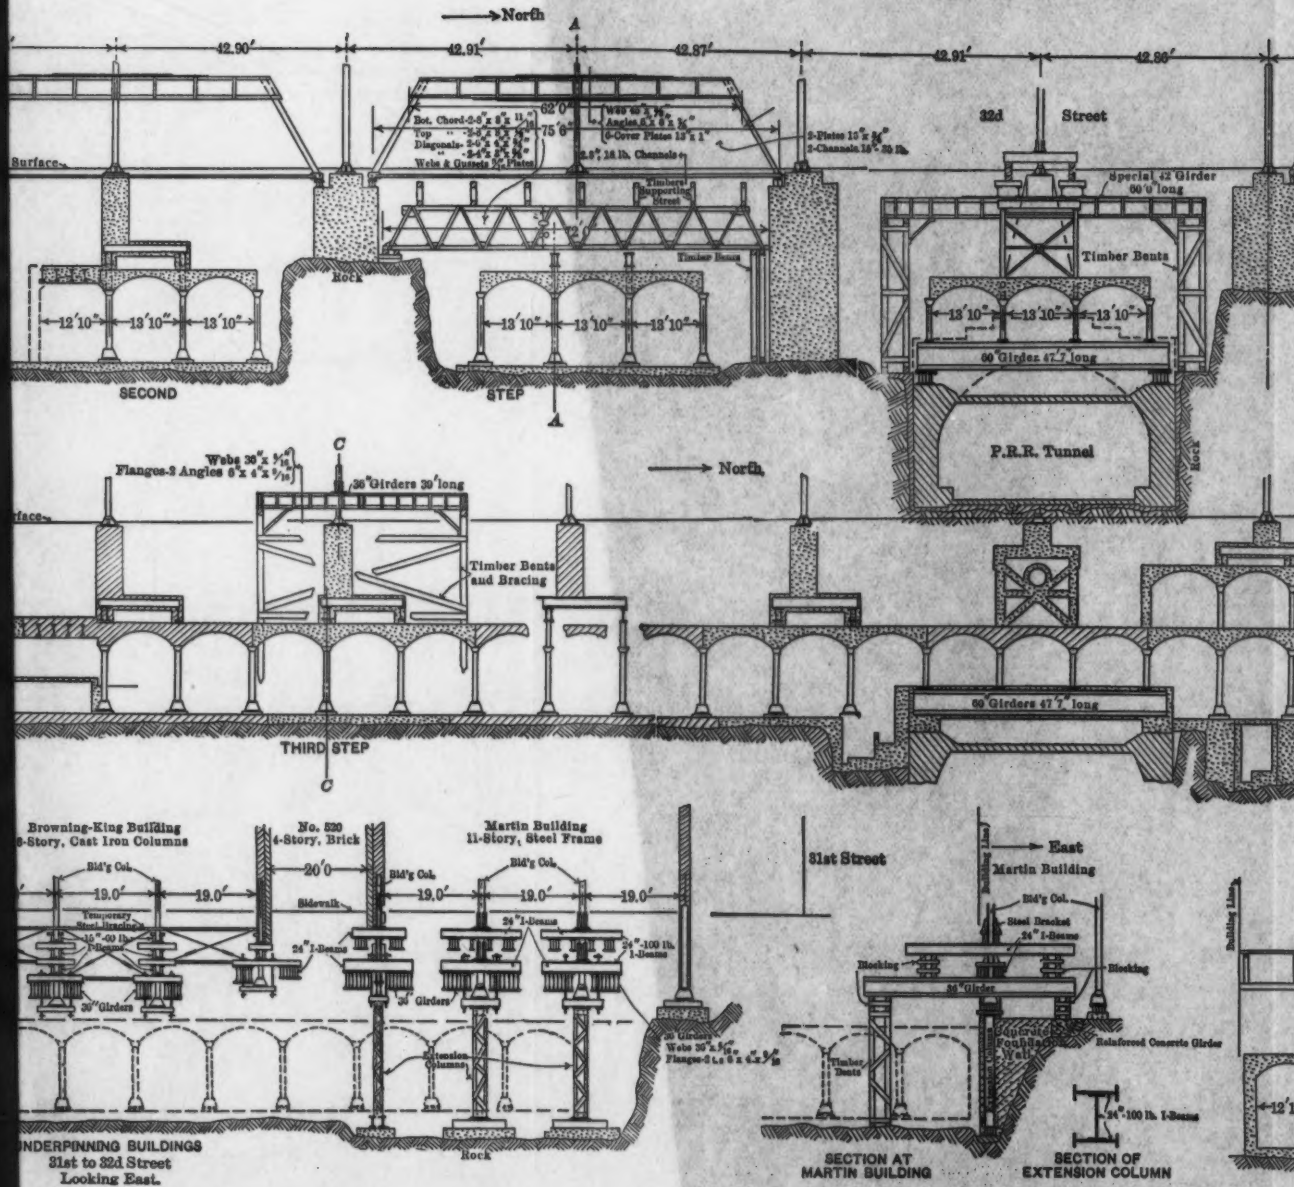
A yard and storehouses were provided at 17th Street and Tenth Avenue for the work between 12th and 27th Streets, and at 42d Street and East River for the work between 27th to 33d Streets. In these yards were the usual storehouses and shops for the storage of materials and plant. The storage of materials in the side streets was limited to 100 ft. on each side of Sixth Avenue. All the cast iron and most of the steel was stored in these yards, in addition to the rods, timber, concrete materials, etc. The two yards were similar, but that at 42d Street contained the power-house for the supply of compressed air.



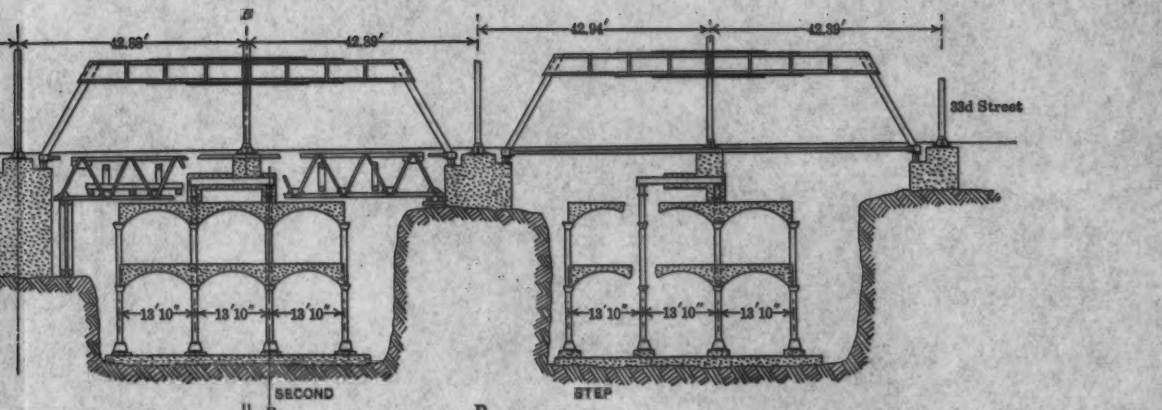
The haul from the 17th Street yard was from ¾ to 1 mile, and that from the 42d Street yard was from 1½ to 2 miles. The latter yard had the advantage of a dock on the East River at which practically all the materials were delivered, consequently the cost was less than for those delivered at the other yard, which had no dock.



Some of the items which secured economy at the 42d Street yard were as follows:



The use of derricks for unloading material from scows;



The rapid unloading of scows, thus saving demurrage;

PROGRESSIVE STEPS OF BUILDING
THE 33D STREET STATION.

The elimination of dockage cost and rentals;
The reliable delivery of the materials in large quantities by scows, as compared with trucking in small quantities.

The greater haul from the 42d Street yard involved a small additional cost over that of the 17th Street yard, but this was more than compensated by the loading of the materials directly from scows into trucks, which, without further delay, could then haul directly to the work.

Besides the storage and loading of materials, the following labor was performed at the yard:

The repair and assembly of plant,
The bending of reinforcing rods to shape,
The building of special forms for the concrete work,
The repairs and assembly of special shapes, etc.

Plant.

The plant was composed of the following main items:

1 power-house equipped with two Ingersoll-Rand compressors having a total capacity of 9 000 cu. ft. of free air per min.;
2 derricks having 25-h.p., Lidgerwood, double-drum engines, operated by compressed air;
8 derricks with Lambert and Lidgerwood 25 and 30-h.p., double-drum, electric engines;
2 cableways with 25-h.p., Lidgerwood, double-drum engines, operated by compressed air;
2 cableways with Lambert, 25-h.p., double-drum, electric engines;
8 concrete mixers—¾-yd., Ransome—operated by compressed air;
26 pumps—Cameron and Worthington—operated by compressed air;
13 electric pumps—centrifugal;
40 rock drills, 2¼ and 3-in., operated by compressed air.

The cableways spanned one city block, or from 240 to 260 ft. between towers, and the derricks were all stiff-legged, with masts and booms of such sizes as to suit the conditions at the points of operation. All riveting hammers used for the steelwork were operated by compressed air. The power-house, supplying all the compressed air for the work, was in the yard at 42d Street and East River, and was that previously used for driving the Belmont Tunnel.

The curves on Figs. 25, 26, and 27 show the relative costs of the different items of the construction. The cost of plant is not included. The installation and operation are included in the different items of cost.

The value of the plant was estimated as follows:

Electric and compressed air hoist engines, new and old	$39 400
Concrete mixers	6 520
Pumps—new and old	4 980
Drills—new and old	6 550
Depreciation of power-house during use on this work	15 000
Frames and cables and supplies—new and old	7 000
Total estimated value of plant, as furnished on the work	$79 450

Other items usually considered as plant are included in the different cost curves.

The progress of the excavation, concrete work, etc., at various times is shown by the curves on Fig. 27.

The construction was carried on in two sections, the first (between 12th and 27th Streets) was completed before the commencement of the upper one, between 27th and 33d Streets.

The section between 12th and 27th Streets was commenced in September, 1906, and completed in September, 1909. The section from 27th to 33d Street was commenced in August, 1909, and completed in December, 1911.

The cost of the engineering on the work (exclusive of the main office, which is not included in the curves) was 2.78% of the construction.

Statistics.

The work was commenced in October, 1906, and was finished in November, 1911. In two portions of the work—between 12th and 24th Streets, and between 27th and 33d Streets, including the 33d Street Station—the time required from the commencement of the excavation to the operation of trains in the subway was 14 months, which is considered rapid construction. On the whole work there were only 5 deaths due to accidents of any character.

FIG. 27.

The total quantities of the different kinds of work were:

Earth excavation	220 900	cu. yd.
Rock "	95 350	" "
Concrete	65 180	" "
Reinforcement rods	7 090 000	lb.
Elevated railway underpinned	277	columns.
Sewers of different sizes (exclusive of the 18th Street main outlet sewer)	9 500	lin. ft.
Electric ducts in subway	278 500	duct feet.
Miscellaneous brickwork, not included in other items	5 200	cu. yd.
Structural steel and cast iron	2 834	tons.
Interior finish of stations	5	stations.
Street restored	5 400	lin. ft.
Buildings (from 4 to 11 stories) underpinned.	340	lin. ft.
Field engineering	5	years.

The loadings of the street were estimated to be:

Surface railway	7½ tons per lin ft. of street.
Roadways	6½ " " " " " "
Sidewalks	3 " " " " " "
Total	17 tons per lin. ft. of street.

The total quantity of timber used in the excavation, including the planking for the street surface, was 7 703 000 ft. b. m., or 24.36 ft. b. m. per cu. yd. of excavation of both earth and rock, unclassified.

Between July, 1909, and August, 1910, there were 30 700 drill holes blasted, each hole requiring an average of 1.20 lb. of dynamite. The average quantity of dynamite for all rock excavated from 12th to 33d Streets was 0.58 lb. per cu. yd.

The proportions of labor and material for each kind of work was as follows:

	Percentage for labor.	Percentage for material.
In earth excavation	67.78	32.22
In rock excavation	72.95	27.05
Concrete	49.70	50.30
Reinforcing rods	29.98	70.02
Underpinning elevated railway	51.64	48.36
Sewer construction	57.81	42.19
Structural steel and cast iron	21.36	78.64

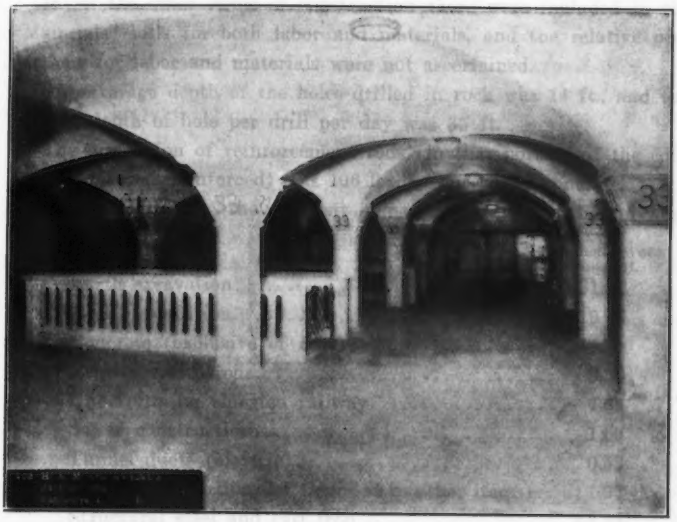

FIG. 28.—VIEW ACROSS CONCOURSE FLOOR OF THIRTY-THIRD STREET STATION.

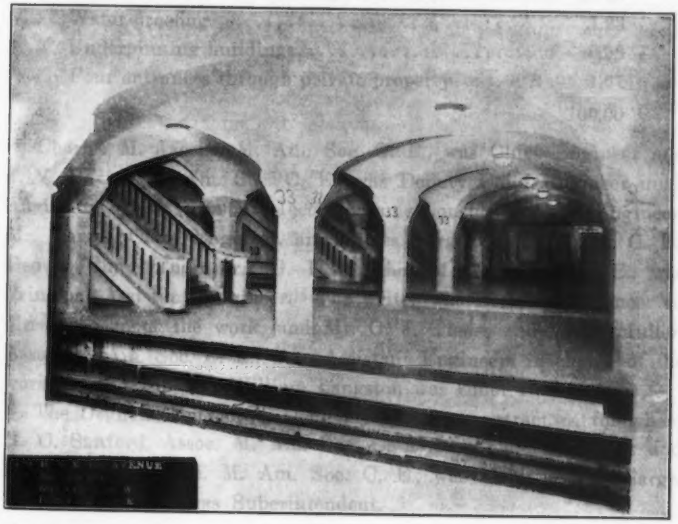

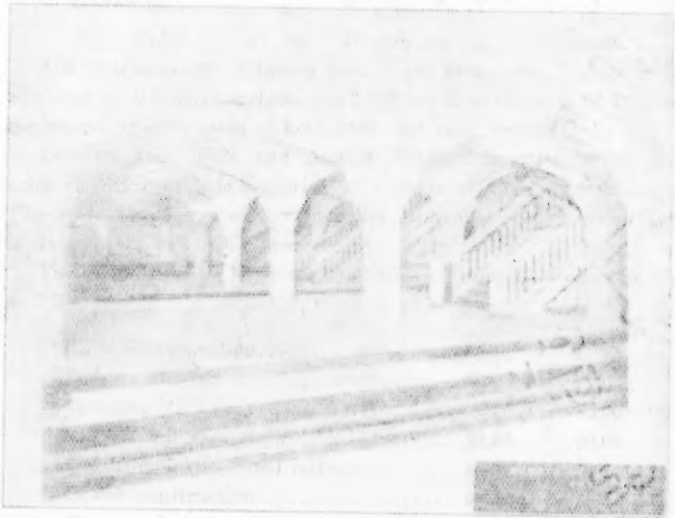

FIG. 29.—VIEW ACROSS THIRTY-THIRD STREET STATION SHOWING TRAIN PLATFORMS.

In all the other items of construction there were included in the "Materials" bills for both labor and materials, and the relative proportions for labor and materials were not ascertained.

The average depth of the holes drilled in rock was 14 ft., and the average depth of hole per drill per day was 35 ft.

The proportion of reinforcement rods (in that portion of the concrete which was reinforced) was 106 lb. per cu. yd. of concrete.

The proportions of the different items of cost of construction were as follows:

	Percentage of total cost.
Earth excavation	31.32
Rock excavation	19.16
Concrete (exclusive of rods)	11.74
Reinforcement rods	3.50
Underpinning elevated railway	4.55
Sewer construction	1.69
Tunnel ducts (electric)	0.52
Brickwork (portion not included in other items)	1.35
Structural steel and cast iron	3.34
Station, interior finish	3.29
Street restoration (including relaying pipes, etc.)	15.66
Water-proofing	1.23
Underpinning buildings	0.98
Four entrances through private property	1.67
	100.00

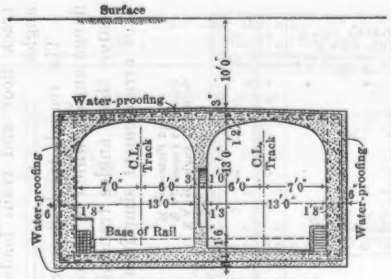
Charles M. Jacobs, M. Am. Soc. C. E., was Chief Engineer and J. V. Davies, M. Am. Soc. C. E., was Deputy Chief Engineer until August 1st, 1909, when Mr. Jacobs became Consulting Chief Engineer, Mr. Davies, Chief Engineer, and James Forgie, M. Am. Soc. C. E., Deputy Chief Engineer. G. D. Snyder, M. Am. Soc. C. E., was Principal Assistant Engineer. The writer was Resident Engineer in direct charge of the work, and Mr. O. J. Theiss and Leslie Muller, Assoc. M. Am. Soc. C. E., were Assistant Engineers in charge of the work in the field. Mr. William Langston was Chief Inspector.

The Degnon Contracting Company were the contractors, for whom H. C. Sanford, Assoc. M. Am. Soc. C. E., was Chief Engineer and R. P. Gustin, Assoc. M. Am. Soc. C. E., was Engineer in Charge. Mr. M. J. Morris was Superintendent.

DISCUSSION

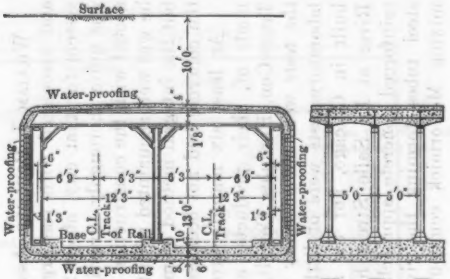
Mr. Whitney.

T. B. WHITNEY, JR., M. AM. SOC. C. E. (by letter).—Judging from the author's statement that the weight of the reinforcing steel per cubic foot of concrete is excessive, it might be inferred that some abnormal percentage of steel was used in the design of the reinforced concrete in this structure. However, the steel ratio is not more than three-fourths of 1%, except in the side-walls which required reinforcing in both faces, where it amounts to 1.20 per cent. The longitudinal bars used to prevent shrinkage cracks averaged about fifteen-hundredths of 1 per cent. A minimum spacing of 6 in. from center to center was used for the steel in order to facilitate the pouring of the concrete.



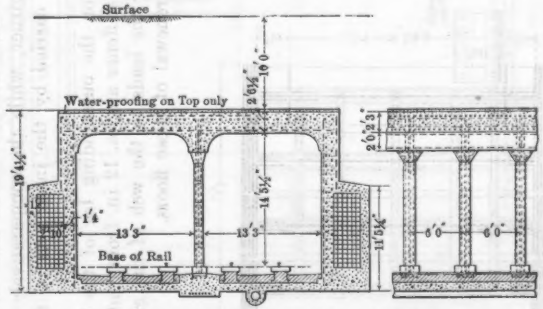
The arched roof formed a characteristic feature throughout the underground structures of the Hudson and Manhattan Railroad, and this led to its consideration in the design of the subway section on Sixth Avenue. The adopted section consists of a double, arched roof supported by a center wall and side-walls. The side-walls are designed as reinforced concrete slabs to carry the earth pressure as well as the thrust of the arches, and are tied together at top and bottom by tie-bars in the roof and floor.

A comparison of this subway section with two other well-known subway sections shows that the quantities of excavation, steel, and concrete, are slightly in its favor, when the sections are reduced to the same dimensions, using the same loading and unit stresses in each case. The economic features may be compared by referring to Fig. 30. It will be noticed that the New York Subway has the smallest side clearance and that the steelwork is calculated on a basis of a unit stress of 20 000 lb., which accounts for the smaller quantities.



The permanent structure was designed to conform with the live and dead loads as given by the specifications of the New York Public Service Commission, though lower unit stresses were used than are prescribed by these specifications.

In each group of girders spanning the Pennsylvania Tunnel at 32d Street, the girder adjacent to the track carries half the trough track floor and train loads, in addition to its equal share of the permanent overhead loads, consisting of station platform, columns, roof, 20 ft. of fill, street railway, street loads, and elevated railroad structure. Economy of space was essential, so the over-all dimensions of all the girders were kept the same, and the additional flange area required for the girders carrying the track floor and train loads was provided by extra sets of angles placed inside the main flanges of the girder. The increase in web thickness, to provide proper rivet spacing, gave a surplus of material sufficient to carry the additional shear, as



Mr. Whitney.

HUDSON & MANHATTAN R.R.CO.

NEW YORK

FIG. 20

Mr. Whitney.

shown by Fig. 31. Thus, the extremely heavy overhead loads are carried by the main body of the girder, while the comparatively light track floor and train loads are carried by the inner sets of flange angles.

The trough track floor rests on the outstanding leg of the inner flange angles, which is braced by stiffener angles, 12 in. from center to center, these angles transmitting the loads to the web of the girder. This arrangement simplifies the renewal of these floors.

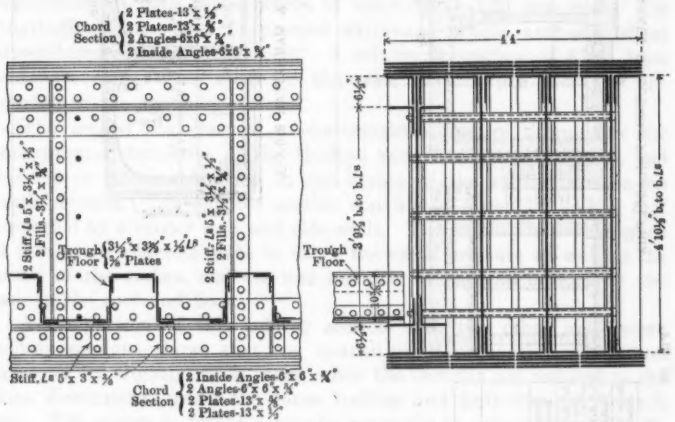

FIG. 31.

Mr. Boucher.

WILLIAM J. BOUCHER, ASSOC. M. AM. SOC. C. E.—While in Chicago and associated with the organization planning the proposed subway system for that city, about 2 years ago, the matter of water-proofing was quite thoroughly investigated by the speaker. Having been connected with the construction of the New York Rapid Transit Railroad, he was well acquainted with the membranous method of water-proofing, but the integral method of mixing a powdered or liquid substance with the concrete had not been examined to any extent.

At least six manufacturers of compounds offered, and had tests made of, their products, among which were McCormick, Medusa, Truss-Con, Hercules, Ceresit, and Hydrolithic. Due to various causes, the tests were not in every way satisfactory, but it was learned that laboratory tests were of little or no value. No subway has yet been built in Chicago, but the street railway tunnel under the Chicago River at La Salle Street has now been in use about a year. The reinforced concrete approaches to this tunnel, and the concrete-lined steel tubes forming the river crossing are water-proofed solely by mixing McCormick compound with the concrete. The speaker has

Mr. Boucher.

CROSS-SECTION OF ORIGINAL REINFORCED CONCRETE SUBWAY ON LINE OF RAPID TRANSIT RAILROAD, LENOX AVENUE AND 14TH ST., NEW YORK.

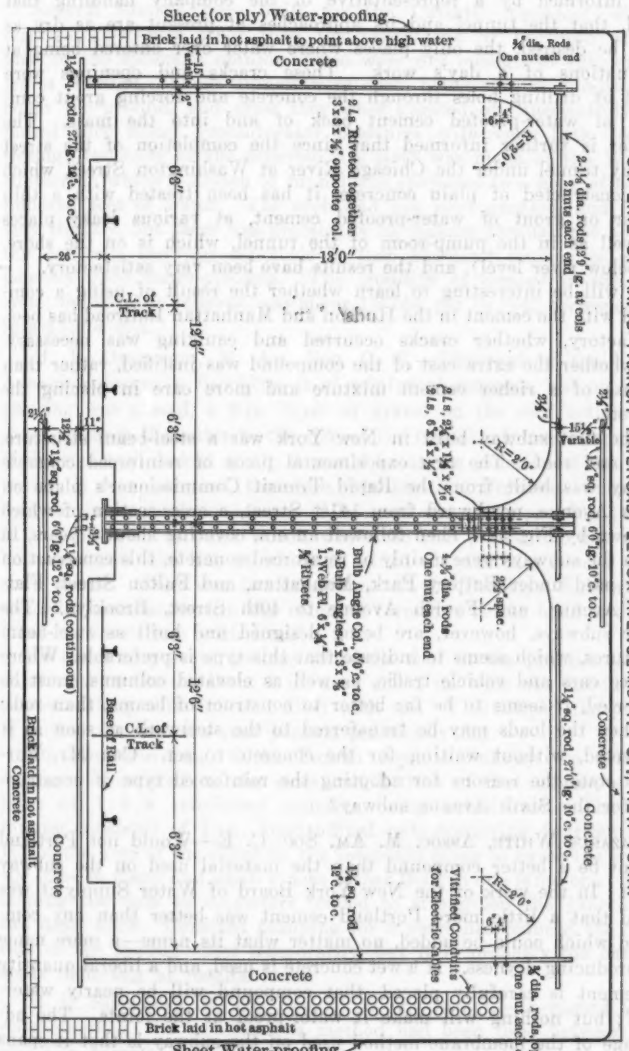

Fig. 32.

Mr. Boucher.

been informed by a representative of the company handling that brand, that the tunnel and its approaches at present are as dry as could be desired, the only places where water ever entered being at terminations of a day's work. These cracks and openings were closed by drilling holes through the concrete and forcing grout composed of water-proofed cement back of and into the mass. The speaker is further informed that since the completion of the street railway tunnel under the Chicago River at Washington Street, which was constructed of plain concrete, it has been treated with a thin mortar or grout of water-proofed cement, at various leaky places (as well as in the pump-room of the tunnel, which is on the shore, but below river level), and the results have been very satisfactory.

It will be interesting to learn whether the result of using a compound with the cement in the Hudson and Manhattan Railroad has been satisfactory, whether cracks occurred and caulking was necessary, and whether the extra cost of the compound was justified, rather than the use of a richer cement mixture and more care in placing the concrete.

The first subway built in New York was a steel-beam structure, walls and roof. The first experimental piece of reinforced concrete subway was built from the Rapid Transit Commissioner's plans on Lenox Avenue, northward from 141st Street, a cross-section of which is shown by Fig. 32. Then followed an era, covering about 6 years, in which the subways were mainly of reinforced concrete, this construction being used under Battery Park, Manhattan, and Fulton Street, Flatbush Avenue, and Fourth Avenue to 40th Street, Brooklyn. The newer subways, however, are being designed and built as steel-beam structures, which seems to indicate that this type is preferable. Where surface cars and vehicle traffic, as well as elevated columns, must be supported, it seems to be far better to construct of beams, than rods, for then the loads may be transferred to the steelwork as soon as it is riveted, without waiting for the concrete to set. Can Mr. Burrowes state the reasons for adopting the reinforced type of construction for the Sixth Avenue subway?

Mr. White.

LAZARUS WHITE, ASSOC. M. AM. SOC. C. E.—Would not Portland cement be a better compound than the material used on the subway work? In the work of the New York Board of Water Supply it was found that a little more Portland cement was better than any compound which could be added, no matter what its name—a mere name not producing dryness. If a wet concrete is used, and a liberal quantity of cement is carefully placed, that compound will be nearly waterproof; but nothing will make it water-proof at the joints. The advantage of the membrane method used on the subway is that it spans the joints and prevents water from getting through them.

Mr. White.

Several tunnels were built for the Catskill Aqueduct without any water-proofing other than the liberal use of Portland cement, and, in the speaker's opinion, these were dry enough to run subway trains through. These tunnels were deep, being several hundred feet below the ground, and after they were grouted off, successfully sustained very heavy ground-water pressures with very little leakage through the body of the concrete. A test* was made at the Wallkill Siphon, in which a stretch of tunnel was subjected to a head of several hundred feet of water. The arch had not been grouted, and leaked very slightly, but there was practically no leakage through the body of the concrete, showing conclusively that Portland cement is a sufficiently good water-proofing. The quantity of cement in this concrete, the speaker believes, was about 1.8 bbl. per cu. yd., corresponding to a 1:2:4 mix.

Mr. Oestreich.

H. L. OESTREICH, M. AM. SOC. C. E.—The roof of the Fourth Avenue Subway, in Brooklyn, is of reinforced concrete, but no water-proofing was placed, a 6-in. layer of gravel on the roof acting as a drain to carry the water to the side of the tunnel. It was found that, if the structure leaked at all, it would be at the junction of two days' work. It is a question, therefore, whether Mr. Burrowes would not find the same conditions, even if he used the water-proofing powder in the concrete; in other words, while the slab placed one day might be water-proof, the line at which it joined the next day's work would show a leak. That was the experience on the Brooklyn Subway. It seemed almost as though the concrete formed a better bond with any other material than with itself.

In order to prevent leakage from the roof at the junction of two days' work, a furrow about 1 in. deep and 2 in. wide was cut into the concrete along this line and filled with tar. This helped the process of silting up, and the roof became practically dry.

On two contracts of the Fourth Avenue Subway the brick in mastic was omitted on the sides and bottom of the subway, a 6-in. layer of 1:2:4 reinforced concrete being substituted. The reinforcing consisted of ¾-in., longitudinal rods occupying four-tenths of 1% of the area of the concrete, the intention being to cause the shrinkage to be in many and small cracks rather than in one large one. Overlapping the rods 48 diameters tended to strengthen the junction of two days' work. Constant pumping for 2 years has reduced the elevation of the ground-water temporarily, but it is probably too early to speak definitely of results.

Mr. Burrowes.

H. G. BURROWES, M. AM. SOC. C. E. (by letter).—In regard to the water-proofing, the membranous method had been used between 12th and 27th Streets, and had not given entire satisfaction, as leaks had

* *Engineering News*, December 14th, 1911.

Mr. Burrowes.

developed after completion; therefore, in order to obtain better results, Keystone Water-Proofing Compound was used experimentally between 27th and 33d Streets. In general, it was satisfactory, except at stations, because a leak which would be unnoticed between stations, would be very unsightly and objectionable at a station.

As it was necessary to construct the subway in alternate slices or sections, first under the elevated column bents and then between these bents, there were numerous joints, and it was there that the leaks occurred, and also at places where structural steel extended through the concrete or where reinforcing rods ended close to its inner face. These leaks were stopped by cutting away several inches of concrete from the inside and then plastering with cement mixed with water-proofing compound, by grouting, and, in some cases, where the back-fill had not been completed, by stripping the roof and then placing brick laid in hot asphalt.

The cost was much less than with the membranous method, for not only was the cost of the compound less than that of the membrane, but the outer protecting masonry and the additional excavation for it became unnecessary; even by adding the amounts spent on stopping leaks, there was an ultimate saving.

It is very doubtful whether better results could have been obtained by the use of additional cement, as the leaks were due to the joints in the concrete between sections as built and to the presence of steel which extended through or nearly through the concrete roofs.

Under the practical conditions that prevail in executing such work, it is probable that some leaks would have occurred, no matter what class of water-proofing had been used. The conclusion reached was that the use of the compound was satisfactory between stations, but that at the stations the water-proofing results were not positive enough.

The decision to use reinforced concrete instead of structural steel was made for the reason that there is a slight saving in quantities due to the use of the former, as stated by Mr. Whitney; and, in addition to this, the unit cost of the rods was less, and at the time that this structure was designed, prompt delivery of structural material could not be obtained, while rods could always be had.

Paper No. 1240

MAXIMUM STRESSES IN BASCULE TRUSSES.

By W. Watters Pagon, Jun. Am. Soc. C. E.*

To the best of the writer's knowledge, nothing has been published on the subject of the maximum dead stresses in the trusses of bascule bridges, of the trunnion, rolling lift, or combination types, and, as a result, several instances have come to his notice where the stress sheet showed only the dead stresses for the bridge closed, and not the maximum stresses. In one case the true stress was three times the stress

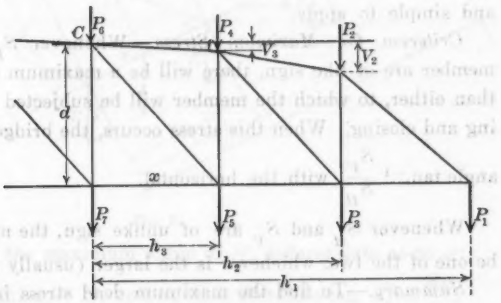

FIG. 1.

shown, though, fortunately, in this particular member, this was not the governing stress. There were several members, however, where the dead stress was the governing one, and in some of these the section had to be increased about 6 per cent.

Method of Determining Maximum Stresses.—Assume the truss shown in Fig. 1, subjected to the joint loads, P_1, P_2, P_3, etc.; the

* Now Assoc. M. Am. Soc. C. E.

problem is to find the maximum dead stress in the lower chord member, x. Let the truss revolve about a horizontal axis at O. Find the dead stress in x with the truss in the horizontal position. Call this stress S_H. Find the dead stress in x with the truss vertical, or 90° from the first position. Call this stress S_V. Then the true maximum dead stress is $S = \sqrt{S_H^2 + S_V^2} = \frac{1}{d}\sqrt{M_H^2 + M_V^2}$, where M_H and M_V are the respective moments about the moment center, C. In parallel chord trusses without secondary system, $S_V = (P_1 + P_3 + P_5$, etc.) $\times$ $d \div d$, equals the sum of the bottom chord loads between the member and the free end of the truss; but for parallel chord trusses with secondary system, S_V equals the sum of all the bottom chord and half of the middle joint loads between the member and the free end.

In the foregoing, attention has been devoted to bottom chord members only, for, although the theory applies to all members, the top chords and web members* receive their maximum dead stresses when the truss is in the horizontal position. In any special case, it will be easy to determine which members need to be investigated for maximum stress by the use of the following criterion, which is easy to remember and simple to apply.

Criterion for Maximum Stress.—Whenever S_H and S_V for any member are of like sign, there will be a maximum dead stress, greater than either, to which the member will be subjected during every opening and closing. When this stress occurs, the bridge will be open at an angle $\tan.^{-1}\frac{S_V}{S_H}$, with the horizontal.

Whenever S_H and S_V are of unlike sign, the maximum stress will be one of the two, whichever is the larger (usually S_H).

Summary.—To find the maximum dead stress in any member in a truss revolving about an axis perpendicular to it: Find S_H for the bridge closed. Find by inspection whether S_V will have the same sign as S_H. If of like sign, find S_V and then the maximum stress from $S = \sqrt{S_H^2 + S_V^2}$. If of unlike sign, S_H (or S_V) is the maximum stress.

As the methods and theory given are perfectly general, any two directions at right angles to each other may be substituted for

* For web members this is strictly true only in parallel chord trusses.

"horizontal" and "vertical." They may also be applied to any revolving truss subjected to a number of parallel loads which are not vertical.

Theory.—In Fig. 2, which shows the truss open at an angle, α, let the loads and dimensions be the same as in Fig. 1. To find the stress in x for this position:

$$S' = \frac{M}{d} = \frac{(P_1 \cos.\ \alpha\, h_1 + P_3 \cos.\ \alpha\, h_2 + \ldots\ldots P_2 \cos.\ \alpha\, h_2 + \ldots\ldots \text{etc.})}{d}$$

$$+ \frac{(P_1 \sin.\ \alpha\, d + P_3 \sin.\ \alpha\, d + \ldots\ldots \text{etc.} + P_2 \sin.\ \alpha\, v_2 + \ldots\ldots \text{etc.})}{d}$$

$$= \frac{\Sigma P\, h \cos.\ \alpha + \Sigma P\, v \sin.\ \alpha}{d} = \frac{M_H \cos.\ \alpha + M_V \sin.\ \alpha}{d}$$

$$= S_H \cos.\ \alpha + S_V \sin.\ \alpha.$$

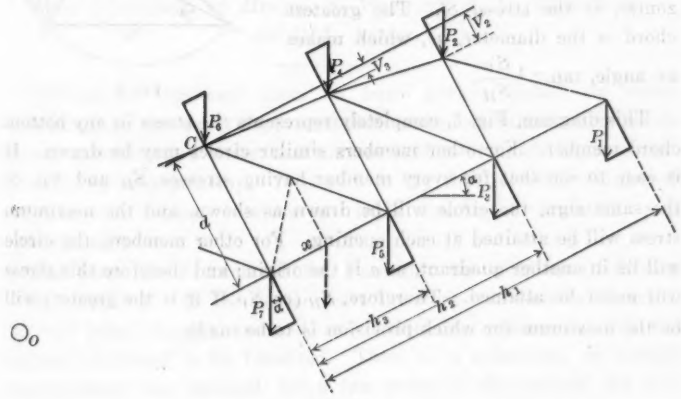

FIG. 2.

In order to find the maximum value of S', differentiate as to α:

$$\frac{dS'}{d\alpha} = -S_H \sin.\ \alpha_o + S_V \cos.\ \alpha_o = 0, \text{ therefore } \tan.\ \alpha_o = \frac{S_V}{S_H};$$

and $$\sin.\ \alpha_o = \frac{S_V}{\sqrt{S_H^2 + S_V^2}},\ \cos.\ \alpha_o = \frac{S_H}{\sqrt{S_H^2 + S_V^2}};$$

therefore, $$S = \frac{S_H^2}{\sqrt{S_H^2 + S_V^2}} + \frac{S_V^2}{\sqrt{S_H^2 + S_V^2}} = \sqrt{S_H^2 + S_V^2}$$

= the maximum, S'.

For any member in a secondary system, the same reasoning holds true.

To find a criterion for the position giving the maximum stress, lay off, in Fig. 3, $ab = S_H$, horizontally and measured to the right, if in compression. Then lay off $bc = S_V$, upward if in compression, making abc a right angle. Then $ac = \sqrt{S_H^2 + S_V^2} = S$. Draw a line, ad, at an angle, α, with ab. Project b to e, and c to d. Then $ae = S_H \cos. \alpha$, and $ed = S_V \sin. \alpha$; and, therefore, $ad = S'$ for the angle, α.

Draw a circle through a, b and c. Then, as $abc = 90°$, ac is a diameter, and as adc is a right angle, d lies on the circle. Therefore the length of any chord, ad, at an angle, α, with the horizontal, is the stress, S'. The greatest chord is the diameter, ac, which makes an angle, $\tan.^{-1} \frac{S_V}{S_H}$.

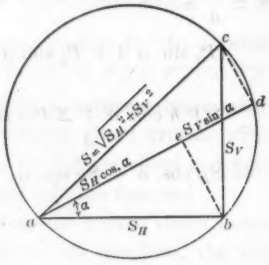

FIG. 3.

This diagram, Fig. 3, completely represents the stress in any bottom chord member. For other members similar circles may be drawn. It is easy to see that for every member having stresses, S_H and S_V, of the same sign, the circle will be drawn as shown, and the maximum stress will be attained at each opening. For other members, the circle will lie in another quadrant, as a is the origin; and therefore this stress will never be attained. Therefore, S_H (or S_V if it is the greater) will be the maximum for which provision is to be made.

Paper No. 1241

STREET SPRINKLING IN ST. PAUL, MINN.*

By C. L. Annan, M. Am. Soc. C. E.

With Discussion by Messrs. S. Whinery, A. H. Blanchard, and C. L. Annan.

"Municipal engineers seem to have always looked on street sprinkling as an every-day, matter-of-course operation, not worth serious attention and study, and not susceptible of much improvement in efficiency and economy. It is safe to say that no other municipal function or process receives so little intelligent attention and supervision."†

For years the citizens of St. Paul put up with unsatisfactory street sprinkling. In the earlier years the work was done by contract, the cost being roughly assessed, at considerable expense, against the property supposed to be benefited. Then, as a substitute, an annual appropriation was included, for a few years, in the general tax levy to meet the cost of sprinkling by day labor. The result was intolerable. Finally, at the general election in May, 1908, a sprinkling amendment was submitted to the people, and in 1909 the Commissioner of Public Works took charge of street sprinkling under this amendment.

The system inaugurated at that time has been fairly perfected, and it has been demonstrated that systematic attention to details has brought results at least commensurate with the cost.

The amendment provided for an appropriation of $60 000 for the first year and an additional $40 000 for the second year. By that

* Presented at the meeting of September 18th, 1912.
† *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 33.

time the system should be smoothly running under the revolving fund fed by the assessment of the property benefited.

The third season under the new law opened with about 230 miles of streets to be sprinkled. New routes were added from time to time and a few were discontinued, resulting in a total gain for the season of about 9 miles. There is generally strong opposition to the discontinuance of a route once started.

From two to eight trips, depending on the nature of the street surface and the amount of traffic, are made each day. There are nine sprinkling districts, each under the supervision of an inspector at $75; a chief inspector or overseer at $110 is also employed. The ten inspectors report daily. The chief inspector advises and assists local inspectors and makes special examinations. The inspectors' reports are tabulated daily; all complaints are investigated, and the written reports are filed for reference. The foreman of stand-pipe construction and repair crews receives daily instructions, and the yardmaster returns a daily statement of sprinkler distribution and repairs. Careful itineraries on each team route are taken from time to time, and, in short, the head of the department is intimately informed of all details concerning equipment and operation.

In assessing the cost of the work, the abutting frontage, number of trips per day, and length of time sprinkled, are taken into consideration. For the season of 1911, 43 assessment rates thus resulted, ranging from less than 1 cent to 11½ cents per front foot of abutting property. The cost of water is not included in the assessment, the City charter so providing.

Water sprinkling of macadam was superseded early in the season by oil spraying. It was estimated that about ½ gal. per sq. yd. of a 20% liquid asphalt might be applied three times during the season at a cost not to exceed that of water sprinkling for the same period. The latter part of the season being unusually wet, comparatively few streets required the three coats of oil.

The sprinkling wagons are city property; 40 new and 31 second-hand sprinklers, varying in capacity from 600 to 750 gal., were purchased in 1903. Twelve 750-gal. tanks were added in 1909, and as many more in 1910. These 95 sprinklers allowed a 10% reserve. All were in good repair after a thorough overhauling during the winter.

Teams were used for 7 days in the week at $100 per month, rain

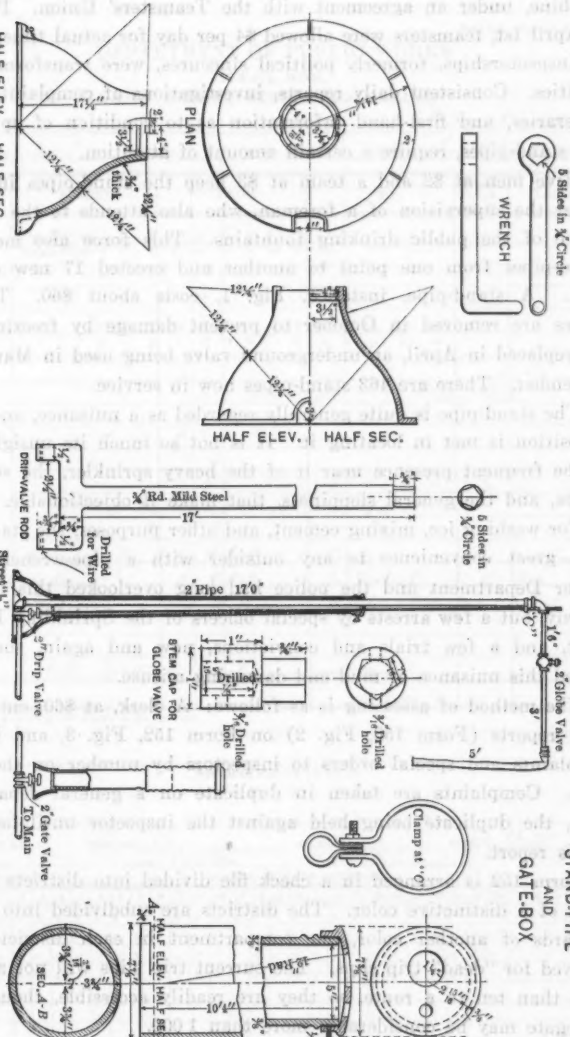

Fig. 1.

STAND-PIPE AND GATE-BOX

or shine, under an agreement with the Teamsters' Union. Previous to April 1st, teamsters were allowed $4 per day for actual time.

Inspectorships, formerly political sinecures, were transformed into realities. Consistent daily reports, investigations of complaints, route itineraries, and first-hand information as to condition of sprinklers and stand-pipes, require a certain amount of attention.

Five men at $2 and a team at $3 keep the stand-pipes in repair under the supervision of a foreman, who also attends to the maintenance of the public drinking fountains. This force also moved 16 stand-pipes from one point to another and erected 17 new ones in 1911. A stand-pipe, installed, Fig. 1, costs about $60. The top valves are removed in October to prevent damage by freezing, and are replaced in April, an underground valve being used in March and November. There are 463 stand-pipes now in service.

The stand-pipe is quite generally regarded as a nuisance, and much opposition is met in locating it. It is not so much its unsightliness as the frequent presence near it of the heavy sprinkler, the standing horses, and the general sloppiness, that make it objectionable.

For washing ice, mixing cement, and other purposes, the stand-pipe is a great convenience to any outsider with a pipe-wrench. The Water Department and the police had long overlooked this kind of larceny, but a few arrests by special officers of the Sprinkling Department, and a few trials and convictions, now and again, somewhat abated this nuisance of mud and damaging misuse.

The method of assessing is as follows: A clerk, at $60, enters the daily reports (Form 150, Fig. 2) on Form 152, Fig. 3, and indexes complaints and special orders to inspectors by number on the same form. Complaints are taken in duplicate on a general department form, the duplicate being held against the inspector until he turns in his report.

Form 152 is arranged in a check file divided into districts by tab cards of a distinctive color. The districts are subdivided into routes by cards of another color, one compartment in each district being reserved for "dead" trip slips. The current trip slips will not average more than ten to a route, so they are readily accessible, though the aggregate may be considerably more than 1 000.

Trip and route numbers may be changed on a trip slip (Form 152) but a change of limits necessitates new slips and cross-references

FIG. 3.

and the consigning of the obsolete slip to the "dead" division until required for assessment purposes. All assessment forms are handled on the loose-leaf system.

Two men, at $80, are employed from March 15th to August 1st in making a transcript from the County Auditor's records on Form 151 (Fig. 4) and preparing assessment sheets (Form 166, Fig. 5). The force is then doubled to make the assessment, post, and check it, the work to be completed early in October.

The assessment rate, A, per front foot of property abutting on any particular section of sprinkled street is derived as follows:

D = trips per day on the particular route,

M = sprinkling period, in months and tenths, for the same route,

$C = D \times M$ (nearest integer),

F = total frontage on same route,

$P = C \times F$,

S = sum of products, P, for all routes,

T = estimated total cost of sprinkling all routes. (From the five months actual record a close estimate can be made for T.)

$$R = \frac{T}{S},$$

Then $A = C \times R$.

An idea of the method of procedure and of the relation of volumes may be obtained by particular reference to the assessment of 1911. The daily record, on Form 152, was summarized on Form 154 (Fig. 6), embracing 1 439 sheets in twelve groups, one for each ward, each group arranged alphabetically by street names and bound with flat-head fasteners. The coefficient, C, having been determined for each slip, the 1 439 slips were rearranged in 43 groups, corresponding to the variations of C. A five-column table was then prepared with a line for each value of C, thus:

C	F	P	$F \times R$	$C \times R$
1	34 006	34 006	62.91	0.00185

The total of Column P is S. The total of Column $F \times R$ is T. R is obviously the first item in Column $C \times R$. R being constant, there are as many values of A as there are of C and $F \times R$, for each group is checked by the total.

The entries on Form 154 are now completed, and the slips are rearranged in ward groups. In the meantime, Form 166 has been prepared to correspond with each sheet of Form 154, of which it is an extension applied to the property to be assessed. Form 166 is arranged alphabetically. When complete, the sheets are paged consecutively from the first sheet of Ward 1 to the last sheet of Ward 12.

The assessment is finally made on Form 151, there being as many sheets of this form as there are block numbers involved on the various plates and subdivisions named on Form 166.

FIG. 6.

For instance, on page 720 of Form 166 there are four blocks of property containing lots to be assessed. There will consequently be four corresponding sheets of Form 151. These sheets are arranged alphabetically by plot names in ward groups, and they are also paged consecutively.

Page 1290 (Fig. 4) is a specimen sheet whereon the seven lots in the Auditor's Sub. No. 30, noted on the first line of page 720, are entered in detail. The 1911 assessment contained 3 472 sheets of Form 151.

The cost of making the assessment of 1910 was a little more than 2%, but City Railway complications raised this ratio to more than 3% in 1911.

Early in May, 1911, the Supreme Court of the State decreed that the St. Paul City Railway Company must at once comply with the Ordinance of October, 1909, requiring this company to sprinkle its tracks. As an immediate alternative, the company agreed with the Commissioner of Public Works to pay the Sprinkling Department for doing the work. The cost of sprinkling streets traversed by the City Railway was to be prorated as to time and space from the totals of the general assessment for the same streets. Form 190 (Fig. 7) was provided for this record.

Form 190 9-19-1911 1M.

Standard size 6¼ by 4 in.

FIG. 7.

As soon as arrangements could be made, the City Railway Company sprinkled many miles of its track space with road oil.

The occasional itinerary which has been referred to has proved to be a practicable and an excellent feature. It was called for at irregular intervals, and the returns assisted in determining the efficiency of both teamsters and inspectors. Each teamster and inspector is furnished with a specific route sheet, and the care taken to equalize routes is generally appreciated and tends to the good of the service. The routes as traveled are reported on Form 173 (Fig. 8). They are platted on light blue prints. A summary is made of the number of

tanks of water used and of the feet of effective and idle travel in a half day. The 45 sq. miles of sprinkling area are covered by 34 tracings (8½ by 13½ in.) on a scale of 600 ft. to 1 in., and from these tracings the blue prints referred to are made as required.

Among the many owners of the 50 000 lots, more or less, assessed, there are many complainants who desire to know the particulars, and, for the benefit of this class, a special form has been prepared. Occasionally, a correction is necessary; there were only twenty on the first assessment made under this system.

Form 173 3-22-1910 1M.

Inspector

Standard size 8¼ by 6⅛ in.

FIG. 8.

The assessment for each ward is cross-checked and balanced to a cent. A concluding word may be said as to the daily reports, Form 150 (Fig. 2). Each section of street has its trip number. The small figures under the trip numbers show the number of trips actually made for the day. Under Route 4 it will be noted that Trip No. 31 lacks the sub-number. The explanation immediately follows. To write "31" is equivalent to writing "Indiana Avenue, from South Robert Street to Hyde Street." On May 18th Trip No. 31 was divided. A portion of it (No. 84) being transferred from Route 4 to Route 7.

Each inspector keeps a consecutive list of last numbers in his district, and can thus assign a new number when necessary.

DISCUSSION

S. WHINERY, M. AM. SOC. C. E. (by letter).—This paper is so interesting and valuable that the reader reaches its end hungry for more information. Mr. Whinery.

It is so seldom that this branch of municipal work receives, from city engineers and city officials, anything like the attention it deserves or that is given to other departments of city work of no greater importance, that any one who takes an interest in the matter must welcome this account of an intelligent and efficient organization for street sprinkling in St. Paul. It is sincerely to be hoped that the author will favor the Society with another paper dealing with experiences and results. It would be very interesting to know about the practical working of the system, the efficiency attained, as compared with the usual unsatisfactory organization—or lack of organization—and the degree in which the service is successful in abating the dust nuisance and in meeting the reasonable demands of the public.

Particularly would engineers be glad to know the detailed cost of the service, reduced to units readily comparable with results in other cities.

The writer would suggest, as the most simple and satisfactory unit of quantity, 1 000 sq. yd. of street sprinkled once, and that all other elements of cost and service be based on this unit. The units commonly used (where statistics are reported at all) are often so indefinite or general as to be of little use for comparison. Thus, the number of miles of street sprinkled through the season is of little value unless one knows the widths of the streets and the number of times they are sprinkled daily, or rather the number of times they are sprinkled during the season.

The method described for assessing the cost of the service on abutting property owners seems to indicate that the width of the street is not taken into consideration. It seems proper that this should be done. Those owning property on a wide street certainly receive more service than those on a narrow street; and as property on a wide street is usually more valuable than that on a narrow street, the owners might justly be required to pay in the ratio of the work done, that is, the area of the street. To provide for this, of course, would introduce another factor into the computation of the assessments, but if the widths (or half widths) of the streets are known, the actual work of computation would not be increased greatly, though the unit on which the assessment is based would be changed from front feet to square feet, or square yards.

Mr. Whinery.

It is not stated how street intersections are dealt with in assessing the cost, though the inference that the cost of sprinkling intersections is taxed on the property owners seems to be warranted; nor is it stated how corner lots, sprinkled on two sides, are assessed.

As it is stated that street oiling is used to some extent, it would be interesting to know the relative cost, efficiency, and general merits of oiling and sprinkling in St. Paul.

It is not only in St. Paul that stand-pipes for supplying sprinkling wagons are regarded as nuisances. Their unsightliness might be overcome in most locations by using a valve and connection placed under the edge of the sidewalk and covered by a hinged plate. The chief source of dissatisfaction is usually the "sloppiness" around these stand-pipes. This is chargeable largely to the carelessness of drivers in allowing the tanks to overflow, and, where the hose is permanently connected to the tank, in allowing the water contained in it to waste on the street after it is disconnected. In this form of connection the trouble would be largely overcome if a valve were placed at the rear end of the hose, and closed before the hose is disconnected from the hydrant. Certainly this trouble can be overcome by the use of appropriate devices and reasonable care on the part of the driver.

While in most cities the municipality supplies, free of charge, the water used for sprinkling, and its value is not charged to the account, it is very desirable that the approximate quantity and cost should be reported, in order that a complete statement of cost per unit area may be deduced.

Mr. Blanchard.

A. H. BLANCHARD, M. AM. SOC. C. E.—This paper brings to the attention of municipal engineers the value of cost data and accurate records of construction details. The speaker, however, only refers to this feature of the paper in order to express his appreciation of the author's services in bringing before the Society a comprehensive plan covering cost data and records in a field in which very little work of this character has been done.

A paper on the broad problems of the economics of street watering seems to be opportune. Up to this time there has been comparatively little discussion relative to the efficiency of street watering. In considering the problem from this standpoint, a question which occurs to any one interested in the subject is: What are the fundamental reasons for sprinkling streets with water? There are engineers who claim that the reason is mainly to lay the dust. Street sprinkling, as done by these engineers, is used for that purpose not only on macadam roads, but on pavements of all types. If pavements are properly cleaned (by methods which are adaptable in practically all American cities), is there any necessity to sprinkle them to lay the dust? The answer is in the negative, because, with a proper system of street cleaning, dust should not exist in such quantities as to require any

process of dust laying. The question of laying dust on macadam roads naturally brings up for consideration the relative economics by watering and by other methods which have come into use within the past decade. This feature will not be considered by the speaker, as it has formed the subject of many discussions before this Society.* Mr. Blanchard.

Another reason advanced by some municipal engineers is that street watering materially cools the atmosphere. These engineers, however, use street sprinkling methods from the middle of April to the middle of October. It is doubtful if, in the majority of cities, engineers could state conscientiously that it is necessary to cool the atmosphere during two-thirds of the time when streets are watered. It would be of material value if a series of experiments should be undertaken to determine how much the atmosphere is cooled within a certain reasonable distance above the pavement and on adjoining property by street sprinkling with water. G. A. Soper, M. Am. Soc. C. E., who has spent considerable time in investigating the subject, is particularly positive in the statement that no cooling effect is appreciable. Although it is admitted by many that it may not be appreciable from the standpoint of the actual temperature, it is believed, however, that on macadam roads, under certain local conditions, there is a cooling effect—at least mentally. One excellent example of this effect is seen in the method used in Monte Carlo. Although the macadam roads of the Principality of Monaco are rendered dustless in the main by the use of bituminous materials, in the instance of the light-colored limestone macadam roads in the vicinity of the Casino, surrounding the beautiful gardens laid out in front of that magnificent yellow limestone building, the streets are watered not only to give the effect of coolness, but also, from the esthetic standpoint, in order that the limestone macadam thus treated will harmonize with the beautiful buildings and residences which border these boulevards.

A third reason which has been advanced by some engineers is that street watering serves to clean the streets. The speaker does not believe that it is a question for consideration whether street sprinkling properly conducted does or does not clean the streets. Certainly, it is usually impracticable to clean macadam roads by watering without the creation of mud or the disintegration of the surface. With the figures at hand, it certainly is not economical to clean pavements by street sprinkling when they are used under conditions for which they are suitable and economical.

C. L. ANNAN, M. AM. SOC. C. E. (by letter).—In reply to Mr. Whinery, the following statement of unit costs is presented: Mr. Annan.

Total travel of 80 teams per day.....	5 248 000	lin. ft.
Total effective travel (76%).....	3 883 520	" "
Total area (width of spray, 22 ft.)....	9 493 050	sq. yd.

* *Transactions*, Am. Soc. C. E., Vol. LXV, pages 462 to 466, and Vol. LXXIII, pages 33 to 43.

Mr. Annan.

Daily expense:

80 teams @ $100 per month	$267
10 inspectors @ $75 per month	25
Stand-pipe repairs, average	15
Sprinkler " "	13
2 000 000 gal. water @ $90	180
Total	$500

Consequent cost of sprinkling 1 sq. yd. once.	0.00527	cent.
Average cost of sprinkling 1 sq. yd. four times per day for 210 days	4.4	cents.

During the summer of 1910, 80 000 gal. of a 45% liquid asphalt, heated to 150° Fahr., were applied to 300 000 sq. yd. of macadam surface, the cost per square yard being as follows:

Cleaning street surface	0.35	cent.
Road oil	1.00	"
Application	0.15	"
Total	1.5	cents.

Three applications would be required for the full season, which would make the cost practically the same as for water sprinkling.

There was much opposition and complaint of damage and annoyance by residents along the smeared streets, however, and, furthermore, as the oil dried out, it left the street surface in a badly disintegrated condition. During the following year a 20% oil was used. No heating was required; and three applications were sufficient for the season. The surface damage was less, but the popular outcry was not much abated.

In making the assessment, the factor of street widths is provided for in the trip element. Three trips are necessary to cover some wide streets; one trip suffices for a narrow street. The same frontage is assessed three times as much in one case as in the other, as a trip is a single line of travel in one direction.

The total cost of the season's sprinkling is prorated to the frontage participating. The law provides that 10% of this cost may be for equipment. The sprinkling of street intersections must also be regarded as a general charge, as there is no provision for payment otherwise. The law has also been construed to prohibit rebates for corner lots abutting on two sprinkled streets.

The matter of the concealed hydrant received attention early in 1910. Neither of the two eastern manufacturers approached could furnish just what was wanted, and it was late in the season before the desired article was obtained. In the meantime, the conclusion had been reached that the main objection to the stand-pipe is not its un-

sightly appearance. The ungainly sprinkler itself is no more esthetic, but worst of all is the faithful but inconsiderate horse at his 5 to 10-min. stands. Mr. Annan.

The teamster would view the innovation with no favorable eye. He would consider it a hardship to be forced to descend and climb again whenever he filled his tank, to say nothing of lifting the hydrant cover off and putting it on, and of stowing his loaded hose. The new hydrant was never put in.

The mud at the base of the stand-pipe, of course, must be eliminated as soon as possible by draining and paving, to insure the departure of a free tank.

When the St. Paul pavements are bare in freezing weather they are sprayed with calcium chloride (1 lb. per gal.) dissolved with a steam jet.

The following figures are approximately correct for a period of 3 weeks in December, 1910:

27 tons calcium chloride @ $14	$378
8 tons coal @ $4.75	38
4 teams, 18 days, @ $4	288
3 men, 18 days, @ $2	108
Total	$812

At intervals during the period, 100 000 sq. yd. of pavement were treated.

Mr. Blanchard asks: "If pavements are properly cleaned, * * * is there any necessity to sprinkle them to lay the dust? The answer is in the negative * * *."

Another answer is that the use of methods commonly considered effective does not down the demon "dust." Until perfection of method can be more nearly reached, a little water must be used here and elsewhere. Hand sweeping by day and power flushing by night and day do not hold dust in subjection. It is unceasingly making. It is tracked and blown in from adjoining unpaved streets, and arises from the sites of building operations. Whatever the theory, the condition must be met.

A light oil, especially designed for use on pavements, was tested last year on asphalt, brick, and stone surfaces in St. Paul, but with unsatisfactory results.

The vacuum cleaner may eventually do away with the use of the universal solvent, but it will be necessary to apply it to the sidewalks as well as the roadways, and even then will it get the impalpable, harassing dust emanating from all sources of friction in the busy life of a city's streets?

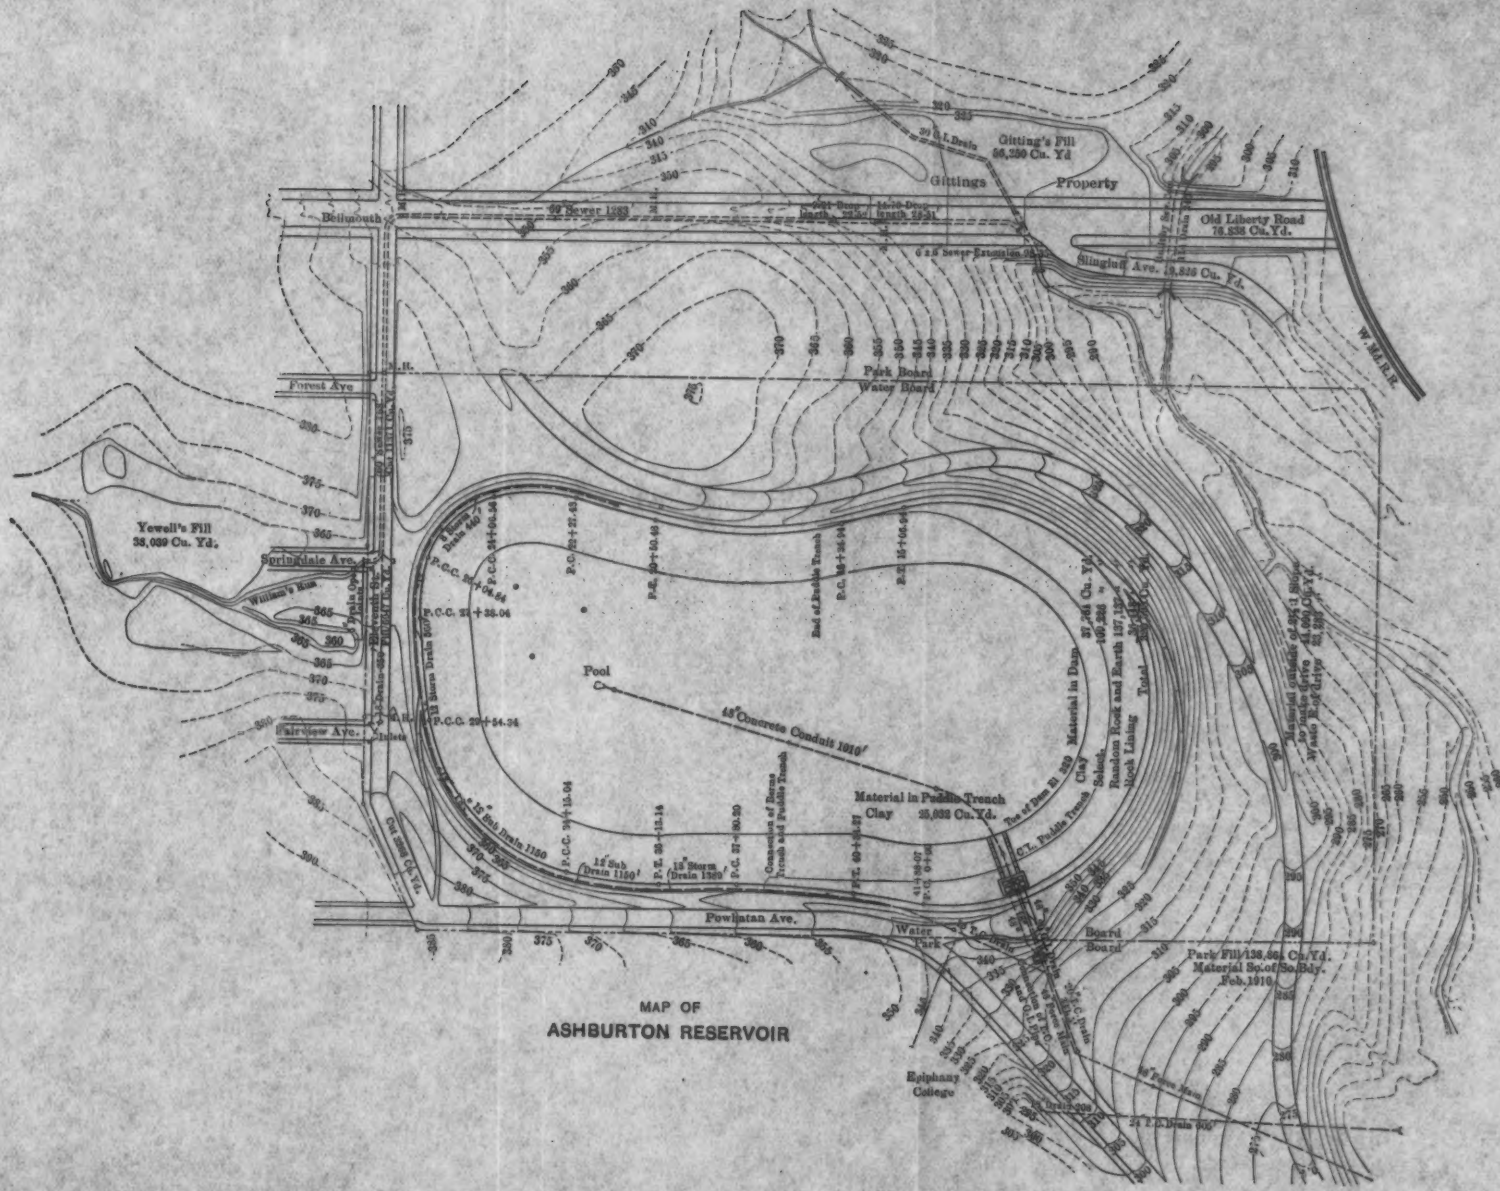
TRANSACTIONS

Paper No. 1242

CONSTRUCTION OF A HIGH-SERVICE RESERVOIR AT BALTIMORE, MD.*



By P. A. Beatty, M. Am. Soc. C. E.

The new high-service reservoir, Lake Ashburton, constructed by the Water Department of Baltimore in 1908-10, is on a site near the intersection of Slingluff Avenue and Liberty Road, and only a short distance west of the Western Maryland Railroad. The spot selected is between two low spurs which run eastward from a plateau, about 450 ft. above mean tide, and terminate in the low ground at Pecks Run. Between these spurs there flowed a small stream, Williams Run, carrying the cesspool overflow from a small suburban development and the storm-water flow from a few hundred acres.

Sub-surface investigations indicated that, underlying a foot of top soil, there was a stratum of clay, from 1 to 4 ft. in thickness, beneath which the formation consisted of "rotten rock" (a decomposed serpentine) of varying depth, blanketing and lying between ledges of semi-decomposed rock and hard serpentine, more or less shattered, and with occasional nests of boulders. A portion of the site which was in timber was cleared and grubbed under a separate contract.

The work to be done consisted of the construction of an earthen dam, and the excavation of a basin, with appurtenant structures; and also the construction of a concrete storm-water sewer for the diversion of Williams Run.

MAP OF
ASHBURTON RESERVOIR

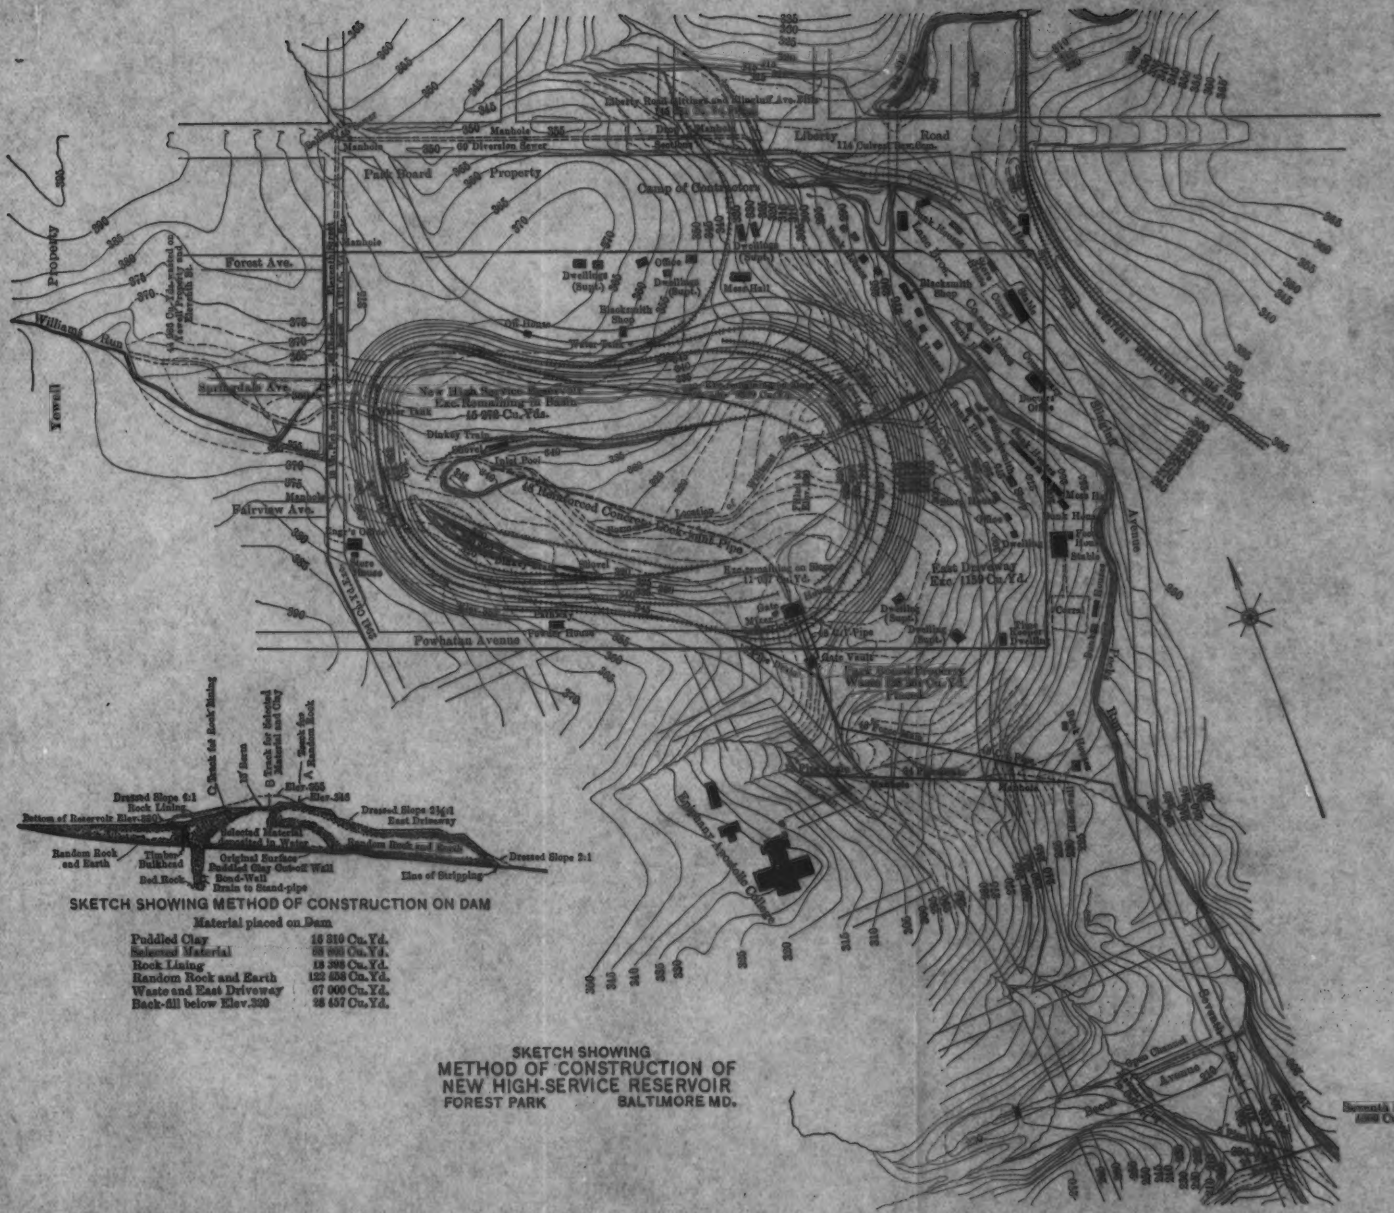
The work was let on a unit price basis, the reservoir work to Lane Brothers Company and Jones, of Altavista, Va., and Baltimore, the time being limited to 400 working days; and the diversion sewer to C. B. Clark and Company, a local firm, the limit being 200 working days. In the ten bids received for the construction of the reservoir, the total prices ranged from $494 810 to $837 241, and the working time from 200 to 700 days. In the thirteen bids received for the construction of the diversion sewer, the total prices ranged from $33 572 to $73 986, and the working time from 100 to 650 days.

Except for some topographical modifications, the work was completed substantially as laid out originally. Between the Western Maryland Railroad and Ninth Street the grade of Liberty Road was raised, and Slingluff Avenue was brought to the grade of Liberty Road on a curved fill with a 4% grade. This necessitated the construction of a 6 by 6-ft. box culvert, the extension of the diversion sewer 98.3 ft., caring for the flow from an existing box culvert, and the construction of a 9½-ft. arch culvert 240 ft. long to carry Pecks Run. The latter was built by the Baltimore Sewerage Commission. These modifications are shown on Plate VII, which covers the work as completed.

The original plans provided for a dam to be built in 6-in. lifts, thoroughly rolled, and for a reinforced concrete diaphragm against the outer wall of the cut-off trench, the trench to be back-filled with rolled or rammed clay. The former was changed to a fill deposited under water; the diaphragm in the cut-off trench was eliminated, and the trench was back-filled with clay, deposited under water.

Ground was broken on July 6th, 1908. The soil within the basin area was removed with wheeled scrapers and stored along the margins of the Water Board's property where convenient, after which the clay was similarly removed and stored near the soil banks, or within the basin area, adjacent to the cut-off trench. Meanwhile, that portion of the dam site which lay in the valley was being cleared of boulders and stripped of loam, roots, muck, etc., this waste material being deposited beyond the toe of the dam proper, and in the base of the East Drive fill. Several small springs, discovered near the bottom of the valley in the dam foundation, were led beyond the toe in blind drains.

Williams Run was diverted at the point where it crossed Contour 320, and was carried along the side of the south spur, crossing the



dam site at Elevation 315, being conducted over the cut-off trench in a 4 by 4-ft. box.

The cut-off trench was excavated with plows and scrapers, and with carts on the hillsides where it could be benched, derricks being set up to cover the work as the excavation deepened. The material through which the trench was sunk consisted of rotten rock, semi-decomposed rock, hard seamy rock, and hard serpentine ledges. At one point there was a mass of boulders, many of them containing 1 cu. yd. or more, extending from the surface to bed-rock and bedded in a matrix of gray, fully decomposed rock. On the north side, the trench cut a dike of felsite, which crossed it nearly at right angles, was about 18 ft. thick between nearly vertical faces, and extended from the surface to the bottom of the trench, about 62 ft. deep at this point.

When bed-rock was reached, it was found to be more or less seamy in places, making it necessary to continue the excavation until the conditions became satisfactory. Very little water was encountered at any point, the few small springs exposed being led to 2-in. stand-pipes through smaller pipe connections, and these stand-pipes were ultimately grouted. The average depth of the trench was 40 ft., the length 2 100 ft. The timbering consisted of 2 by 10-in. sheeting, 6 by 8-in. rangers 4 ft. 6 in. from center to center, and 6 by 8-in. braces 8 ft. apart.

In August a shovel was placed in Eleventh Street, and the fill at Williams Run was made. The water was allowed to pool to a depth of about 10 ft. on the upper side, and was carried thence through two lines of 18-in. pipe through the south end of the fill. Later, the pool was filled from the Eleventh Street cutting. When the run was finally diverted through the sewer, the pipes were followed into the fill and removed as far as practicable; they were then plugged with concrete, and a mass of clay was tamped into the excavation. An excavation was made afterward in the fill to the west of Eleventh Street, and a sub-drain was laid in a shallow trench in the original soil, well surrounded with broken rock, the purpose being to prevent the collection of a pool of stagnant water in the fill and the attendant danger of pollution of the water in the reservoir.

Eleventh Street being completed, the shovel was removed to the basin and began work on the north side, following down the slope with a series of curved cuts until Elevation 355 was reached, where a 15-ft.

berm was left; thence, the shovel followed the slope and shape of the reservoir to the bottom, at Elevation 320, after which successive parallel cuts were made until the cutting of Shovel No. 2 was joined.

Before the dam site was prepared for rolling, this shovel stored select material on the hillside immediately east of the cut-off trench, the random rock and earth being deposited in the base of the driveway fill, and tracks being laid across the valley on an embankment which had been built with carts.

On the north side, the first layout of tracks from the shovel ran eastward on a descending grade on the hillside, crossing the cut-off trench on a bridge, and curved northward through a shallow cut in the end of the spur to a switchback near the intersection of the north boundary line with Contour 315, from which the cart fill just mentioned was reached by a sharply falling grade. As this fill increased in height, the grade of the switchback became flatter and ultimately was reversed, giving a steep grade from the switchback to the dam. It was then abandoned, and the tracks were laid as shown on Plate VIII.

As the shovel descended the slope, switchbacks were necessary to get the spoil out of the basin. Plate VIII shows the loading track running to a switchback in the eastern end of the basin, from which the running track ascends the slope westward to a second switchback at the west end, at Elevation 350; thence it ran eastward, crossing the berm and curving northward on a descending grade to Liberty Road. Near the water tank, Track "C" curved around the inner slope of the dam. A second track, "A," gave access to the outer slope.

Plate VIII shows the Liberty Road and Gittings fills completed, and the Slingluff Avenue fill nearly finished, with the dam brought to Elevation 345.

Shovel No. 2 was started at Contour 320 on the south side, having first made a cut through the south spur immediately east of the gate-house site, through which a running track was laid. In the first position, with the shovel and loading track on the reservoir floor, the track reached the cut east of the gate-house by an ascending grade, from which point, with a descending grade, it curved around the end of the spur and reached the dam through the East Drive cut.

A switchback, near the south boundary line, gave access to the fill on the Park Board's property south of the gate-house. With this

location of the tracks, the dam was brought to Elevation 300, and the first lift of the fill on the Park Board land was made. Two relocations of tracks were necessary, the last being that shown on Plate VIII, from which position the dam and the last lift of the Park fill were completed, and the fill for Powhatan Drive was made. The last relocation was made when Shovel No. 2 was moved from the floor of the basin to the top and began to work down the slope, which was rendered necessary, in part, by the scarcity of proper material for construction in the lower cut.

Plate VIII shows that Shovel No. 2, having worked down the slope, is again on the reservoir floor, removing the long, narrow ridge between the foot of the slope and the previous cutting. The track runs from the shovel to a switchback near the west end of the basin at Elevation 340, thence eastward along the slope to a point near the gate-house, where it bifurcates, one branch being continuous with Track "A" from the north side, the other, "B," lying between "A" and "C." "A" is in position for raising an outer embankment of random rock and earth; "C" can place either "rock lining" or clay; while "B" is just completing a lift of select material. The fill on the Park land is shown as completed, the terraces indicated by the contours being dressed to a regular slope later.

The necessity of getting out certain classes of material as they were needed required considerable moving of the shovels back and forth, but less, on the whole, than might have been expected, as it was usually possible, by careful planning, to have the shovels working in the materials needed, and thus very little time was lost.

The total quantity removed from the basin below the clay was 582 458 cu. yd., of which 161 307 cu. yd. were earth, 98 752 cu. yd. were loose rock, and 322 399 cu. yd. were solid rock. The only unusual features connected with the construction were the methods used on the dam and the cut-off wall. A short description of the excavation of the trench for the cut-off wall has been given. When the question of the elimination of the reinforced concrete diaphragm was taken up, a series of experiments was undertaken with rammed clay and clay deposited in water. Clay and rotten rock, rammed in cylinders and placed under water pressure, were tested for penetration. When compressed in cylinders, under a pressure of 150 lb. per sq. in., the clay weighed 131.6 lb. and the rotten rock 129 lb. per cu. ft.

FIG. 1.—CUT-OFF TRENCH AT INNER TOE OF DAM, LOOKING NORTH.

FIG. 2.—LOOKING NORTH OVER RANDOM ROCK SECTION OF DAM FOUNDATION. TO LEFT, EMBANKMENT AT TOE OF SELECT SECTION. TO RIGHT, EMBANKMENT ON EAST DRIVEWAY FILL. DEPRESSION TO BE FLOODED AND FILLED WITH RANDOM ROCK AND EARTH.

Several 9 by 12-in. boxes, 8 ft. long, constructed so that the sides could be removed by loosening nuts and rods, were placed on end and filled with water. Clay was shoveled into some of these, and rotten rock into others, and some were filled with mixtures of the two in varying proportions. In several of the boxes a number of clods and lumps of clay and rotten rock were placed. About two weeks later, the sides of the boxes were removed and the contents examined, and found to be compact and homogeneous, the clods having fused with the surrounding material and practically disappeared. The material was compact and tough, and only slightly damp. The clay weighed 125 lb. and the rotten rock 118 lb. per cu. ft. This material had been subjected to no extraneous pressure; in the dam, the weight would certainly be very much greater, owing to the pressure exerted by the superincumbent material.

A section of the trench having been completed, several feet of clay were rammed into it in 3-in. layers, a picked foreman having charge of this work. It presented a good appearance, and seemed to be quite solid. Several 20-ft. lengths of 2-in. pipe were then set vertically at various points, their lower ends being deeply sunk in the clay (which was firmly rammed around them). Then these pipes were filled with water. The water usually forced its way to the surface around the pipes, but in several cases found lines of weakness in the clay and appeared several feet away. Several pits were also sunk in the clay and filled with water; two or three of these, placed directly beneath the braces, leaked, showing that the ramming was imperfect at these points. This led to the conclusion that satisfactory results could not be obtained by ramming. The cost of this work was 87.4 cents per cu. yd. It was then decided to fill the trench with clay deposited in water, using a certain percentage of rotten rock where practicable, care being taken to insure thorough mixing.

It was impracticable to remove the sheeting, but every fifth or sixth plank was cut away as the clay arose, permitting the puddle to fill the spaces between the planking and the trench walls. Heavy vertical timbers were placed at short intervals and braced hard against the rangers. The lower rangers were held by the cantilever ends of the verticals, and the original bracing was removed as the clay reached it. Usually, two sets of cross-braces were removed before the verticals were shifted. When the clay neared the third set, the jack-braces

were eased off and the verticals were lifted and rebraced, auxiliary braces being placed where required during this change.

Through the deeper part of the trench a concrete toe-wall had been placed. This contained the drainage pipes from the springs, leading to the stand-pipes. This wall was not carried the entire length of the trench, the irregularity of the bottom seeming to form a sufficient obstruction to the passage of the water.

In placing the clay, picked foremen were employed, and they were constantly supervised by the inspectors. Care was taken to remove all foreign matter, and lumps were broken to the size of an orange, all stones of greater size being rejected. The shovelers were directed to cast the clay and rotten rock so that it would scatter in falling.

When rotten rock was accessible, from 40 to 50% was used. It was cast in from one side while the clay was being cast in from the other. The desired proportions were obtained by regulating the number of shovelers on each class of material.

The water was usually about 4 ft. deep at the beginning of each lift, and the casting was stopped when the clay was within about 1 ft. of the surface of the water. Fine roots, chips, cinders, etc., not noticeable in the clay, floated to the surface, and were kept skimmed off.

As the puddle reached the ground surface in the lowest part of the valley, clay bulkheads, several feet in height, were built across the trench, water was turned in, and a new lift was begun. In this way the puddle was carried up the hillsides in successive terraces, filling the trench to the surface throughout. Very little trouble was experienced from the slipping of these dry clay bulkheads, although founded on freshly puddled clay; there was usually some movement, accompanied by a slight heaving of the clay below the bulkhead, but it was so small that it was of no consequence. The city paid 25 cents per cu. yd. for the clay thus deposited, which covered all charges from the storage pile to its place in the trench, and the placing and removal of the timbering rendered necessary by this method. The clay settled about 2 ft. in two or three months, but little settlement took place thereafter. Investigations made several months later showed that the clay was compact, firm, and slightly moist at a depth of 7 ft. below the surface.

The first fill across the valley was at the toe of the East Drive,

and was made with carts; on this a track was laid, connecting with the switchback on the north side, and later joining the track from Shovel No. 2, passing through the cut on the East Drive south of the dam.

A second embankment was built across the valley at the line of junction of the select and random rock sections, and Williams Run was turned into the depression thus caused, forming a pool, into which the random rock and earth were dumped.

There was not enough earth in the filling material to make an impervious embankment, nor was this desired, the intention being to obtain a compact but somewhat pervious fill, which would allow the escape of any water percolating through the select section of the dam. This method was followed on the random rock section until the narrowing of the dam, as the height increased, rendered it impracticable.

The question of building the entire dam by depositing the materials in water had been under discussion for some time, and it was finally decided to adopt this method, the contractors making a satisfactory rebate on the cost of this portion of the work. It was expected that the principal difficulties would be the placing of the materials under water in their designated positions and the preservation of the proper slope on the inner side.

The following method was adopted: The inner slope of the random rock section was given a lining of select material dumped from cars, to prevent the escape of water from the proposed pool; and a narrow embankment was built across the valley just outside of the cut-off trench, to prevent the water from entering the latter.

This basin was then flooded, and select material was dumped along the outer edge of the pool, the track being thrown inward as the fill widened. The tracks had to be kept 2 ft. or more above the surface of the water, the fill showing a tendency to slip out, particularly where the water had considerable depth, and the submerged portion took a very flat slope, the finer portions of the select material running far ahead and forming a bed of mud, in which the solid materials were thoroughly bedded.

This tendency of the toe to advance had to be watched carefully, in order to prevent it from encroaching on the clay section, a difficulty which was overcome later by raising a low ridge of clay on the line between the select and clay sections. A surprising quantity of air

FIG. 8.—SWALE AND BERM AT ELEVATION 355. DAM IN BACKGROUND.

FIG. 9.—LOOKING SOUTHWARD ACROSS BASIN. DAM AND GATE-HOUSE IN BACKGROUND.

seemed to be entrained in the select material, and somewhat less in the clay. That this was expelled at an early date seems conclusive, in view of the small amount of settlement in the finished structure.

The clay having reached the top of the cut-off trench, a wooden bulkhead was erected, 12 ft. from its inner edge, on the line of the proposed extension of the clay above the ground surface and the fill inside of the dam, which was being placed to bring the floor of the reservoir to Elevation 320.

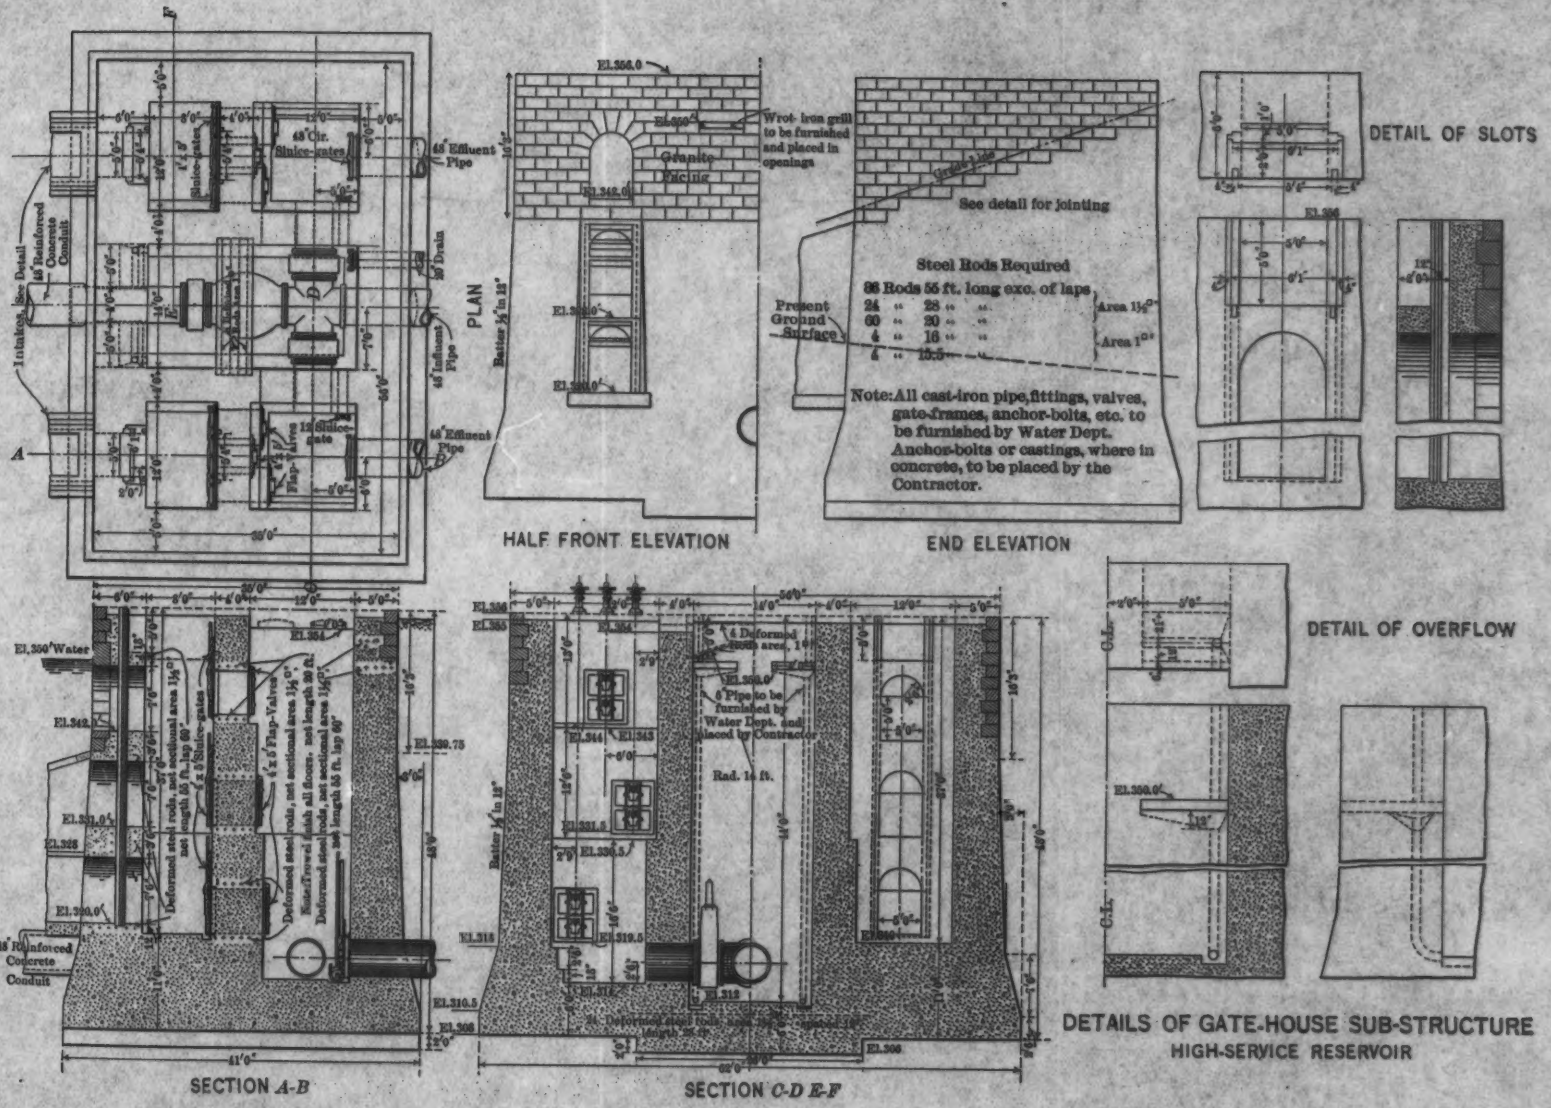
A trench was excavated to a depth of several feet, in which a continuous sill piece was laid, to which posts, 6 ft. from center to center, were fastened with ¾-in. iron pins passing horizontally through both posts and stringers. The posts were braced in a vertical position, and the trench was packed with rock. To these posts 2-in. planks were spiked as the fill was raised.

The first lift of the select section having reached the clay line, clay was brought from the storage banks, being loaded on the trains with scrapers by means of a trap. This clay was dumped on the edge of the select embankment and cast into the water, the same care being taken as in filling the cut-off trench, the limit of the clay puddle being the bulkhead.

Meanwhile, the random rock and earth section had been started on the next lift and lined as before to form the outer embankment of the next pool, the depression was again flooded, and the foregoing operations were repeated. There was considerable difficulty in keeping the bulkhead standing, but it was accomplished by judicious dumping on the inside to counterbalance the pressure of the clay. These operations were repeated on each lift.

Above Elevation 320 it became necessary to raise an embankment on the inner as well as on the outer side, on a 3:1 slope, to conform to the profile. For this purpose, the best rock that the shovels could reach was used to form the "rock lining," the first lift being deposited at the intersection of the 3:1 slope with the floor at Elevation 320, and reaching from hill to hill. This embankment was 5 ft. high, and just sufficiently broad on top to hold a track. A light blanket of clay was dumped on the pool side and a new pool was formed. Water was delivered to the dam site by a 6-in. main connected with the city supply. From this elevation up the pools were usually 3 or 4 ft. deep, the lifts being about 5 ft. Each successive lift of rock lining over-

lapped the clay sufficiently to give the required slope, and this operation was repeated until the top of the dam was reached.



In order to insure a tight job at the gate-house, the space between the walls of the foundation pit and the concrete was filled with clay puddle, and a mass of clay, from 8 to 10 ft. in thickness, was placed entirely around the structure, extending from the foundation to above the water line. This was brought up with the successive lifts of the dam.

Everything progressed in a satisfactory manner until an elevation of about 335 was reached, when, a little north of the middle of the dam, a movement was observed in the rock lining. At the time, rock lining was being placed, and a considerable quantity had been dumped above the place in question. The movement consisted of a steepening of the slope a short distance above the toe, covering a space of 200 ft. or more, and a swelling of the surface. As soon as this came to the writer's notice, the dumping was stopped at this point, and the track was thrown down to the part affected. Rock was first dumped over the toe to buttress it and prevent kicking out, after which the track was thrown up the slope, and a good weight placed on the swelling. By midnight, it was thought that the danger was over, and the men quit work. In the morning, as early as possible, the Water Engineer and his assistant made a thorough examination, and found that for about 500 ft. the toe of the rock lining, Elevation 320, had moved inward from 1 to 3 in., the slope appearing to be unaffected except at the point mentioned.

It was decided to buttress the toe from side to side of the valley, and weight the slope with a gradually diminishing mass of rock, giving it a 4:1 slope between the hills, warping back to a 3:1 slope as the ends were approached. A line of centered stakes was placed across the disturbed portion of the dam and kept under observation for several months, but no additional movement was observed, nor has there been any sign of movement in any portion of the dam since.

In June, 1909, several test-pits were sunk in the select material between the rock section and the pool for the purpose of examining the condition of the material which had been deposited under water, and to get an idea of the quantity of seepage. These pits penetrated two lifts, reaching a third, the bottoms being 7 or 8 ft. below the surface of the pool. No. 1 pit, 12 ft. from the edge of the pool, on

HIGH-SERVICE RESERVOIR

the third day contained 2 ft. of seepage. Nos. 2 and 3, 35 ft. from the pool, remained dry. No. 4, 10 ft. from the pool, on the third day contained 3 ft. of water, and the bottom showed a tendency to heave. Later, the pool was drained, and an examination was made of the bottom, which consisted of gray mud in which matrix all the stones were thoroughly bedded.

The dam was finished at Elevation 356, 1 ft. above the grade called for by the plans, the last 3 ft. being placed dry. The extra foot was added for settlement. It seems, however, that the settlement was about completed before the crest was placed. Stakes were set every 50 ft., and observed for a year, during which period the maximum observed settlement was 0.2 ft. It was impracticable to ascertain the shrinkage during construction, as the entire surface was being worked over, affording little opportunity to maintain a permanent bench.

The total quantities placed in the dam were: 37 784 cu. yd. of clay; 109 226 cu. yd. of select material, and 137 137 cu. yd. of random rock and earth. The East Driveway fill, outside of the dam, contained 67 373 cu. yd. of random material, and the cut-off wall, 25 032 cu. yd. of clay.

At the west end of the reservoir, a cut-off trench was excavated well into the rock, with an average depth of 20 ft., and extending into the hills to the north and south. This was filled with puddled clay, which was brought up as a core-wall to the berm level, random material being placed on either side to support it above the natural ground. The Liberty Road fill was begun from a trestle, erected along the south side of the road, the caps and stringers being removed later. In the track giving access to this fill, 132 800 cu. yd. were placed. A bench was cut along the south slope of the fill, corresponding to the grade of Slingluff Avenue, and 18 000 cu. yd. were used in connecting the two streets. West of Eleventh Street 38 000 cu. yd. were wasted in the Williams Run valley, 159 000 cu. yd. were placed on the Park property south of the gate-house, and 2 800 cu. yd. were placed in the basin to bring the floor to Elevation 320.

To take care of the surface and sub-surface flow which would approach the reservoir from the west end, a trench has been excavated at the outer edge of the berm, and extends from a point near the north end of the dam around to meet the cut-off trench at the south end, with the bottom on a 5% slope. Along the outer side of this

trench there is a 6-in., open-joint sub-drain, surrounded with broken stone, to intercept any seepage which might reach the trench; 3 ft. above this there is laid a line of pipe, connecting with the surface by intakes placed 250 ft. apart, to carry off all surface water flowing toward the reservoir. The trench was back-filled with clay. The two lines of pipe discharge into a manhole west of the gate-house, from which there is a line of pipe connecting with the 20-in. drainage line from the gate-house, running to a manhole on the Park property, whence the flow passes through a 24-in. pipe to a point near the bank of Pecks Run.

Beginning at the north face of the gate-house, the first joint being concreted into the wall, and making connection with the 48-in. force main, a 48-in. reinforced concrete, lock-joint pipe (Meriwether system) extends 1 010 ft. to a pool near the western end of the basin, forming a continuation of the force main. This conduit is laid in the reservoir floor, and crosses the cut-off trench on a reinforced concrete beam. A concrete collar has been placed around the pipe at the cut-off trench.

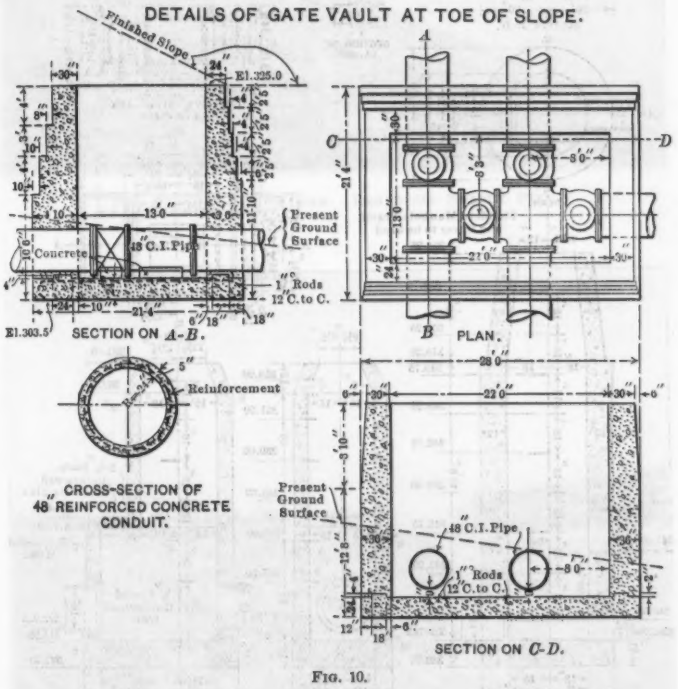
The force main passes through the central chamber of the gate-house, where there is a check-valve and a four-way branch, and is controlled by a gate-valve. Between the gate-house and the gate-vault, there are three lines of 48-in. pipe. These are connected by a four-way branch in the gate-vault, where there are additional gate-valves. The west line extends through the south wall of the gate-vault, and is closed with a cap. The central line—the force-main—extends to the North Avenue main, which is laid in Seventh Street after leaving the Park property.

From the central chamber of the gate-house, a line of 20-in. cast-iron pipe, for drainage purposes, extends to a point south of the gate-vault, which it also drains through a 2-in. pipe connection; from this point the line is of double-strength vitrified pipe, laid in concrete. Through this pipe and a blow-off at the lowest point on the force-main the reservoir is drained.

The gate-house substructure, extending from Elevation 308 at the foundation to Elevation 356 at the floor level, contains a central and four side chambers. The four-way branch in the central chamber, connects with the south side chambers, and is controlled by gate-valves, operated from the central chamber. The side chambers discharge through the two lines of 48-in. effluent pipe, above mentioned, and

into the central line at the gate-vault, or directly into the force-main in the central chamber, back of the check-valve, and are controlled by sluice-gates.

Three 4 by 5-ft. openings, at Elevations 320, 331, and 342, pierce the walls between the north and south chambers, being controlled on the north and south sides by sluice-gates and flap-valves, respectively. The north chambers are connected with the lake through arched openings at the elevations above given, and have stop-log grooves.



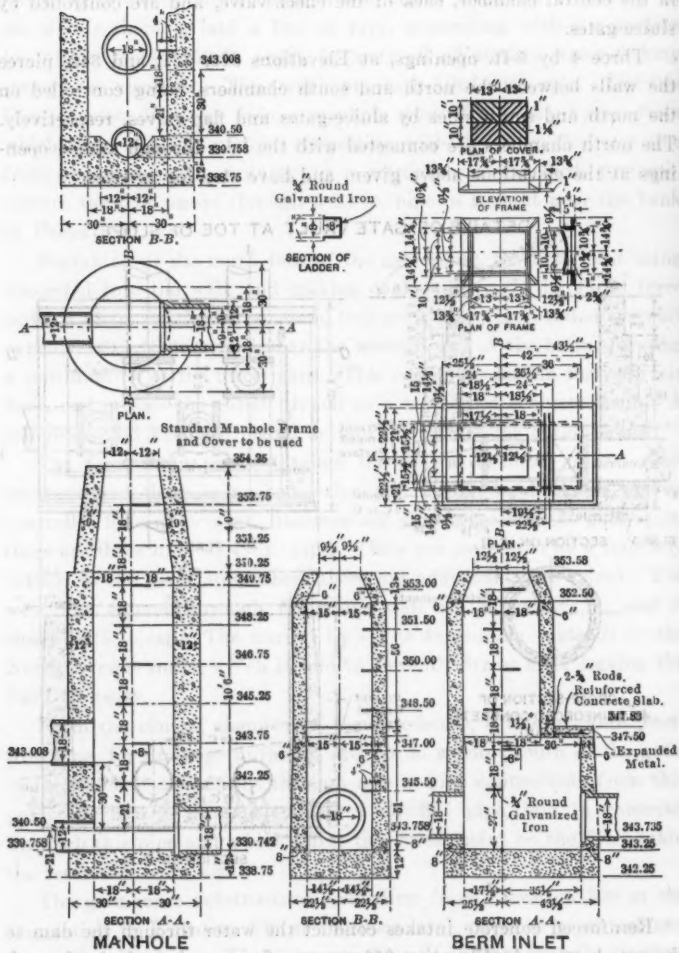


FIG. 10.

Reinforced concrete intakes conduct the water through the dam to the gate-house. At Elevation 350 two overflow openings drain through two lines of 6-in. pipe to gutters on each side of the floor of the central chamber. The central and south side chambers are connected by 12-in. drain pipes, controlled by sluice-gates.

wall trench, and to the fact that more rock was found than was estimated.
should be $57 289.41 at the original prices for depositing the different materials in the dam.
cluding the force accounts and the rock lining, was $4 143.39 less than the original esti-
‡ A manhole was built which was not in the original contract.
sewer extension, $2 531.03; and drainage, springs, etc., $1 864.70.

Under normal conditions, the reservoir will act as an equalizer between the pumps at the Mt. Royal pumping station and the main on North Avenue, which supplies a large territory. Any surplus pumped, greater than the consumption, passes through the check-valve to the basin at the west end of the reservoir, the flap-valves in the side chambers preventing any discharge into the reservoir through these chambers and the intakes. If the pumpage is less than the consumption, or if the pumps are shut down, water is drawn through the side chambers, the check-valve preventing its return by way of the force-main. By this arrangement, circulation is obtained in the reservoir, as all water enters at the west end through the force-main and is drawn out through the intakes at the east end.

The excavated portion of the basin was hand-paved between Elevations 340 and 353 with rock from the shovels. On the dam, after the rock lining was dressed, rip-rap was laid as an additional protection to the slope.

In December, 1910, chloride of lime having been used freely, about 5 ft. of water were pumped into the basin and drawn off. On December 16th pumping recommenced, and was continued until January 11th, 1911, when the water surface reached Elevation 350.

As far as it is possible to determine, no water has passed through the dam, the insignificant quantity of seepage observed to date seeming to come entirely through the natural ground, and, with the exception of the springs led from the dam foundations through blind drains, being considerably removed from the toe of the dam.

The cost of the work is given in Table 1.

The work was designed by Emory Sudler, Assoc. M. Am. Soc. C. E., Assistant to Alfred M. Quick, M. Am. Soc. C. E., Water Engineer, and was executed under his supervision.

Paper No. 1243

A WESTERN TYPE OF MOVABLE WEIR DAM.*

By W. C. Hammatt, M. Am. Soc. C. E.

With Discussion by Messrs. Thomas C. Atwood and W. C. Hammatt.

Much has appeared recently, in the technical press and the publications of this Society, with regard to dams, due partly to the present activity in irrigation matters, and partly to the interest aroused by the failure of the Austin Dam. This paper, describing a dam of a kind rather common in California, but little known elsewhere, is presented with the hope of promoting profitable discussion and perhaps suggestions as to the construction of a weir of equal cheapness without the disadvantages of the type described.

This is a movable-weir dam with horizontal flash-boards and fixed bents. Its purpose is to maintain a uniform, or approximately uniform, level of water in a canal, river, or spillway, and have the ability to allow the free, or approximately free, passage of water in time of flood. Consequently, the type is used as diverting dams in rivers, as controlling and regulating gates in canals and spillways, and often even as head-gates for canals and ditches. From the nature of their use, these structures are generally located on soft and permeable foundations. Until the last few years they have generally been of timber, but the recent tendency toward concrete construction has also been felt. Their construction has largely been a growth of local or individual custom and experience, rather than of engineering design, and in many cases this is painfully apparent.

* Presented at the meeting of September 18th, 1912.

The writer will take up first the various forms of superstructure and foundations of the timber weirs, giving each a form letter, and afterward discussing them in detail.

The form shown in Fig. 1 will be called "Type A." In this the flash-boards move in a vertical plane between posts with guide-strips, nailed or bolted on, to hold them in place. The flash-boards are removed with grappling hooks hanging from tackle on head-frames over the boards. This type is often used as a combination wagon bridge and weir, and existing wagon bridges are sometimes converted into weirs.

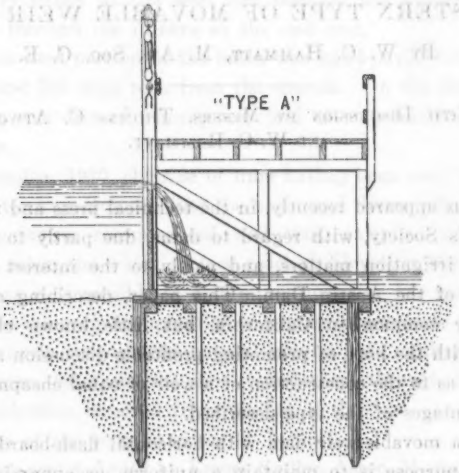

FIG. 1.

In "Type B," Fig. 2, the flash-boards are in a plane inclined down stream, moving in grooves formed by strips fastened to inclined timbers, or rafters. These boards are removed by men using pike-poles from the top of the weir, the incline enabling the operator to work a board upward until he can reach it without the aid of any elevating apparatus. This type, also, is sometimes used as a wagon bridge. Both types require an operating bridge above the high-water level for the storage of the flash-boards when not in use, and for a runway for operators while putting in and taking out the flash-boards.

Various methods are in vogue for anchoring these timber structures, and for shutting off the underflow. In some cases, they are placed on sills drift-bolted to standard piles, with one or more curtain-walls to cut off the underflow. In other cases, sheet-piling is used for both purposes, the sills being held in place by spiking sheet-piles to them.

The writer illustrates several systems for placing the cut-off walls which he has encountered. Figs. 1 and 2 show the floor system, consisting of mud-sills nailed to sheet-piling, with a continuous wall of equal depth above and below. This is sometimes varied by omitting the up-stream wall, sometimes by leaving gaps in the down-stream

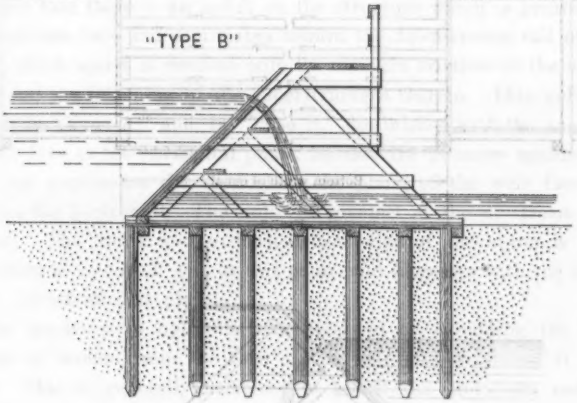

FIG. 2.

wall, and sometimes by boring holes in the floor to relieve the upward pressure. Occasionally, cross-walls are put in between the upper and lower cut-off walls at the bulkhead lines, and sometimes intermediate ones are put in. Fig. 3 shows a typical floor system on which the various cut-off walls are indicated.

Another device for overcoming the upward water pressure is shown in Fig. 4. It consists in laying a false floor from 4 to 6 ft. below the regular floor level, tying it to the regular floor by planking spiked to the sills, and filling the box thus formed with sand or gravel.

From an inspection of the forms illustrated, the following facts are apparent:

(1).—Since the form and material of the superstructure is such that its stability against translation and overturning depends on its attachment to its foundation, or anchorage, all forms fail if conditions are such that the foundation is intermittently wet and dry. Under this condition, the life of the timber is very short, and the fastenings give way as soon as rot starts, whereupon the structure inevitably

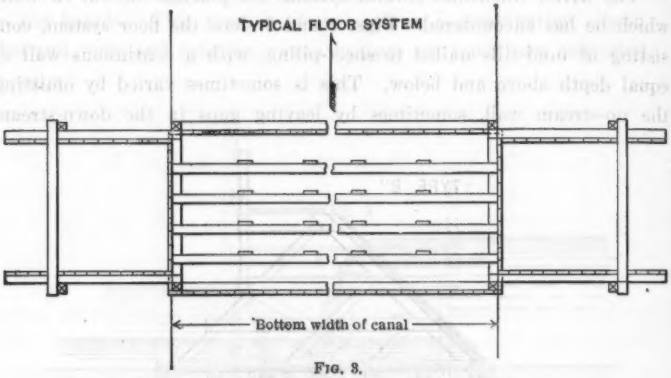

FIG. 3.

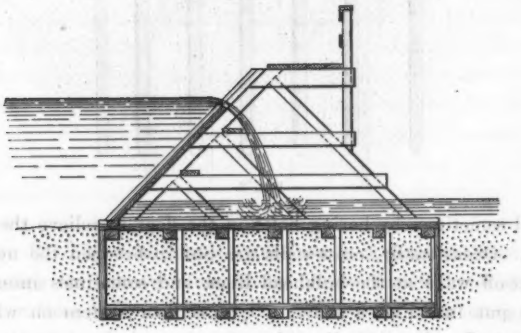

FIG. 4.

fails either by sliding or rising, according to whether or not the water has passed the upper cut-off wall.

(2).—If the foundation, or floor system, is always covered by water, the life of the timber is practically permanent, and the safety of the structure depends on the resistance of the fastenings to the deterioration of time. As these fastenings can be, and generally are, made

with a sufficient excess of material to withstand successfully the attacks of rust indefinitely, the matter of stability can be considered without regard to the life of the materials.

Let it be supposed that the soil in the bottom of the canal or river is fairly permeable, as is nearly always the case, and consider "Type A" of superstructure, with a water-tight floor and two water-tight cut-off walls of equal depth. According to the testimony of Mr. W. G. Bligh, as to experiments made in India, the loss of pressure due to a cut-off wall is equal to that of a base of double the length of the depth of the cut-off wall. Under this assumption, a calculation of the pressures acting both against the face of the weir and below the floor will show that there is an uplift on the structure which is greatest at the up-stream face and diminishes toward the down-stream end of the apron, which uplift is resisted only by the skin friction of the sheet-piling and the fastening of the superstructure thereto. This uplift is greatest in "Type A," and, in "Type B," diminishes with the angle of the weir face to the horizontal plane, because the pressure against the weir face approaches the vertical as the plane of the weir face approaches the horizontal. The uplift is greatest at the up-stream cut-off wall. The uplift at the down-stream edge of the apron is least when there is no cut-off wall at this point, and increases with the depth of the cut-off at that place.

This tendency to uplift is often resisted by extending the floor a little up stream from the face of the weir and weighting it with earth. This is generally sufficient to guard the up-stream end, so that the failure is nearly always by pulling the down-stream piles. If the bent does not extend the whole length of the floor, in a well-braced triangular form, the failure is occasionally by upheaval of the intermediate floor.

Destructive criticism is of little value unless accompanied by the remedy; therefore, although there is little to recommend the timber structures but their cheapness, the writer will suggest a method of construction which will make them less objectionable. Fig. 5 shows a general plan which he proposes as a substitute for the unstable structures just described. This combines a simplicity and cheapness nearly equal to those obtained in them, with conditions of greater stability. The bents, *B*, *C*, *D*, should be founded on standard piles, driven to sufficient depth to give the necessary bearing value as well

as safety against undermining. *J F* is the main cut-off wall, which should be of sheet-piling driven to sufficient depth and with sufficiently tight joints to reduce the velocity of the seepage flow to less than that which would carry with it the foundation material. Triple-lap, tongued and grooved, or some such piling should be used, and great care should be taken not to split it in driving and thus destroy its imperviousness. Another row of sheet-piling, *A E*, not necessarily as deep, may be driven up stream from the first, and a battened floor, *A J*, may be laid between the two rows. This floor need not rest on piling, but may be laid on mud-sills, if the bottom soil is thoroughly compact. Between the bents, there should be an apron, *J K*, of open

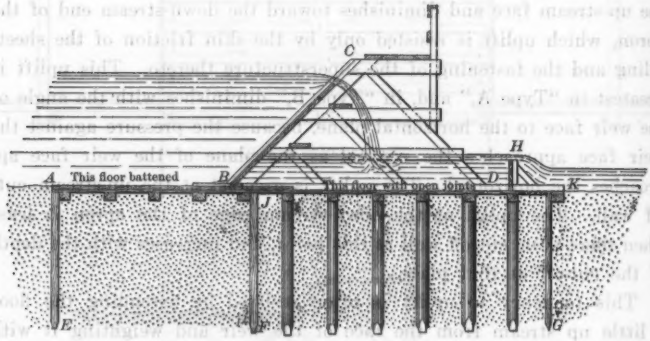

FIG. 5.

design, in order to avoid under pressure, and extending down stream a sufficient distance to protect the bottom against erosive action. At or near the end of the apron, another line of sheet-piling, *K G*, may be driven, not necessarily of great length or tightness, but merely as a precaution against undermining. If the fall is greater than 4 ft., a small bulkhead, *H*, should be built across the floor a few feet back from its lower edge, in order to form a pool to act as a water cushion. Instead of this, the floor may be built about 2 ft. lower than the bed of the stream or canal, but the former is the simpler construction, especially where the lower floor level might cause great additional inconvenience and expense of construction.

If the foregoing design is used, and the construction is carefully superintended, special care being taken to keep *A E*, *A J*, and *J F*

water-tight, and *J K* with free passage for the seepage flow, there will always be a pressure on the piles instead of a pull, and consequently less likelihood of failure.

The cost of these structures is comparatively small. The diverting dam of the San Joaquin and Kings River Canal and Irrigation Company, across the San Joaquin River, near Mendota, Cal., 16 ft. in height and 380 ft. in clear width, passing 40 sec-ft. of water per ft.

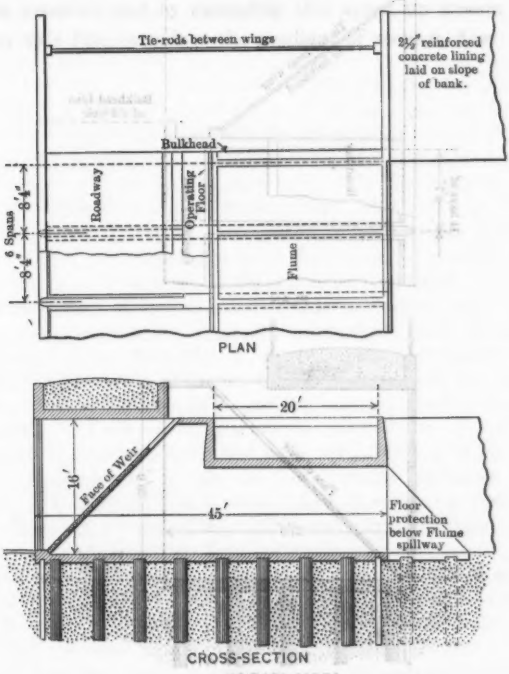

FIG. 6.

of width when open, cost about $140 per ft. of width. Records of cost of smaller structures in canals and sloughs, passing from 6 to 50 sec-ft. of water per ft. of width, show a total cost of from $25 to $100 per ft. of width, according to size and difficulty of construction.

Recently, there has been a tendency toward concrete construction. With the going out of use of timber for irrigation structures, the type

itself is disappearing, being replaced in general by regulators with submerged openings. There have been a few cases, however, where the material of construction has been changed without essentially changing the design. Among the latter are two reinforced concrete weirs, one at the head of Temple Slough, Merced County, California, and

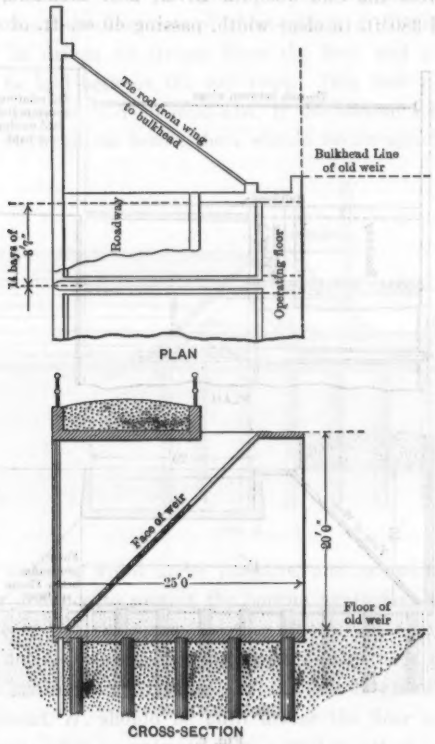

FIG. 7.

the other in the Kern Valley Water Company's canal, in Kern County, California, both designed by John B. Leonard, M. Am. Soc. C. E., for Miller and Lux, Incorporated. The former carries the Poso Canal across in a flume, and is of the dimensions and form approximately given in Fig. 6. The one in Kern County is shown in

Fig. 7, and relies on the bulkheads and floor of the old timber structure below for bank and bottom protection, which accounts for the short length of the apron. It will be noted that the uplift in the up-stream toe, in both cases, is counterbalanced by a reinforced concrete bridge carrying a roadway.

The writer sees nothing to criticize in these designs, for they are as strong and stable structures as could be built of this type. Some expense might be saved, however, by putting weep holes in the apron, to relieve the pressure, and by extending this apron up stream from the up-stream weir face to reduce the gradient of seepage flow.

DISCUSSION

Mr. Atwood.

THOMAS C. ATWOOD, M. AM. SOC. C. E.—The author has performed a distinct service by bringing before the Society the subject of inexpensive movable dams for use in irrigation canals, small streams, etc., and in pointing out correct principles of design.

As he well states, "Their construction has largely been a growth of local or individual custom and experience, rather than of engineering design, and in many cases this is painfully apparent." It is to be hoped that the recent agitation for a stricter supervision of dams, following the failure of that at Austin, Pa., may extend even to such small structures as these, and that all of them may be placed in the hands of competent engineers.

This type of dam seems to be better adapted to irrigation canals than to streams, due to the likelihood of driftwood in the latter lodging against the bents in time of flood and holding back the water, in spite of the removal of the flash-boards, and, perhaps, causing the loss of the structure. For such locations, especially where the dam is a high one, as the diverting dam of the San Joaquin and Kings River Canal and Irrigation Company across the San Joaquin River, where the height is given as 16 ft., a type of movable dam which gives a clear waterway when lowered is usually to be preferred. Many such dams have been built by the United States Army Engineers, and have proved very successful. Although permanent in character, the cost of the waterway is not excessive, the principal expense being in the provision for navigation. The cost of the navigable pass of Dam No. 26, on the Ohio River, is given by the U. S. Engineers' office as about $175 per ft., the dam being built on a rock foundation, and for a maximum head of 14.2 ft. Mr. J. W. Arras, U. S. Assistant Engineer, gives the probable cost of a Chanoine dam on piles in a gravel foundation as from $250 to $300 per ft. for a structure about 16 ft. in height, according to local conditions.

The failure of Dam No. 26 was due apparently to the failure of the rock foundation, although the unwatering of the site may reveal some other cause. This is worthy of note, in view of the almost uniform success of these dams when founded on the river gravel.

The author does well to lay stress on the importance of the foundation, and his suggested design, as shown in Fig. 5, is excellent in this respect on most points.

The subject of scour does not seem to be adequately treated, however, although Mr. Hammatt called attention to this point in his discussion* on the Yuma River Débris Barrier, where he suggested an unattached apron of large concrete blocks which would follow the bottom down, as scour takes place below the dam, and prevent the

* *Transactions*, Am. Soc. C. E., Vol. LXXI, p. 229.

gravel under the dam itself from being washed away. This method is excellent, and has been used successfully, as have a number of others, as described by the writer in discussing the paper on the Yuma River Débris Barrier mentioned above. Mr. Atwood.

The suggested design, as given in Fig. 5, is weak in this respect, as scour may reasonably be expected when the flash-boards are raised and the direct current strikes the small bulkhead, *H*, and jumps over it. This can be helped by moving this bulkhead nearer to the main dam, extending the plank apron farther down stream, or placing rip-rap below the apron to prevent scour and follow the bottom down if any occurs.

The best method, however, and probably the cheapest, is to slope the apron upward in the direction of the flow, with perhaps 2 ft. rise in 20 ft., giving the same depth of water just below the dam, but doing away with the bulkhead, *H*. There will still be scour, but it will be transferred to such a distance below the dam that the foundation of the structure will not be endangered, the tendency of the eddy being to bring gravel back toward the apron, rather than to scour that immediately adjacent.

W. C. Hammatt, M. Am. Soc. C. E. (by letter).—The writer is glad if his paper has added anything to the knowledge of small inexpensive structures for canals, etc., but does not wish to be understood as recommending the use of timber as a construction material, except in the extremely rare occasions of economic utility. Under ordinary conditions, the cost of reinforced concrete is only 50% more than the equivalent timber construction, and this should generally make its use preferable. Mr. Hammatt.

Mr. Atwood states that this type of dam is more adapted to use in irrigation canals than in streams, due to the likelihood of driftwood in the latter lodging against the bents in time of flood. As a matter of fact, dams of this type are used extensively in rivers, the drift being taken care of by floating log booms arranged so as to conduct it into still water. On the other hand, structures of any type having removable parts which are seated in grooves or sockets in the floor are found to be impracticable in Western rivers because of the deposition of sand on the floor on the recession of the flood. In the case of the flash-board weir, this sand is scoured by the increased velocity on the approach of the board as it is dropped in the grooves, and the board seats itself in a few minutes, regardless of the quantity of sand which has been deposited.

In the rivers of the West the flow conditions differ from those of the East. For example, the flow in the San Joaquin River ranges from about 200 sec-ft. minimum to more than 50 000 sec-ft. maximum. The sudden termination of one of these floods will cause the deposit of sometimes as much as 3 ft. of sand on the floor of the weir.

Mr. Hammatt.

Regarding the question of scour: In general, the weir floor is made long enough so that there is not much tendency in that direction. If the length of the floor is such that a line from the top of the weir, making an angle of 45° with the horizontal, falls within the limits of the floor, there is little tendency to scour. Generally, there is no occasion to put in the small auxiliary bulkhead shown in the writer's plan, as a sand-bar almost always forms a short distance below the weir, which has the same effect, as it backs up the water and forms a water-cushion to break the impact of the overpour. The same effect is obtained by placing the elevation of the weir floor 1 or 2 ft. below the grade of the canal or river bottom.

The expedient suggested by Mr. Atwood, namely, that of sloping the floor upward, would have an effect the opposite of that desired. The velocity of a certain volume of water falling over a vertical weir is less than that of the same volume falling over a weir inclined down stream. Consequently, the scour would be less in the former case.

In conclusion, it may be stated that this type of structure, built of the material which will give the maximum service, and with the substructure best adapted to the foundation on which the weir is to stand, is probably the least expensive of any of the movable types for waterways where the floods are flashy and a large, and at the same time accurate, regulation is desired.

Paper No. 1244

A SHORTENED METHOD IN ARCH COMPUTATION.

By H. A. Sewell, Esq.

With Discussion by William Cain, M. Am. Soc. C. E.

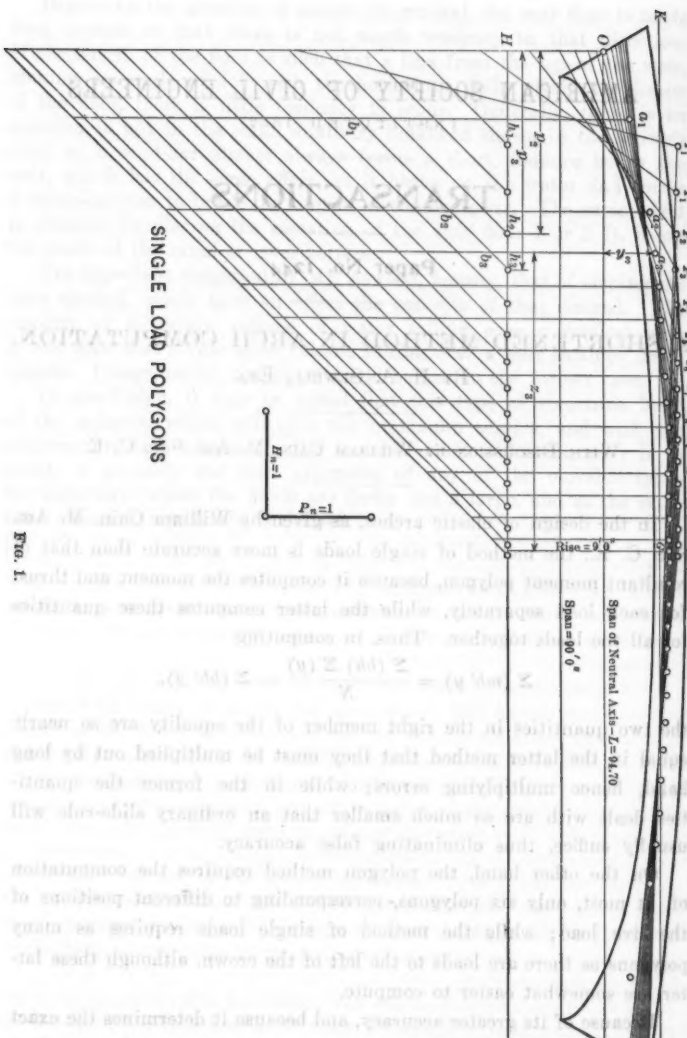
In the design of elastic arches, as given by William Cain, M. Am. Soc. C. E., the method of single loads is more accurate than that of resultant moment polygon, because it computes the moment and thrust for each load separately, while the latter computes these quantities for all the loads together. Thus, in computing

$$\Sigma\,(mb'\,y) = \frac{\Sigma\,(bh)\,\Sigma\,(y)}{N} - \Sigma\,(bh'\,y),$$

the two quantities in the right member of the equality are so nearly equal in the latter method that they must be multiplied out by long hand, hence multiplying errors; while in the former the quantities dealt with are so much smaller that an ordinary slide-rule will usually suffice, thus eliminating false accuracy.

On the other hand, the polygon method requires the computation of, at most, only six polygons, corresponding to different positions of the live load; while the method of single loads requires as many polygons as there are loads to the left of the crown, although these latter are somewhat easier to compute.

Because of its greater accuracy, and because it determines the exact position of the live load for maximum moment at any given section, rather than assumes its arbitrary position for maximum moments, the single-load method, doubtless, would be much more widely used,



SINGLE LOAD POLYGONS

Span=90' 0"
Rise=9' 0"
$H_n=1$
$P_n=1$

FIG. 1.

especially for very flat or very high arches, were it not for the much greater labor involved. However, in the following method, the computations are greatly reduced, while, at the same time, a check is introduced, which cuts the labor of computing moments again by making the computations self-checking.

The summations, $\Sigma\ (y)$, $\Sigma\ (y^2)$, $\Sigma\ (z)$, and $\Sigma\ (z^2)$, having been computed for the arch ring by the usual method, the quantities, $\Sigma\ (bh)$, $\Sigma\ (bh'\ z)$, and $\Sigma\ (bh'\ y)$, should next be obtained for each of the trial polygons corresponding to loads unity and horizontal thrusts unity at each of the load points, P_n.

The force polygon for load unity and horizontal thrust unity is taken so that the pole point is one unit horizontally to the left of the lower extremity of the load vector unity, thus making the right component of each trial-moment polygon horizontal and the left component inclined downward at an angle of 45 degrees. By reference to Fig. 1, the following relations are discovered:

$$\sum_o^n (bh) = \sum_o^{n-1} (bh) + (n-1)\,(p_n - p_{(n-1)}) + \left(p_n - \frac{L}{2} + z_n\right)$$

$$\sum_o^n (bh'\ z) = \sum_o^{n-1} (bh'\ z) + (p_n - p_{(n-1)}) \sum_o^{n-1} (z) + \left(p_n - \frac{L}{2} + z_n\right) z_n$$

$$\sum_o^n (bh'\ y) = \sum_o^{n-1} (bh'\ y) + (p_n - p_{(n-1)}) \sum_o^{n-1} (y) + \left(p_n - \frac{L}{2} + z_n\right) y_n$$

in which:

L = span of the neutral axis;
y = ordinate at a of arch from horizontal through spring, OO';
z = distance of a to left of crown, G;
p = distance of load considered from left spring, O;
n = number of load considered from left;
bh = ordinate of polygon from horizontal, HH'.

Thus, each summation is made to depend on the one preceding it and the quantities $(p_n - p_{(n-1)})$ and $\left(p_n - \frac{L}{2} + z_n\right)$. The work of these computations on a hypothetical flat arch is shown in Table 1.

In order to make the use of the formulas clear, a case is taken, $P_n = P_3$, from Table 1. Then for $P_{(n-1)} = P_2$, $\Sigma\ (bh) = 12.77$, $\Sigma\ (bh'\ z) = 504.0$, and $\Sigma\ (bh'\ y) = 35.74$; and, by adding the values of $z_{(n-1)} = z_2$, and $y_{(n-1)} = y_2$ to the last totals, we obtain $\sum_{o}^{n-1}(z) = 72.77$ and $\sum_{o}^{n-1}(y) = 6.93$. Multiply these latter quantities by the value of $(p_n - p_{(n-1)}) = 3.53$ and place the products under the values of $\Sigma\ (bh'\ z)$ and $\Sigma\ (bh'\ y)$ given above; and multiply $(p_n - p_{(n-1)})$ by $(n - 1) = 2$, placing the result under $\Sigma\ (bh)$. Next obtain $\left(p_n - \frac{L}{2} + z_n\right) = z_n - \left(\frac{L}{2} - p_n\right) = 1.66$, and place it in the $\Sigma\ (bh)$ column; then multiply it by $z_n = 28.13$ and $y_n = 4.95$, placing the results in the $\Sigma\ (bh'\ z)$ and $\Sigma\ (bh'\ y)$ columns. Finally, add the quantities below the last addition, in order to obtain the totals, $\Sigma\ (bh) = 21.49$, $\Sigma\ (bh'\ z) = 807.7$, and $\Sigma\ (bh'\ y) = 68.42$.

The check on the totals is shown by $\Sigma\ (z)$ being equally distant from $\Sigma\ (bh)$ for the loads, P_{14} and P_{15}. Likewise, $\Sigma\ (z^2)$ should be midway between $\Sigma\ (bh'\ z)$ for the loads P_{14} and P_{15}. No check was discovered for $\Sigma\ (bh'\ y)$ except to compute $\Sigma\ (bh'\ y)$ for Point P_{14} independently by the usual method. $\Sigma\ (z)$ and $\Sigma\ (y)$ are checked by direct addition. Checking the totals for P_{14}, checks all the others, because they are all carried forward in making the totals. All the multiplications may be made with an ordinary slide-rule.

These summations being obtained, the work is carried forward in the usual manner, as outlined by Professor Cain.

TABLE 1.

Point	(z)	(y)	(z^2)	(y^2)	Load P	$\frac{L}{2} - p$	$p_n - p_{n-1}$	$\Sigma_o^{n-1}(z)$	$\Sigma_o^{n-1}(y)$	$\Sigma\ (bh)$	$\Sigma\ (bh'\ z)$	$\Sigma\ (bh'\ y)$

DISCUSSION

Mr. Cain.

WILLIAM CAIN, M. AM. SOC. C. E. (by letter).—The author has made a successful attempt to shorten certain calculations pertaining to the theory of the arch without hinges, where single loads are considered. As the number of parts into which the arch ring is divided is increased, the burden of computation is very much increased, and any device for shortening the work will be appreciated by the computer.

As the subject is of such practical importance, the writer will give a method of computing the quantities in question by a brief and independent procedure, and will incidentally derive check formulas for the difference method proposed by the author.

In the diagram, Fig. 2, the horizontal distances of the loads, P_1, P_2, . . . , from the center of the span, A, will be denoted by d_1, d_2, ...

From any P, as P_2, are drawn the two sides of the trial equilibrium polygon pertaining to this load, the one to the right of the load, $P_2\ A$, being horizontal, the one to the left, $P_2\ B_2$, being inclined at an angle of 45° to the horizontal. It follows that $b_4\ h_4 = h_4\ P_4$, $b_4\ h_3 = h_3\ P_4$, etc.; whence, for the lines, $P_4\ B_4$, $P_3\ B_3$, we have,

$$\begin{aligned} b_4\ h_4 &= z_4 - d_4 \\ b_4\ h_3 &= z_3 - d_4 \\ b_4\ h_2 &= z_2 - d_4 \\ b_4\ h_1 &= z_1 - d_4 \end{aligned}$$

$$\sum_o^4 b_4\ h = \sum_o^4 (z) - 4\ d_4,$$

$$\begin{aligned} b_3\ h_3 &= z_3 - d_3 \\ b_3\ h_2 &= z_2 - d_3 \\ b_3\ h_1 &= z_1 - d_3 \end{aligned}$$

$$\sum_o^3 b_3\ h = \sum_o^3 (z) - 3\ d_3.$$

Or, more generally, dropping the b subscripts, the sums can be indicated thus:

$$\sum_o^n (bh) = \sum_o^n (z) - n\ d_n \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Thus, for $n = 4$, referring to the load, P_4, and the side of its equilibrium polygon, $P_4\ B_4$,

$$\sum_o^4 (bh) = b_4\ h_4 + b_4\ h_3 + b_4\ h_2 + b_4\ h_1; \qquad \sum_o^4 (z) = z_1 + z_2 + z_3 + z_4.$$

This formula enables us to compute directly $\sum_o^n (bh)$ corresponding to $P_n\ B_n$ for any P_n, or for $n = 1, 2, 3, \ldots$ in turn.

Now let,

$$\sum_o^n (bh.z) = bh_1.z_1 + bh_2.z_2 + bh_3.z_3 + \ldots + bh_n.z_n.$$

Mr. Calu.

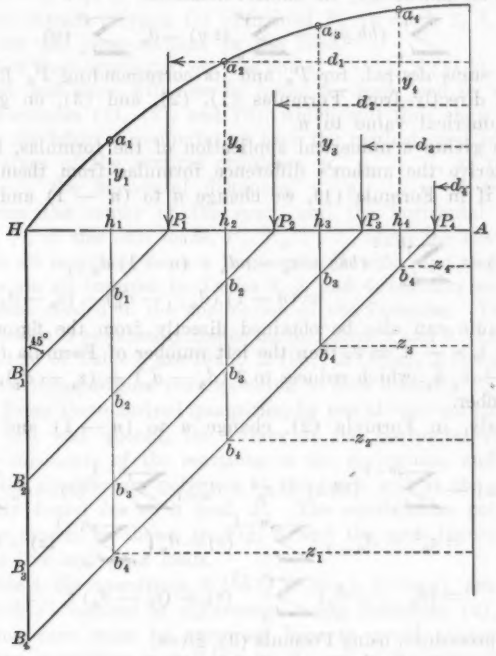

FIG. 2.

Thus, if $n = 4$, the bh's refer to the line, $P_4\ B_4$. It follows, from the relations given above, that,

$$\sum_o^n (bh.z) = (z_1 - d_n)\, z_1 + (z_2 - d_n)\, z_2 + \ldots + (z_n - d_n)\, z_n$$
$$= (z_1^2 + z_2^2 + \ldots + z_n^2) - d_n\,(z_1 + z_2 + \ldots + z_n)$$

or,

$$\sum_o^n (bh.z) = \sum_o^n (z^2) - d_n \sum_o^n (z) \quad \ldots\ldots\ldots\ldots (2)$$

in which the notation is sufficiently explained by the equivalent expansions above. Similarly, if,

$$\sum_o^n (bh.y) = bh_1.y_1 + bh_2.y_2 + \ldots + bh_n.y_n,$$

indicates the sum of quantities of the type $(bh.y)$ for any line $P_n\ B_n$ corresponding to a load, P_n, we have,

$$\sum_o^n (bh.y) = (z_1 - d_n)\, y_1 + (z_2 - d_n)\, y_2 + \ldots + (z_n - d_n)\, y_n$$
$$= (z_1 y_1 + z_2 y_2 + \ldots + z_n y_n) - d_n\,(y_1 + y_2 + \ldots + y_n)$$

Mr. Cain.

which can be indicated by the shorter notation,

$$\sum_{o}^{n}(bh.y) = \sum_{o}^{n}(z\,y) - d_n \sum_{o}^{n}(y) \ldots\ldots\ldots (3)$$

Thus the sums desired, for P_n and its corresponding $P_n\ B_n$, can be computed directly from Formulas (1), (2), and (3), on giving the proper numerical value to n.

Before giving a numerical application of the formulas, it may be well to derive the author's difference formulas from them.

Thus, if in Formula (1), we change n to $(n - 1)$ and subtract, we find,

$$\sum_{o}^{n}(bh) - \sum_{o}^{n-1}(bh) = z_n - nd_n + (n-1)\,d_{n-1}$$
$$= (n-1)\,(d_{n-1} - d_n) + (z_n - d_n) \ldots\ldots (4)$$

This formula can also be obtained directly from the figure. Thus, take $n = 4$, $n - 1 = 3$, then the left number of Formula (4) equals $3\,(b_4\,b_3) + b_4\,h_4$, which reduces to $3\,(d_3 - d_4) + (z_4 - d_4)$, or to the right member.

Similarly, in Formula (2), change n to $(n - 1)$ and subtract. Therefore,

$$\sum_{o}^{n}(bh.z) - \sum_{o}^{n-1}(bh.z) = z_n^{\,2} + d_{n-1}\sum_{o}^{n-1}(z) - d_n\sum_{o}^{n}(z)$$
$$= z_n^{\,2} + d_{n-1}\sum_{o}^{n-1}(z) - d_n\left(\sum_{o}^{n-1}(z) + z_n\right)$$
$$= (d_{n-1} - d_n)\sum_{o}^{n-1}(z) + (z_n - d_n)\,z_n \ldots\ldots\ldots (5)$$

A similar procedure, using Formula (3), gives,

$$\sum_{o}^{n}(bh.y) - \sum_{o}^{n-1}(bh.y) = z_n y_n - d_n\sum_{o}^{n}(y) + d_{n-1}\sum_{o}^{n-1}(y)$$
$$= (d_{n-1} - d_n)\sum_{o}^{n-1}(y) + (z_n - d_n)\,y_n \ldots\ldots\ldots (6)$$

Formulas (5) and (6) can likewise be derived directly from the figure by developing the left members and reducing. It will be observed that Formulas (4), (5), and (6), are equivalent to the author's formulas on noting that $d_n = \dfrac{L}{2} - p_n$.

To illustrate the application of Formulas (1), (2), and (3), take the segmental arch considered in the writer's "Theory of Solid and Braced Elastic Arches,"* where only eight divisions of the semi-arch were made. Of course, in a practical design, a greater number of divisions are essential for fairly accurate results, so that this particular investigation is only intended to illustrate the method for any arch, using any number of dimensions.

* Chapter V, Second Edition.

Mr. Cain.

The neutral line of the arch is shown in Fig. 3, also the two sides of the equilibrium polygon for each load P_n ($n = 1, 2, 3, \ldots$) are drawn from the computations in the book.

To effect these computations, the sums, $\Sigma\,(bh)$, $\Sigma\,(bh.z)$, $\Sigma\,(bh.y)$, are needed, and these will now be found for each load by aid of the writer's Formulas (1), (2), and (3), which will thus show the great saving in the labor of computation over the method used in the text.

The values of the vertical ordinates, $y_1, y_2, \ldots$, at the points, $a_1, a_2, \ldots$, the horizontal distances, $z_1, z_2, \ldots$, of these same points from the center of the span, and the horizontal distances, $d_1, d_2, \ldots$, of the unit loads, $P_1, P_2, \ldots$, from the center of the span, were all measured from a large-scale drawing, and their numerical values are all inserted in Tables 2, 3, and 4, together with certain derived sums needed in the application of the formulas. The method of computation is sufficiently indicated in Tables 2 and 3. In Columns 16, 18, and 20 of Table 3 are found $\Sigma\,(bh)$, $\Sigma\,(bh.z)$, $\Sigma\,(bh.y)$, for the trial equilibrium polygons corresponding to each load, $P_1, P_2, \ldots, P_8$ in turn. From these derived quantities, by use of very simple formulas given in the text quoted, the values of the horizontal thrust, the vertical components of the reactions at the springings, and the ordinates of the equilibrium polygons at the loads and at the springings are quickly found for each load, P. The equilibrium polygons are now to be drawn, as shown in Fig. 3, and the arch investigated for the actual live and dead loads.

In Table 4, the quantities, $\Sigma\,(bh)$, $\Sigma\,(bh.z)$, $\Sigma\,(bh.y)$, are computed by the author's method of differences, using Formulas (4), (5), and (6). Some care must be exercised here to avoid mistake. Thus, suppose the quantities pertaining to P_3 are to be computed. Substitute $n = 3$ in each of the formulas at the tops of the columns and put the results in the same line with P_3. Then add the results in Columns (4) and (5) on the same line with P_3 to the previous $\sum_0^2 (bh) = 6.05$ to get $\sum_0^3 (bh) = 10.46$, as given in Column (6). Similarly, proceed with Columns (8) and (9) to find $\sum_0^3 (bh.z) = 117.01$, as given in Column (10), and with Columns (12) and (13) to find $\sum_0^3 (bh.y) = 40.47$, as given in Column (14).

With a little care, it is hardly necessary to repeat the numbers added, so that the table can be compressed to about one-third the space here used. As a complete check on the results, the values given for $n = 8$ in Columns (6), (10), and (14), can also be found by use of Formulas (1), (2), and (3), exactly as indicated in Table 3, where n is given the value 8. Further, a check may be given where any value of n, as $n = 4$, is reached, by the use of the same Formulas

Mr. Cain.

(1), (2), and (3). The independent method illustrated in Table 3 is somewhat shorter than the difference method, but it can only be checked by repeating the computations. This complete check on the work is the principal gain afforded by the author's method of differences, and he is to be congratulated on having derived such a brief and valuable method of computation.

In conclusion, a few words may not be inappropriate concerning the advantage of the method of single loads in arch analysis. This consists not only in an increased accuracy, but it is the only practicable method by which maximum fiber stresses can be ascertained. Thus, after the equilibrium polygons for the various unit loads have been

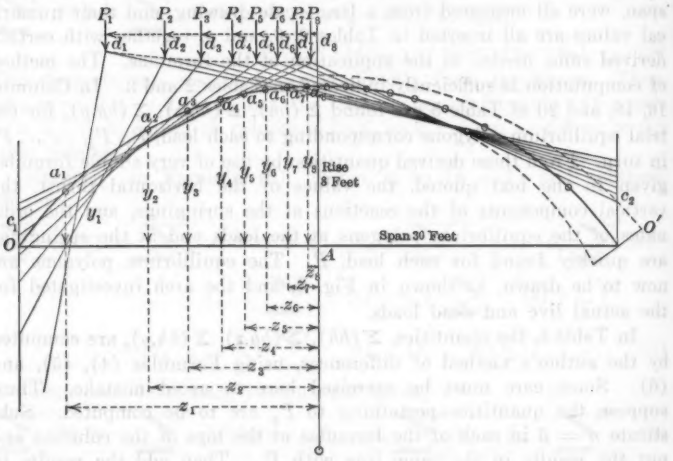

FIG. 3.

drawn, the exact position of the live load to give the maximum stress at any section of the arch can be at once determined from the figure. The writer has shown* the great variations in stress at the critical sections of an arch as a live load moves across it, and has indicated probable positions for this load to cause maximum fiber stress at certain sections. Evidently, however, the positions will depend on the shape of the arch, and will thus vary as the arch is thicker or thinner and also with the curves of the intrados and extrados. The method of single loads gives certainty, the usual method uncertainty, in endeavoring to find maximum stresses. It is feared, therefore, that of the tens of thousands of concrete arches built in the United States, the maximum stresses in but very few have been ascertained. The subject is a vital one, and of practical importance.

Paper No. 1245

THEORY OF REINFORCED CONCRETE JOISTS.

By John L. Hall, M. Am. Soc. C. E.

With Discussion by Messrs. Ernest McCullough and John L. Hall.

In computing the strength of reinforced concrete floor slabs, it is usual to disregard the tensile resistance of the concrete. That portion of the concrete on the tensile side of the neutral plane is considered only useful for covering the steel, for helping to resist shear, and for forming a ceiling. A small part of this concrete would ordinarily be sufficient to cover the steel and furnish the necessary resistance to shear. The remainder is a heavy and somewhat expensive material for a ceiling. Particularly is this true in the case of long spans which require thick slabs.

By keeping the reinforcing steel in large units, a series of parallel concrete joists may be formed, instead of a flat slab. With a thin slab over the top, lightly reinforced transversely, the joists become a system of small T-beams. The expensive form work of such a system is one objection to it, and the preference for a flat ceiling is another. To obviate these objections, burned clay hollow tile with plaster ceiling, or sheet-metal tile with metal lath and plaster ceiling, has been used.

The purpose of this paper is not to discuss the relative merit or economy of these several methods of construction, but rather to discuss the things which should be considered in computing the strength of such a system of joists. Various claims are made as to the work performed by clay tile in combination with concrete joists. It is not

the intention to discuss this matter at present. The spaces between joists, therefore, will be assumed to be voids. Fig. 1 shows how such a system was used in a recent design. See also the plan, Fig. 6. Fig. 2 is a section through the joists, and Fig. 3 is a section through the beams. Fig. 4, illustrating the mode of bending, in a beam with fixed ends, is introduced for the purpose of reference in what follows.

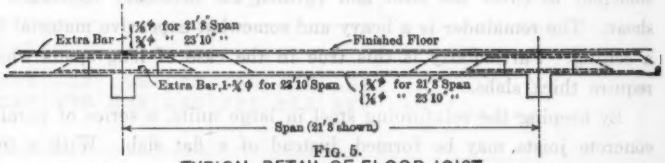

FIG. 5.

TYPICAL DETAIL OF FLOOR JOIST

The bending moment of a simple beam resting freely on end supports is determined solely by the amount and distribution of the load (including the weight of the beam itself), entirely regardless of its sectional shape or materials.

In a continuous beam, however, the bending moment depends on the amount and distribution of loads and also on the elastic curve or deflection of the beam. The elastic curve is influenced by the shape and composition of the beam. What the actual bending moments are in reinforced concrete, therefore, is not known. It is a matter of much difference of opinion among engineers, as shown

by the discussion before this Society following the Progress Report of the Special Committee on Concrete and Reinforced Concrete.

As commonly given in books on mechanics, the bending moments and reactions for continuous beams are calculated for the ideal case of homogeneous beams of uniform sections resting freely on level supports evenly spaced. Such cases do not occur in building construction. After many tests of actual construction, the formulas given in the building laws, although based on the ideal case, are recognized

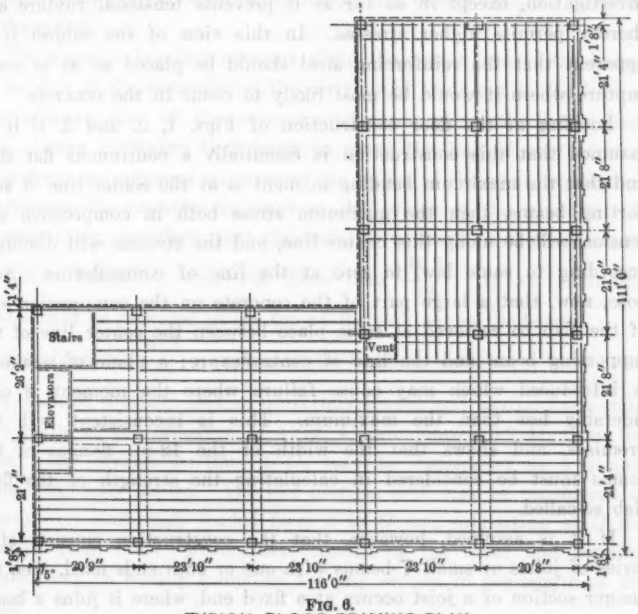

FIG. 6.
TYPICAL FLOOR FRAMING PLAN

as safe, and are in general use; yet it is well to remember always that these formulas are only approximations. The nearer a design approaches the ideal case referred to, the more nearly do the formulas approach the truth. Any material deviation in design from the ordinary approximation to the ideal condition presents a case for special study and determination.

It is thought that the laws of deflection and the amount of deflection under working loads are much the same in reinforced and

in plain concrete. Certainly, the small deflections in reinforced concrete, as compared with those in structural steel, show that in the former the concrete is more of a controlling factor in deflections than the steel. This theory is consistent also with calculated deflections using the moment of inertia of sections containing usual percentages of steel. It would seem, therefore, that the reinforcing steel has very little influence on the elastic curve of the kind of construction under investigation, except in so far as it prevents tensional rupture and thereby permits higher stresses. In this view of the subject it is apparent that the reinforcing steel should be placed so as to resist rupture where it would be most likely to occur in the concrete.

Looking at the floor construction of Figs. 1, 2, and 3, if it be assumed that this construction is essentially a continuous flat slab, and that the maximum bending moment is at the center line of supporting beams, then the maximum stress both in compression and tension will be along this center line, and the stresses will diminish, according to some law, to zero at the line of contraflexure. Suppose, now, that a large part of the concrete on the compression side of the slab be removed at some place between the center line of the supporting beam and the line of contraflexure; a plane of weakness is introduced which may cause failure where the moment is considerably less than the maximum. This is inconsistent with the premises, and shows that the width of the 12-in. flanges of the beams must be considered in calculating the strength of the floor slab so-called.

If it is assumed, however, that the construction consists of a series of joists or small T-beams with one or both ends fixed, then the danger section of a joist occurs at a fixed end, where it joins a beam, and the analysis becomes straightforward and consistent. It is thought, therefore, that the joists should be designed for fixed ends, in accordance with actual conditions.

An objection which might be made to this procedure is that the beam flanges, into which the ends of the joists are said to be fixed, are themselves capable of deflection, so that the ends of the joists are inclined slightly instead of level. This deflection at the edge of the flanges, however, must necessarily be very small, being estimated according to the respective moments of inertia, and is only 40%

of what it would be at the same line if the joist section ran without change to the center of the beams.

The effect of this slight inclination of the supports would be to increase slightly the positive moment at the center of the joists and to reduce slightly the negative moment at the fixed ends. This reduction of negative moment would cause the calculated negative moment to err on the side of safety, and the slightly increased positive center moment would utilize more economically the excess strength provided at the center.

The negative bending moment along the center line of the beams is the sum of the moments of the distributed loads out to the line of contraflexure, and of the concentrated loads along the latter line. Any change in design that tends to move the line of contraflexure away from the supports and toward the center of the span, would tend to increase the negative moment at the center of the supports. It is conceivable, therefore, that the negative moment in the case under discussion might be somewhat more than $\frac{WL}{12}$. If so, additional steel should be provided in the top of the slab across the beams.

The formula, $\frac{WL}{12}$, expresses the bending moment at either end of a beam of constant section uniformly loaded and having fixed ends. The points of contraflexure, *O* (Fig. 4), are located $0.211L$ from the ends. The central portion, *O-O*, may be considered as a simple beam, uniformly loaded. The end portion, *a-O*, may be considered as a cantilever uniformly loaded from *a* to *O* and supporting at *O* the reaction from *O-O*. From these conditions the shear and bending moment can be readily computed for any section in the length of the beam.

In similar manner, a continuous beam is restrained by bending moments at the supports. The points of contraflexure, however, from which the moments may be computed, are not located as easily. Their position is affected by the number and the relative length of the spans and by the distribution of the live loads, whether on some or all of the spans, and by other considerations. In order to simplify the computations, the building laws authorize the use of the formula, $\frac{WL}{12}$, for interior spans, and, $\frac{WL}{10}$, for end spans. This method of

calculating is only approximately correct. Its error is usually, although not always, on the side of safety. The formula for interior spans is the same as that for beams with both ends fixed. For end spans, the formula indicates one fixed end and one partly fixed.

When applicable, the theorem of three moments permits the accurate determination of moments and shears for actual conditions; and, if all the conditions are actually considered, it affords a more scientific method of calculation than the approximate formulas previously stated. The building law recognizes the validity of scientific analysis, and caution would seem to require such analysis, if attainable, whenever the design varies materially from ordinary conditions of continuity, as, for example, when the spans are very unequal in length, or when the conditions of constant section and free support are deviated from in any marked degree.

The features of this design, which vary from usual conditions of continuity, are: (1) the massive character of the supporting beams; and (2) the sudden change in section where the joists join the flanges of the beams.

The joists in interior spans were assumed to have fixed ends, and an attempt was made to determine the location of the points of contraflexure. Investigations by F. E. Turneaure, Assoc. M. Am. Soc. C. E., indicate that, within ordinary working stresses and percentages of steel, the elastic curve of a concrete beam is not greatly influenced by the position of the reinforcement. It appears to be desirable, therefore, to ascertain the natural elastic curve of the concrete joists and place the steel where it is needed in conformity thereto.

Two assumptions were tested: (1) That the ends of the joists are fixed at the face of the beam web; (2) that they are fixed at the edge of the beam flanges. The location of the points, O, was calculated for both conditions, on the basis of a constant section.

The position, O_1, Fig. 3, obtained by the first calculation, would be correct if the flange, F, were as flexible as the joist, J, while the position, O_2, would be correct if the flange, F, were perfectly rigid. As the flexibility of F is intermediate between these assumptions, the true position, O_3, must lie between O_1 and O_2, and closer to the one derived from that assumption, which is nearer the truth.

A beam of the section, F, it was estimated, would deflect four-tenths as much under a given load and span as one of the section J

It is then more nearly a rigid beam than one of the same flexibility as J. The point, O_3, therefore, lies nearer O_2 and is four-tenths of the way from O_2 toward O_1.

Having fixed the position of the points, O, the remaining calculations are very simple. The typical detail of the joist, Fig. 5, is designed in accordance with the actual conditions as understood, and the necessary resistance is provided. The moments and shears are stated on that figure.

In view of the fact that the moment at the center of the span of a beam with fixed ends is only one-half of $\frac{WL}{12}$, it may be asked why this formula is required by law generally for the center of continuous interior spans, and whether such requirement would be justified in the present instance. Analysis of the spans under consideration by the ordinary theory of continuous beams showed that if only one span be fully loaded, the other spans having dead load only, the fully loaded span will have a moment at the center about two-thirds of $\frac{WL}{12}$. If the live load on one span only were greatly increased over the dead load, the moment at the center of the span would be increased in a larger ratio; but, in the absence of those conditions, there appears to be nothing gained by increasing the reinforcement at the center of the span.

Again, the theory of continuous beams does not take into account the torsional stiffness of the supporting beams, which, in the present case, is very considerable. Manifestly, the more nearly we approach the ideal condition of fixed end supports for the joists, the less influence will be exerted by conditions outside the particular span considered, so that the probable maximum moment at the center of the span of the joists will always be less than two-thirds of $\frac{WL}{12}$, in this particular design.

In the detail herewith submitted, Fig. 5, the reinforcing steel is disposed in accordance with the foregoing statement of theory.

DISCUSSION

Mr. McCullough.

ERNEST MCCULLOUGH, M. AM. SOC. C. E. (by letter).—In some recent correspondence with Sanford E. Thompson, M. Am. Soc. C. E., the writer's attention was called to a too common error on the part of designers in reinforced concrete, wherein the sum of the middle bending coefficient and the coefficient at one support is always assumed to be equal to $\frac{1}{8} wl^2$. The moment of inertia of the section is not considered as being affected by the quantity of steel, the result being that, if a middle coefficient $= \frac{1}{10}$ is assumed, the coefficient over supports is taken as $\frac{1}{40}$. The writer checks a great many plans for contractors and owners, these plans being generally furnished free of cost by steel salesmen. The almost uniform practice is to use the clear span, face to face of T-beams, for floor slabs, and the clear span, face to face of columns, for beams and girders, the foregoing coefficients being used for steel distribution. The writer has never been able to make the designers do more than use a coefficient of $\frac{1}{12}$ in the middle and $\frac{1}{24}$ over supports. He has sometimes failed to secure a concession of even that much, as the designers can refer owners to a large number of buildings, erected in every State in the Union, designed with the foregoing distribution of bending coefficients. When possible, he compels the use of $\frac{1}{12}$ over supports and $\frac{1}{18}$ in the middle, whereas, the building ordinances of Chicago and most cities call for a total of $\frac{1}{6} wl^2$, with a coefficient of $\frac{1}{12} wl^2$ in the middle, of course, then obtaining equal steel areas in the middle and over each support.

Two weeks ago a designer gave as authority for his method, Turneaure and Maurer's "Principles of Reinforced Concrete Construction," second edition, page 307, where the following occurs:

"* * * but the use of $\frac{1}{10}$ for the general coefficient will provide ample strength in all ordinary cases. This would require an actual resisting moment at each support of only about $\frac{1}{40} pl^2$ in order that the center moment be reduced to $\frac{1}{10} pl^2$."

His attention was called to a line on the same page where the following appeared:

Mr. McCullough.

"The foregoing calculations assume uniform moment of inertia and therefore that about the same amount of steel is used for negative as for positive moments. The effect of variation in moment of inertia is discussed in Art. 166."

In the preceding paragraph, on the same page, the authors propose certain coefficients, saying plainly that they are for both positive and negative moments. To the writer, it seems impossible to make any mistake in the matter, if it is carefully studied, even with no other authority than that above quoted.

Turning to Art. 166 in the above-mentioned book, it is found to deal with columns, the reference being a misprint, Art. 165 being meant. This section is a valuable discussion of the effect of varying moments of inertia, being based, for the most part, on a discussion by P. E. Stevens, Assoc. M. Am. Soc. C. E.* A table is given, based on the moments of inertia varying with the quantities of steel, showing that if the assumption be made that the middle coefficient $= \frac{1}{8} wl^2$ and about one-fifth of the quantity of steel in the middle in the bottom be placed in the top over supports, the stress at the center will be 55% of the working stress and at the end will be $4.1 \times 0.55 = 2.25$ times the working stress.

In the last edition of "Concrete, Plain and Reinforced," by Taylor and Thompson, the following is found on page 439:

"In applying this to the various cases, the assumption is made that the moment of inertia of the beam is constant throughout its length. While this is not strictly true, extensive studies of various cases in reinforced concrete show that a large change in the moment of inertia makes a very small change in the bending moment, so that the relations are substantially correct until a member enters a much larger member."

Mr. Thompson, in a letter to the writer, says:

"Many designers have the very erroneous idea that, because they design a beam for $\frac{wl^2}{8}$, the bending moment is reduced to zero over the supports. This, of course, is not the case, because designing the beam for $\frac{wl^2}{8}$ is an entirely different matter from changing the bending moment to $\frac{wl^2}{8}$. The bending moment still remains in the neighborhood of $\frac{wl^2}{24}$, if the beam is fully continuous; so that the bending moment at the support for uniform load is still a little less than $\frac{wl^2}{12}$."

* *Transactions*, Am. Soc. C. E., Vol. LX, 1908, p. 496.

Mr. McCullough.

In his paper, Mr. Hall has placed the matter in the proper light, but has neglected to call attention specially to the fact that all concrete designs, wherein continuity of construction is considered, should be based on the end moments rather than the center span moments.

A few days ago, in conversation with three structural engineers, members of this Society, the writer discovered, to his surprise, that they believed the sum of the center and one end coefficient $= \frac{1}{8}$; and if the assumption is made for a large bending moment in the center, that only enough steel is required over supports to care for the remainder of the coefficient, it being their practice to use arbitrarily over supports about one-fifth of the quantity of steel used in the middle, in the event that they use $\frac{wl^2}{8}$ in the center. This small quantity of steel they claim is to take care of possible cracks, mainly caused by temperature, and possibly by a bending down of the flanges of T-beams, or unlooked for variations in loading. As such men hold to these views, it is proper to have a full discussion of this phase of the subject, and that some present methods of designing be discouraged. Five or six years ago such views were common, and it is surprising that by this time so many men of standing in concrete work still neglect consideration of the fact that "designing the beam for $\frac{wl^2}{8}$ is an entirely different matter from changing the bending moment to $\frac{wl^2}{8}$," as stated by Mr. Thompson.

Mr. Hall.

JOHN L. HALL, M. AM. SOC. C. E. (by letter).—The writer has read with interest the discussion by Mr. McCullough, who seems to accept the theory. His discussion emphasizes the fact that the prevailing practice among designers of continuous reinforced concrete construction errs in assuming the position of maximum bending moment at the middle of the span, instead of at the supports. Judging from the building regulations of the principal cities of the United States, which the writer has had occasion to examine during the past two or three years, it would seem that Mr. McCullough has much evidence to justify his contention. It is thought to be good practice to calculate the moments as nearly as may be in accordance with the actual conditions of loading, and on the ordinary theory of mechanics.

The records of tests of reinforced concrete and the literature of the subject leave some doubt in the mind as to what the actual bending moments are at the middle of the span in reinforced concrete structures, but it is thought that the moments at the supports are in general as large as the results obtained by the methods proposed by the writer.

TRANSACTIONS

Paper No. 1246

PORTS OF THE PACIFIC.*

By H. M. Chittenden, M. Am. Soc. C. E.,
Assisted by A. O. Powell, M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, E. P. Goodrich, Lewis M. Haupt, and H. M. Chittenden.

To describe any one of the larger ports of the Pacific Coast adequately would exceed the admissible limits of this paper. To describe them all with anything like minute detail is clearly impossible, and it is assumed that, in assigning this topic, the intention was that it be treated only on broad general lines which should give a comprehensive view of the subject as a whole, rather than a study in detail. Even with this understanding, the scope of the subject is so vast that its compression into the compass of a professional paper seems little better than the preparation of a table of contents. The attempt has been made, however, and its results are presented herewith under the following headings:

I.—Strategic Relations of Coast Ports.
II.—Descriptive Data.
III.—Engineering Problems.
IV.—Administrative Systems.
V.—Plans for the Future.
VI.—Influence of the Panama Canal.

The paper will treat only of those ports north of the boundary between Mexico and the United States.

*This paper was presented to the Annual Convention at Seattle, Wash., and also at the meeting of November 20th, 1912.

I.—Strategic Relations of Coast Ports.

Commerce of the Pacific.—Since the days of Magellan, imaginative minds have pictured the Pacific Ocean as the future home of the world's commerce. There is something in the immensity of that ocean, in the present vastness of the population on one shore and the future vastness of that on the other, which conjures up visions of argosies such as the Mediterranean or the Atlantic has never known. The situation as it actually exists, however, makes this picture somewhat of an illusion. The very wideness of the intervening sea is a mighty barrier to economic intercourse across it. The breadth of the Pacific as compared with that of the Atlantic, depending on the latitude, is as two or three to one; and, while the cost of transit and loss of time may not be in the same proportion, there is still a wide disparity against the larger ocean. There are also the almost insuperable barriers of race and economic conditions on the Asiatic Coast. We do not admit the Oriental to our shores as we do the European. That immense source of traffic which has sustained its thousands of ships on the Atlantic is cut off on the Pacific. Likewise those Oriental countries have little to offer the traveler which can compare with the lure of European civilization, ancient and modern. Tourist traffic across the Pacific is a bagatelle compared to that over the Atlantic. Finally, the deep poverty of the hordes who swarm the Asiatic shores, and the backward condition of industry there, are not promotive of vigorous commercial intercourse, for they offer relatively little to sell and less with which to buy.

Thus it results that the commerce of this ocean, great though it be, is small compared with that of the Atlantic, and small to what might be expected from the millions of inhabitants affected by it. Its growth in the near future, strange as it may appear, is more dependent on the countries which border the Atlantic than on those washed by its own waters. As far as the Pacific Coast is concerned, the eyes of its people are turned east rather than west. It is there that their kindred dwell; it is there that the capital exists which shall develop their boundless resources; it is thence that must come those who shall help to populate their shores. It is this fact—that their future is on the Atlantic rather than on the Pacific—which makes the opening of the Panama Canal an event of such tremendous import to them. It is bringing them to their own. It fronts them toward

Europe. It opens to them the treasures of the Occident—far more potent, if less romantic, than those of the Orient. It gives them something of the advantage which the eastern shore of the Continent enjoys by reason of its closer relation to the fundamental sources of our civilization.

If this condition is true of the present, and will remain so, to a degree, for the indefinite future, let it not blind us to the profound changes which are taking place in those ancient, and, but yesterday, non-progressive, countries which lie on the other side of the Pacific. When we consider what a volume of commerce the accidents of political fortune have turned in this direction from the distant Philippines; when we reflect on the marvelous progress of modern Japan; and when we note the amazing changes now going on in that venerable nation which has slumbered indifferent to the rest of the world for thirty centuries or more, we cannot afford to take a pessimistic view of our future relations with that side of the globe. If ever these people accomplish what is within their practical reach; if ever they turn to account, as is done in Europe and America, their wealth of natural resources and their own capacity for industrial development, surely there will result a mighty increase in trade between them and the rest of the world, and of this the American Continent will enjoy the greater share.

Thus, while the Atlantic holds out to us the brighter present prospect, there is brilliant promise in the Pacific, and in every direction the future is big with hope. Visions of the coming day are profoundly stirring the minds of men. Expansion is in the air. The measureless force of unseen psychological influences rushes the world along whether it will or no. Doubtless, it builds exaggerated hopes and paves the way to much disappointment, but its very exuberance of faith is an earnest of vast accomplishment.

This far-reaching movement, which has been crystallized into definite form by the approaching consummation of the greatest engineering work of ages, finds its intensest expression along the Pacific Coast of North America. To other parts of the world, the Panama Canal means simply increased opportunities for trade; to the Pacific Coast it means a new lease of life through the elimination of those barriers which separate it from its true source of sustenance and growth. Everywhere along the Coast, faith in the beneficial results

of this great work is unbounded. It is a faith, moreover, which expresses itself in works. From Alaska to Lower California, the Coast is getting ready for the Canal. It is putting its house in order. It is spending in this work prodigious sums of money. The present decade will witness an expenditure in port development of probably $50 000 000. The slogan which has won this vast sum from the pockets of the taxpayers is: "Get ready for the opening of the Panama Canal," and the formal celebration of that event will find the work well toward completion.

It would be idle to pretend that this prodigious effort springs solely from an actual necessity of providing for the increase of traffic that will result from the opening of the Canal. The popular belief is, of course, that this is the case; but those who have studied the situation closely know better. They realize that the movement is being overdone, but they recognize that it is bound to keep on through the fear which each port entertains of what its sister ports may do. The stigma of possible failure in the race and fear of loss of prestige are the potent forces which are back of these extraordinary efforts. Los Angeles or Seattle would find it difficult on the cold basis of rational business foresight to justify their enormous prospective outlays; but they find ample justification in the necessity of keeping up with a procession which now stalks with tremendous strides from one end of the Coast to the other.

Competition of Ports.—This interesting state of things suggests a primary basis for comparing the ports of this Coast, namely, their relations to one another as commercial rivals. In the long stretch of coast line from Latitude 32° 30′ to Latitude 54° 40′, there are certain points of true strategic value; that is, points the possession of which gives the possessor important advantages over his competitor. Broadly speaking, there are two great divisions of the Coast from a commercial point of view—the north and south—with the Oregon-California line the approximate boundary between them. Only in a very general sense are these two sections of the coast competitors. They both reach out, it is true, to Hawaii, the Orient, and Alaska, and inland to common interior points; but each has some advantage peculiar to itself—a sort of proprietary right in certain spheres in which the other seems rather an interloper. The competition in such cases

is not keen, for the advantage of the more favored rival is too pronounced to be coped with successfully.

It is in a narrower sphere that the competition of these ports becomes really intense. San Francisco, Los Angeles, and San Diego have little to fear from the ports of the North, for their respective hinterlands merge only in the far interior of the Great Basin, but they have a wholesome respect for one another. Portland poaches but slightly on San Francisco's preserves, and Puget Sound still less, but the port on the Columbia never for an instant lets her sisters farther north forget her existence. Puget Sound and the ports of British Columbia are also competitors of a strenuous type in spite of the artificial barriers of nationality, tariff, and different customs and laws. In these local groups competition is really keen, and each competitor is feverishly anxious as to what its rivals are doing, while the still smaller units of the group flourish either by virtue of special advantages or simply on the crumbs which fall from their wealthier sisters' tables.

San Francisco Bay.—Having thus touched in most general terms on the trade relations of different sections of the Pacific Coast, let us consider in some detail the principal ports, still from the point of view of their commercial relations. Whatever changes the future may have in store, it is now true, and for a long while will so remain, that San Francisco Bay is far and away the most important port on the Coast. It is a wonderful port—wonderful in the strategic relation to its California hinterland and to the great interior of the country; wonderful in its physical conformation as a vast sheltered harbor opening in, through a narrow and easily defended entrance, from a coast line almost devoid of harbors for hundreds of miles in either direction; wonderful in its romantic history, and wonderful in its relation to the commerce of the world. Nature wrought a masterpiece when she made San Francisco Bay. Its great expanse and its navigable connections north and south, through the rich valleys of the San Joaquin and Sacramento, fit it perfectly as the entrepôt of a vast empire. The work of Nature was supplemented by the good offices of fortune, which early turned the attention of the world to this port and laid the foundation of its future greatness so deep that neither earthquake nor the growth of rivals can shake it. The Golden Gate—named three centuries before, in beautiful prophecy of

the Argonauts of Forty-nine, whose anchors dropped into yellow sands brought down by the slicken-laden streams of the Sierra—was the scene of a mighty commerce while yet only random traders sought the furry wealth of the harbors farther north. The first transcontinental railway had poured its traffic into the valley of the Sacramento for twenty years before any other portion of the Coast was similarly favored. San Francisco had written the most important chapter of her history while her sister ports were still almost unknown to the world. Congress did well when it selected the California metropolis as the site for the celebration of the opening of the great Canal. What a contrast it will be—the struggling mass of humanity and freight on its way across the fever-stricken Isthmus to the land of golden promise in Forty-nine, and the floating palaces which will then pass safely through Culebra Hill to a scene of resplendent riches undreamed of by even the wildest imagination of sixty-six years before! Where else on the round earth has modern progress wrought so great a change in so short a time?

Los Angeles and San Diego.—In Southern California, the location of highest strategic value, from a commercial point of view, unfortunately, happened to be where Nature did not provide a harbor, while the one really good natural harbor on that section of the Coast is not located where it will best serve the commercial needs of the country. Los Angeles, by virtue of its relation to the great Southern trade routes east, its marvelous resources in agriculture, its close proximity to the oil fields of Southern California, and the inestimable wealth of its winter climate (not exclusive in this, however), is incontestably the center of activity of Southern California. So little did Nature do in the way of providing a port in that vicinity, however, that the town did not grow up on the seashore at all, but twenty miles inland, and the possibility of making it a genuine seaport was clearly an afterthought in its development. Now, this consummation is its chief ambition, and a superb effort is being made to realize it. Los Angeles will become a great port, not because Nature made it so, but because her own virile people have said so. Its future harbor will be almost wholly artificial, but it will be a great harbor nevertheless, and will stand all the more to the credit of its people because of the sacrifices which they will have made to obtain it.

Southeasterly from Los Angeles, 89 miles, lies the splendid land-locked harbor of San Diego, ideal in its physical advantages. The fact that it never has become of first importance, however, shows that it requires something besides Nature's aid to make it a great port. It is not well located with reference to rail routes east; it has not as good a tributary country as Los Angeles; it is hemmed in by bold uplands close to the shore; and, worst of all, it suffers the purely artificial handicap of close proximity to the National frontier. Still, in spite of these drawbacks, the great natural advantages of the harbor, the lack of such advantages at Los Angeles, and the arbitrary rail tariffs which until recently have made freight from Port Los Angeles to the main city cost as much as from San Diego itself, though four times as distant, make San Diego a powerful competitor of her sister city to the north. Of course, she is bound to lose something of her relative advantage as Los Angeles develops her port, and particularly when the proposed municipal belt line connects that city with the sea and reduces freight rates to a nominal figure.

These two Southern ports have naturally cut somewhat into the trade of San Francisco, and will continue to do so. This is to be desired, as far as they may better serve the needs of the public as a whole, and beyond that point they are certain not to prevail if the communities of San Francisco Bay do their duty. California is a State of vast extent and immeasurable resources, and its hinterland is all the country to the eastward. In this illimitable field, and with the boundless ocean to the west, there will be sustenance for all, and the final balance among the ports will be adjusted on the basis of maximum efficiency of service to the public.

The Columbia.—Northward from San Francisco the first location of high strategic value is the Columbia River—the chief river of the Pacific Slope—which here breaks through the mountain barriers and opens a low-grade route to the interior of the country. It is the only point in United States territory where the great Coast-Sierra-Cascade Barrier is completely traversed by a water-grade route. The main valley extends directly back from the sea a distance of 75 miles, where its tributaries begin to spread out until they expand like an enormous fan, giving arterial highways to a water-shed of 250 000 sq. miles, with routes across the Continental Divide to the far-spreading country beyond. The main stream is susceptible of improvement for

navigation as far as into British territory, and its principal tributaries can be navigated for short distances; but the rapid fall of most of the streams, and the invariable accompaniment of rock rapids, make the liberal use of locks a necessity, and this presupposes heavy cost. In any event, it is certain that the river will be improved in the near future so that boats can ascend at all seasons as far as Central Washington, say, to Priest Rapids. This water route and the low-grade rail routes on either side, ramifying along the tributaries in all directions, give the Lower Columbia ideal communications with its hinterland, considering the exceedingly mountainous character of the country.

Plate X shows, to any trained eye, the immense advantage of the situation at the junction of the Columbia and Willamette Rivers. It is a great cross-roads. To this point vessels from the ocean, once over the bar, can safely ascend. Here, rail and river take up the route to the far interior. South is the rich Willamette Valley and Nature's land route to California. North is the Cowlitz Valley and the route to Puget Sound. The possibilities of the situation are enormous and such as will survive all competition. The chief drawback, as far as its commercial relations with the outside world are concerned, is its connection with the sea. The Columbia Bar, built up from the detritus of a vast and steep-sloped water-shed, was originally the most formidable and dangerous known to navigation, and the problem of opening and maintaining a safe and commodious channel across it is one of the most difficult in the whole range of river and harbor engineering. Only a moderate degree of success has been obtained so far, and that at heavy cost. Other plans have been suggested, such as cutting through the sand spit to an artificial harbor to be built south of the jetty, or through the isthmus on the north to the fine natural harbor of Willapa Bay; but they have never received serious attention, and the plan of deepening the bar by jetty construction will probably continue. With it must go, hand in hand, the project of deepening the river itself in its 100-mile channel from the bar to the port. The situation is something like that at Los Angeles in that Man must be relied on to make good the large deficiency of Nature. This, as the writer has elsewhere observed, the enterprising citizenship of Portland is resolved shall be done, cost what it may, to the end that there may be realized, even more than at

present, the prophecy of one of her own poets, who has pictured the time:

"When through this Gate the treasures of the North
Flow outward to the sea."

Puget Sound.—Proceeding northward, the next great strategic point in the commerce of the Pacific Coast, and, in some respects, the most important of all, is Puget Sound. It is a vast inlet from the sea through a strait 15 miles wide and nearly 100 miles long, branching both north and south, in sheltered inland waters which abound in ideal natural harbors. So perfect are these harbors that their chief defect is an excess of what anywhere else would be considered almost the chief advantage, the depth in some being such that anchorage ground is scarce, and extending so close in shore as to make wharf building difficult and expensive. The tidal range is also large, with strong tidal currents, and the teredo is very active. Except for these drawbacks, the Sound harbors are ideal. Take Seattle, for instance. Into the spacious enclosure of Elliott Bay, a ship can enter without tug or pilot and pass directly to berth under her own steam in all conditions of tide, and in almost all conditions of weather, and always feel certain that her hull will not touch bottom. It is the most favored port in the world in this respect, excepting only one or two of its sister ports on the Sound, which enjoy the same advantage.

Nature has certainly lavished her richest favors on these ports and provided them with advantages which no expenditure of money can ever give to a port situated as is Portland or Los Angeles. But, as an offset to this great advantage, she has placed a handicap which is of very serious consequence; she has barred off Puget Sound from its great hinterland to the east by a massive mountain range, the lowest passes of which are more than 3 000 ft. high. These passes have been scaled successfully, it is true, and the terminal rail rates are the same as to Portland, but the handicap is there, nevertheless, and is the most serious commercial problem which Puget Sound faces to-day. It is as if the Catskill Range, with twice its actual height, extended along the coast in an unbroken wall from Boston to Baltimore, shutting out New York from its rightful hinterland. Local enthusiasts in both Portland and Seattle speak of their respective cities as the "New York of the Pacific." In truth, each is only half

New York; or rather, New York, in its natural advantages as a port, is the Seattle and Portland combined of the Atlantic. Its harbor rivals that of Seattle, while its Hudson River route to the interior rivals that of the Columbia. Puget Sound does not fully appreciate this difference. Seattle and Tacoma are spending millions in developing harbors which are already perfect beyond any in the world, but not a cent to overcome this barrier which stands between them and their hinterland. The writer once had the temerity to suggest that a low tunnel, serving all the railroads and giving practically a water-grade connection between the Sound and the Columbia Valley, was essential to the commercial supremacy of Puget Sound ports. Time alone will justify or discredit this prediction, but it is certain that with an outlay no greater than what has been expended on three of the Alpine tunnels, a line could be secured which would serve, on the most favored gradients and with shortest distances, the entire country from the Great Basin to the interior of Canada. Puget Sound is the natural entrepôt for the trade of Alaska, is a day nearer the ports of Japan and Northern China than San Francisco, and has the best harbors in the world. Only the natural barrier which separates it from its hinterland keeps it from playing the part which it should in the commerce of the Pacific.

We have considered Puget Sound as a great harbor whose entrance is the broad, deep Strait of Juan de Fuca. Inside the Strait there are numerous competing ports, of which Seattle is the central and most important. Thirty miles farther south is Tacoma, Seattle's most formidable competitor in United States waters. It has a harbor rivaling that of Seattle, and has been particularly favored by the great railway systems, which have given it an importance even beyond what its comparative advantages justify. Besides Tacoma there are the harbors of Everett, Anacortes, and Bellingham, all of which have splendid natural advantages and do a thriving trade. On the west side of the Sound is Port Townsend, once looked on as the coming port of Puget Sound, but now important mainly as the headquarters of the Customs District of the Sound and the Quarantine Station. It is on the wrong side ever to assume first importance.

All the great strategic points in United States territory, which we have considered, have been guarded by elaborate sea-coast defenses, while San Francisco and Puget Sound have been made great naval bases.

Vancouver, B. C.—Seattle's greatest rival for commercial supremacy north of Portland and Tacoma is Vancouver, B. C., a rival whose strength lies not so much in its natural advantages as in the artificial conditions arising from its being in a different national jurisdiction. It has a good strategic location, it is true, being at the outlet of the second greatest river of the Pacific Coast; but its harbor is inferior to those farther south, and its rail connections east, even to Central Canada, are inferior. Its early growth was due primarily to the fact that it was a Canadian port. That the port would have developed where, or as rapidly as, it has, if there had been no international boundary near by, may well be doubted. As conditions actually exist, however, taken with the present status of American navigation laws by which cheaper foreign shipping is excluded from our coastwise trade, Vancouver is a formidable competitor with ports farther south. In the fish and lumber export trade, particularly, conditions tell heavily in her favor.

Prince Rupert.—Prince Rupert is the northernmost Pacific terminus of the transcontinental lines, and will remain so until some line shall cross into the valley of the Yukon and descend that mighty river on its way to the westernmost apex of the Continent. It is 40 miles south of the international boundary of Alaska (54° 40′) and about 700 miles along the coast from Seattle and that much nearer Alaska. It is the westernmost, as well as the northernmost, transcontinental terminus, and is 500 miles (according to the statement of the Grand Trunk Pacific officials) nearer Asia than any other terminus on the Pacific. It is said that a traveler from China would be able to reach Winnipeg, *via* Prince Rupert, before he could reach Vancouver, if he were to go by that port. Add to this the fact that the gradient over the mountains, with the exception of about 20 miles of 1% on the west slope, is everywhere under five-tenths, and most of the way much less than this, and some of the physical advantages of the route are apparent. Add again the proximity of Prince Rupert to the limitless wheat fields of Canada, the fact that it is in the very center of the salmon and whale industry, among inestimable quantities of virgin timber, and its great future seems doubly assured.

Its advantages are offset to some extent by the severity of northern winters, but chiefly by the different nationality of the territory (Alaska) which it is best fitted to serve.

Secondary Ports.—Somewhat outside the rivalries of the great ports along the Coast, and flourishing on advantages which are peculiar to themselves, are several smaller ports. Among them, and the more prominent, are San Luis Obispo, about half way between San Francisco and Los Angeles; Humboldt Bay, on the North California Coast; Coos Bay, 200 miles south of the Columbia and serving an important section of Western Oregon; Astoria, just inside the Columbia Bar and the first port to be established on the North Pacific Coast; Grays Harbor, a great lumber port on the west coast of Washington, 45 miles north of the Columbia; and Victoria, an important harbor and naval base on Vancouver Island. There are numerous harbors on the Alaskan coast, but they are still in a state of Nature, as very little has been done toward converting them into up-to-date ports. The prospective opening of the coal fields of Alaska, and a more definite Alaskan policy on the part of the Government, will undoubtedly lead to the establishment of permanent facilities at some of these points in the near future.

II.—Descriptive Data.

In its physical characteristics the Pacific Coast line of North America increases in severity from south to north, but there is less diversity in climatic conditions than one might expect, for such great differences in latitude, owing to the moderating effect of the ocean currents. It is not until well up on the Alaskan Coast that one finds the harbors regularly sealed by ice in the winter season. Storms are more severe in the northern latitudes, but this is more than offset, as far as coastwise trade is concerned, by the sheltered inland passages which extend for at least 1 000 miles from Southern Puget Sound north. The tidal fluctuation increases from south to north from a mean of about 4 ft. at San Diego to 14 ft. at Prince Rupert. The teredo is very destructive in all the waters of the Coast, but the limnoria is active only in Californian waters. Nearly all the tributary streams are heavy silt carriers, and the primeval bays and inlets are partly or wholly filled up, making dredging a necessary adjunct of harbor development all along the Coast, and necessitating costly training dikes to scour channels across bars or shoals. In Southern California, the immediate shores were originally lightly timbered; but from Northern California north they were covered with magnificent forests. The coast line is re-

markably uniform, and unbroken by indentations as far as the Strait of Juan de Fuca, but from there north the exact opposite is the case.

With these few observations on the broad physical characteristics of the Coast, more detailed consideration will be given to the several ports.

San Francisco Bay.—The Bay of San Francisco (including, in that term, San Pablo and Suisun Bays) has a total area of 420 sq. miles and a shore line of about 350 miles. The area exceeding 30 ft. in depth at low water is about 190 sq. miles. The extreme tidal range is 8 ft., and the mean is 4.3 ft. The tidal currents are strong in the Golden Gate and Carquinez Straits, amounting to 7 miles per hour at spring tides. The entrance to the Bay is about 1 mile wide and very deep, and is guarded by formidable defenses. In a half circle about the entrance on the ocean side, and some 6 miles distant, is a narrow bar with a ruling depth of 30 ft. at low tide and two crossings of over 40 ft.

The heavily silt-laden streams—the Sacramento and San Joaquin, with a water-shed of more than 60 000 sq. miles, extending 400 miles along the western slope of the Sierra—have brought down immense deposits into the Bay and are progressively reducing its area. It once extended far up the valley of each stream, but is now practically limited to the area below the Straits of Carquinez, for Suisun Bay is shoaled up so as to be of little use for navigation except on the through channel to the rivers above. The deposits have also invaded the Lower Bay and have shoaled the depth, over two-thirds of its area, to less than 18 ft. Due probably to the action of the inflowing tides, this shoaling has been forced mainly on to the east side of San Francisco Bay and the north side of San Pablo Bay, leaving the east shore, where Oakland, Berkeley, and Alameda now stand, quite unapproachable in their natural condition by any craft larger than a rowboat, while the shore of the San Francisco Peninsula has practicable depths for the largest shipping close in to the bank. It was mainly this condition that made the Port of San Francisco Bay develop where it did instead of on the east shore. Now that reclamation work is utilizing the shoal areas to make new lands by dredging out deep slips, shipping will gravitate more and more to the east shore in order to avoid ferry inconvenience.

The shoaling of San Francisco Bay is one of those great natural blessings which the unthinking are so accustomed to look on as a curse. One-tenth of its natural area, with deep connecting channels,

would serve every possible need of commerce, while the other nine-tenths would be of immeasurably greater benefit reclaimed and turned to industrial or agricultural use. Every cubic yard of earth washed down from the rugged slopes of the mountains is worth a thousand times more in those low areas, where it is turned to efficient use in the service of Man.

San Francisco Bay is perfectly sheltered from ocean storms, is not subject to flood effects except in the extreme upper portions, at the outlet of the Sacramento and San Joaquin Rivers, and is absolutely free from ice. There were originally several dangerous rocks in the channels, but these, for the most part, have been removed, the most important removal being that of Blossom Rock. In practically all respects the natural advantages of San Francisco Bay are of the highest order, and, if its human custodians are faithful to their trust, it is destined to remain for a long time the leading port on the Pacific Coast.

San Francisco proper and its port grew up on the narrow peninsula lying between the southern half of the Bay and the ocean, south of Golden Gate. As far as land communication to the north and east is concerned, the city is practically an island, and has to rely exclusively on ferry service. The water-front development extends from the northeast extremity of the peninsula around into the Bay, and as far south as the city and county boundary. The jurisdiction of the Board of Harbor Commissioners stops short at this point, which fact is clearly indicated on Plate X. At present the berthing space for all classes of vessels aggregates more than 10.5 miles. The several ferries to the east shore and other points land near the foot of Market Street, and carry 125 000 passengers daily. Exclusive of fairways or forbidden anchorage, there is, approximately, 100 sq. miles of available anchorage ground in the Bay.

Dock construction consists of three classes: Entire wooden construction, concrete subconstruction only, and complete concrete construction. Much trouble has been experienced with subaqueous concrete work, probably due to defective methods or inspection. Nearly all the sheds are built of wood, and their areas vary from 60 000 to 84 500 sq. ft. The State owns no dry docks, but there are two privately owned graving docks at Hunter's Point and two floating docks at the Union Iron Works Plant, besides the Naval Dock at Mare Island.

San Francisco is the only port on the Coast at which any great

amount of permanent sea-wall construction has been done. Work of this character has been carried on for the past twenty years. In that time, including work now in progress, nearly 13 000 lin. ft. have been built, at costs ranging from a little less than $100 to about $270 per lin. ft. The construction of the sea wall has resulted in reclaiming more than 25 acres, from which the annual rental now amounts to about $1 000 000, or considerably more than half the total revenue of the port.

The port's funds are derived from its regular revenues (rents, wharfage, dockage, tolls, etc.) and the sale of bonds. The regular revenues, from the beginning of the Board's operations in 1863, amount in round numbers to $28 500 000, and the funds from other sources, mainly bond sales, including recent issues still unexpended, to about $12 000 000. The expenditures for construction and repair amount approximately to $22 000 000, exclusive of the recent $10 000 000 bond issue. The running expenses of the port (salaries, law fees, etc.) amount to an average of 21.4% of all the disbursements. The total Federal appropriations for removing obstructions from the harbor amount to $516 000, so that the total outlay on the harbor, including recent bond issues, will be about $32 500 000. This, of course, is not all represented in actual present results, for much of it was for early work which has since been replaced, existing work probably not representing a present cost exceeding $10 000 000.

It is important to note that approximately one-half (of late years more than one-half) the revenue comes from ground rents, without which much larger bond issues would have been required.

The commerce of the port is very extensive. During the fiscal year 1908-09, 39 251 vessels of all descriptions were docked at the State wharves, and the short tons of freight passing over the wharves in the same period was 6 325 000. The Annual Report of the Engineer Department of the United States Army for the calendar year 1910 gives a total short-tonnage of 7 325 000, valued at $222 500 000, distributed as shown in Table 1.

The trade of San Francisco embraces every class of commerce that passes over the Pacific Ocean. The Government Transport Service on that ocean largely centers there, and the chief naval base of the Pacific Coast is at Mare Island in San Pablo Bay. In many other respects San Francisco stands far in the lead of any other port on the Coast.

Total	7 324 577	$222 478 148

Oakland and Alameda.—The physical characteristics of San Francisco Bay, of which Oakland and Alameda occupy the east shore, have already been described. The distinctive east shore harbor is the San Antonio Estuary, which lies between Oakland and Alameda and extends entirely around the land side of the island on which Alameda is situated. It is referred to in Government reports as Oakland's inner harbor. A channel leads in, from deep water in the Bay, between jetties 800 ft. apart, which also serve as moles with ferry slips at the ends. The channel, as developed under the Government project now in force, will be 500 ft. wide and 30 ft. deep to a large "tidal basin" about opposite the center of Alameda, with a channel 300 ft. wide and 25 ft. deep entirely around the basin, and a depth of 18 ft. in the "tidal canal" connecting the basin with San Leandro Bay, an inlet of San Francisco Bay on the southeast end of Alameda Island. This magnificent inner harbor has a shore line on each side of about 7 miles. On the Oakland side there is approximately 10 000 ft. of berthing space for deep-sea vessels and 16 000 ft. for smaller craft. The harbor is a great industrial center, some of the largest plants on the Bay being located there. There are four dry docks.

From the point of junction of the Estuary with the Bay, the shore line to the north is occupied by transcontinental railroad terminals and shops of ferry lines. In this stretch of about 2½ miles frontage is the so-called western water-front on which the Municipal Government is making improvements.

The port's revenues come from tax levies, bond sales, rentals, fees, etc. The City Government has recently issued $2 500 000 in bonds, and contemplates duplicating this issue in the near future.

The commerce of the port is large and varied, amounting, in 1910, to 3 575 000 short tons, valued at about $140 000 000, of which approximately one-half was carried in merchant vessels and one-half in ferries.

All along the east shore, and at many other points on both shores of the Bay and of San Pablo and Suisun Bays, there are wharves and industrial establishments of one kind or another, of which only mention can be made here.

Los Angeles.—As already observed, Los Angeles was less favored by Nature as a port than any other important locality on the Coast, and the making of a great port there is the work of its enlightened citizenship. The harbor was an open bay protected only from westerly and northerly winds. It lay wide open to an exposure of 120° toward the south except for the meager influence of Catalina Island, 18 miles in the offing. From this bay, through a long crescent-shaped bar, formerly called Rattlesnake Island, now Terminal Island, there opened inland, by a channel only 3 ft. deep at low tide, what has come to be under development the inner harbor of Los Angeles. It is really the delta of Los Angeles and San Gabriel Rivers (erratic streams characteristic of the water-courses of that section of the country) which bring down heavy loads of silt in their periods of sudden floods. The outer harbor, being exposed to storms from the southwest, required artificial protection, and this has been provided by one of the largest breakwaters in the United States, extending from Point Fermin, previously referred to, easterly, a distance of 11 000 ft., to a low-tide depth of 48 ft. The space thus enclosed, measured back from a line drawn from the end of the breakwater perpendicularly to the shore, is 960 acres, and of this more than 400 acres has a depth of over 30 ft. The anchorage is good, the kelp which formerly was a great annoyance has died out, and the harbor thus formed serves its purpose excellently well. The mean tidal range is 4.1 ft., and the extreme 10 ft.

Great reliance for port facilities, however, is being placed on the inner harbor, which is almost wholly an artificial creation. Its entrance from the outer harbor is completely sheltered by the breakwater. Beginning with 700 ft., it widens to 1 000 ft. at a point 3 000 ft. in, and then rapidly narrows to 500 ft., which width it retains to a point 7 500 ft. in from the outer end. The width then increases somewhat, and the channel terminates at a distance of 12 000 ft. from the entrance in a turning basin 1 600 ft. in diameter. From the turning basin channels lead off to the main interior docks known as the East and West Basins, respectively, which, with their future ramifications, will become the center of Los Angeles Harbor. The situation can be better grasped by reference to Plate X. The present width and depth are 400 ft. and 20 ft. to "the foot of the wharves"; thence 25.5 ft. to the turning basin. The existing Government project contemplates a depth of 30 ft. up to and including the turning basin, and two channels, 200 ft. wide and 20 ft. deep, from the turning basin to the East and West Basins.

As already stated, the harbor is almost wholly of artificial creation, and it is costing vast sums, entirely apart from docks and wharves, to arrive at a point which Nature unaided has given to most of the other ports on the Coast. Los Angeles, though liberally aided by the Federal Government, is helping herself effectively. It is a fine example of a virile civic spirit refusing to be balked by Nature in the matter of access to the sea. It will eventually rank with such ports as Hamburg and Glasgow in the extent to which Man by his energy and persistence has overcome the deficiencies of Nature.

The total development of berthing space is about 19 000 ft., most of which is directly controlled by the railroads. There is no dry dock. The wharves are principally of timber construction, but in recent years there has been a tendency to extend the use of concrete and steel, and the recent controversy between the Board of Public Works and the Board of Harbor Commissioners turned largely on the choice between concrete and creosote piling for the substructures. There is no seawall construction, unless the great breakwater be classed as such.

The local funds for port development, so far, have come entirely from bond issues, but ground rent will doubtless become a source of revenue in the near future, together with the revenues from docks which the port authorities are planning to build. Local expenditure to

date, including that of the Village of Wilmington prior to annexation to Los Angeles, and including also outstanding contracts, amounts to $625 000. The City has voted $3 000 000 in bonds, and it gave a pledge to the Cities of Wilmington and San Pedro prior to annexation that it would expend not less than $10 000 000 in port development. The expenditure by the United States on the outer and inner harbors, including outside authorizations, is:

Outer harbor	$3 078 000
Inner harbor	2 308 000
Total	$5 386 000

A great saving fact in the enormous labor of building the Harbor of Los Angeles is its close relation to the industrial development of the city. The lands into which the waterways are being dredged are admirably adapted for factory locations, and the material of excavation is being used in making the necessary fills. The whole development goes hand in hand in a way to produce the best results.

The trade of Los Angeles is active and is steadily increasing. The principal articles of commerce are oil, cement, and lumber products. The estimated short-tonnage and valuation for the calendar year 1910 are given in Table 2, the totals being 1 709 000 tons valued at $47 000 000.

As yet no public terminal or belt-railway system has been constructed in Los Angeles, but the city is taking steps to acquire one which will serve the port and connect it with the city.

San Diego.—Nature has provided for San Diego, in the first instance, what Los Angeles with the expenditure of many millions can scarcely expect ever to equal. In general exterior outline the two ports are quite similar. Coronado Beach corresponds to Terminal (old Rattlesnake) Island, Point Loma to Point Fermin, while the entrances to the inner harbors are similarly situated in both cases. The difference is that at San Diego the entrance had a very good depth and ample shelter to begin with, while the inner harbor was already dredged. At Los Angeles there was a depth of 3 ft. at the entrance and no harbor to speak of. If San Diego had been as favorably located with respect to its hinterland as Los Angeles, the natural advantages of her harbor would have been decisive, always provided a virile and wide-awake people were charged with its development.

Total		1 709 294	$47 040 588

The area of San Diego Bay inside the entrance is 24 sq. miles, of which 1 600 acres is more than 30 ft. deep; and the length of shore line is 38 miles. The original depth of 21 ft. in the entrance has been increased by the Government to 30 ft., and the present project contemplates an enlarged channel of this depth 600 ft. wide. The present berthing space amounts to 4 500 lin. ft., with a low-water depth of 22 ft. All the piers are private property, but they are subject to sequestration by the City at any time on payment of actual value. There is no dry dock and no public terminal railway. There is a marine railway for vessels up to 1 000 tons burden. The Government maintains a torpedo and submarine boat station in the harbor, together with quarantine and coaling stations. There is an important ferry service between the city and Coronado Beach.

The present sources of revenue to the port are bond sales, of which only one (for $1 000 000, voted November, 1911) has ever been au-

thorized. The total Government appropriation for the improvement of the harbor is $810 000.

The commercial business of the port is shown in Table 3, which embraces the calendar year, 1910. The totals are 400 000 tons, valued at $22 500 000.

Secondary Harbors South of the Columbia River.—Between Los Angeles and San Francisco is the important secondary harbor of San Luis Obispo; and between San Francisco and the mouth of the Columbia are the important secondary harbors of Humboldt Bay, California, and Coos Bay, Ore. These harbors, roughly speaking, divide by equal intervals the long stretch of coast line between the principal ports. At San Luis Obispo the development work by the Government is in the nature of a breakwater to afford shelter; in the two northern harbors, it consists of jetty construction designed to deepen the natural channels over the bars. In all three ports the outlay has been heavy in proportion to the commerce. Some of the most successful jetty work on the Coast is at Humboldt and Coos Bays, but it is impossible, in this paper, to make more than a passing reference to it.

The Port of Portland.—This is the only port of those considered in this paper which, in its physical characteristics, is strictly a river port. It is so far inland that tidal fluctuation, though perceptible at periods of low water, is negligible. On the other hand, it is subject to all the fluctuations of level characteristic of rivers above tidal influence, and the range between extreme high and extreme low water

is more than 30 ft. The harbor proper is not on the Columbia, but on the Willamette, about ten miles above its mouth, though, in general terms, looking to the future, the whole of both streams, from Vancouver, Wash., to Portland, may be regarded as the port of the Columbia Valley. Being a river harbor, the whole trend of its development shapes itself to that fact, and its counterpart is to be found in such a port as New Orleans rather than in those which have been considered in this paper. Quay development, parallel to the current, is the rule, instead of slips or piers projecting into the stream. While diurnal fluctuations are absent, and no provision therefor is necessary in dock construction, the great seasonal fluctuations introduce even more serious difficulties in providing for differences of level.

The length of available berthing space for deep-sea shipping is about 6 600 ft. on the east side and 8 500 ft. on the west side. The corresponding figures for river boats and the mosquito fleet are 4 725 and 6 040 ft., respectively. Railroads own 25 800 ft. of water-front on the west side and 17 150 ft. on the east side. The port has two floating dry docks, but there is no municipal or belt railway.

As is often the case with a port situated far inland on a river, the problem of providing an adequate channel to the sea is the most troublesome. With 110 miles of river channel in which a low-water depth of 10 ft. was all that could be depended on originally, and with a wild and tempestuous bar at the river mouth over which the natural depth was only 20 ft., the problem of securing and maintaining a channel was the all-important one. The work on the bar must take rank among the greatest, if not the greatest, of the kind ever constructed. It has all been done by the Government. The channel improvement from the bar to Portland has been done jointly by the Government and the port in proportions of expenditure as shown on the following page. There is at present a depth of 26 ft. at low water, and the Government is about to commence work to increase this to 30 ft. The Government now has three dredges available for the work, and the Port of Portland has two, and it is expected that this fleet will be soon increased by two more.

The port's revenues come from tax levies, bond sales, dry-dock charges, dredging, and a few minor sources. Nothing is derived from dockage, wharfage, and similar charges. The total amount of funds provided by the Government and locally is approximately as follows:

By the Government—The Columbia Bar	$10 145 000	
" " " River Channel to Portland	2 725 000	$12 870 000
By the Port of Portland, approximately		3 700 000
By the Portland Dock Commission (bonds voted, but not yet expended)		2 500 000
Total		$19 070 000

As already stated, Portland is admirably situated on the land side to develop a large port business, but the channel difficulties between the port and the sea somewhat offset this advantage. The commerce, nevertheless, is large and varied, as will be seen from Table 4, the totals being:

Exports and imports	415 522	short tons, valued at	$8 451 414
Domestic	2 025 434	" " " "	31 313 990
Local	5 393 317	" " " "	25 116 602
Totals	7 834 273	short tons, valued at	$64 882 006

Grays Harbor.—The most important of the secondary harbors of the Coast is Grays Harbor, forty-five miles north of the Columbia. It is a pear-shaped body of water nearly 100 sq. miles in area. It is really a vast mud flat, much of it being bare at low tide, and the channel to the upper portion where the Towns of Hoquiam, Aberdeen, and Montesano are located, has to be maintained by dredging. Extensive jetty work has been built and is now in progress to develop a channel over the bar. The port has three railroads. Its importance depends primarily on its lumber trade, and it is the largest cargo lumber port in the world. The Government has appropriated about $2 400 000 for improvement of the harbor and bar. The commerce for 1910 amounted to 670 000 tons, valued at $6 000 000 of which more than 80% represented lumber products.

Puget Sound.—In their physical characteristics, the Puget Sound ports are much alike, the water being very deep, anchorage ground scarce owing to depth, the tidal range large, and the teredo active. As a rule, there is absolute freedom from obstructions in the channels of approach. Pilots and tugboats (except the latter for sail boats)

are unnecessary, though pilotage on the larger vessels is customary. In all cases the streams leading into the harbors from the Cascades bear heavy loads of silt, and have filled up the estuaries for long distances. The tide flats thus built up have proven an invaluable asset, for they have made up to some extent the deficiency of low flat lands necessary for industries and terminal facilities. South of Deception Pass rock is scarce, but north of that point it outcrops everywhere, and in some instances forms dangerous obstructions. The whole

conformation of the Puget Sound country is the result of glacial action, and many of the lakes and bays are simply the gouged out paths of glaciers, while the shores are masses of the most heterogenous material. So irregular and broken with indentations and islands is the Sound area that tidal currents and stages are wholly irregular. Tidal predictions are possible only as a result of long observation, and are stated in the Government tables in terms of retardation behind the Port Townsend prediction.

With this general reference to the ports of Puget Sound, a somewhat detailed description will be given of its principal port, Seattle, Wash. Seattle Harbor means primarily Elliott Bay, a not very large indentation into the east shore of the Sound. Between its extreme limits, West Point and Alkali Point, the pier-head line is 10 miles long. The really practical limits of the harbor, as far as the near future is concerned, may better be taken as Duwamish Head and the southern point of Magnolia Bluff, directly opposite. Within the line joining these points is Elliott Bay proper, quite similar in contour (though slightly smaller in area) to Commencement Bay, on which the port of Tacoma is situated. The area of Elliott Bay, as thus limited, is 4.3 sq. miles, and its shore line (pier-head line), not counting slips and waterways, is 6.5 miles. Over this entire area there is ample depth for the heaviest shipping. There is never any ice or rough weather to disturb deep-sea vessels, though southwest winds disturb small vessels in the reach south of Smith's Cove, as north winds do those on the south side of the harbor. The tidal currents are too slight to be drawbacks of any moment.

The water-front development is most pronounced along that portion where the city began its growth. For upward of a mile the entire frontage is in active use. There are some important piers, which, as a rule, are run out at very oblique angles with the shore in order to secure the necessary length without getting out to prohibitory depths. At the north is the important pier of the Great Northern Railway, and near it a still unimproved waterway, Smith's Cove, 1 mile long and 400 ft. wide, which is destined to important use in the growth of that part of the city. On the south side of the harbor, the delta of the Duwamish River has been filled in, except for the reservation of two waterways, the East and the West, inclosing a tract of land popularly known as Harbor Island, from which great things are expected in

the future growth of the city. As the plan will finally work out, East Waterway will be practically a slip, about 1 mile long and 750 ft. wide, with slips and quays on the two sides. The east side of the Waterway is really a part of the main water-front. West Waterway will be 900 ft. wide and will be the outlet of the Duwamish River.

The valley of the Duwamish furnishes the single large tract of bottom land directly adjacent to the harbor, and it must naturally develop into an important industrial center. Plans are perfected and well under way, with a large part of the funds already provided, for straightening the river and excavating a channel 4 miles up the valley to a bottom width of 150 ft. and a low-water depth of 16 ft. The utility of this work in the industrial development of the city is bound to be great.

Such is what may be termed Seattle's outer, or tidal, harbor, with a perimeter, including the three main waterways, of 12.5 miles east of Magnolia Bluff and Duwamish Head, and this is susceptible of almost indefinite extension by pier and slip construction. Every foot of this frontage is served, or readily capable of being served, by railroads, and the possibilities of expansion are all that are likely to be required for a century to come. The extent of existing wharf construction is such as to give about 14 500 lin. ft. of berthing space.

In addition to this magnificent gift of Nature, Seattle has another absolutely unique among the sea ports of the world—what may be called her inner harbor, soon to be opened to the commerce of the seas. The glaciers, in carving out the picturesque topography of this city, left two remarkable troughs or basins, bordered by hills from 200 to 500 ft. high. These basins are just enough above sea level to keep out the tides, and their waters, therefore, are fresh. Their own levels differ by only about 10 ft., the larger lake being the higher. Nearly all the area of both lakes is deep enough for the heaviest shipping; and all that Nature has left undone to make it accessible from the sea is to provide a lock and an artificial channel from Lake Union to the Sound, and a channel between the lakes. This work is being done by the Government and the local community. A channel, 100 ft. wide on the bottom and 36 ft. deep, will be provided, with two parallel locks, one 825 ft. long and 80 ft. wide, interior dimensions, and the other 150 ft. long and 30 ft. wide, for small boats. Salmon Bay, a tidal slough between Lake Union and the Sound, will be raised by the lock

and dam to the level of Lake Union, and Lake Washington will be lowered to the same level, thus giving a uniform level from the lock to the remotest corners of Lake Washington. The canal right of way will admit of double the present proposed width, should commerce ever demand it. The bridges will have 30 ft. clearance, except one railroad bridge which will remain open when not in use. The fluctuation of level will not exceed 2 ft. The lakes are free from obstructions and do not freeze. Incidentally, the lowering of Lake Washington will absorb the floods of its water-shed and of Cedar River, and thus furnish a needed relief to the floods of the Duwamish, besides draining extensive marsh areas around the shore and making them available for industrial use.

There has been much speculation as to the value of this proposed improvement work. On the face of it, it would seem to furnish one of the most ideal opportunities that any port ever had. Think what it would mean to Los Angeles, if, instead of spending tens of millions for a narrow and restricted tidal harbor, she could, at an expense of $4 000 000 or $5 000 000, open up 40 sq. miles of fresh, deep water with a shore line of 100 miles. But at Seattle it does not mean what it would at Los Angeles. The rare perfection of the harbor of Elliott Bay places even this wonderful fresh-water harbor at a discount, as far as over-seas shipping is concerned. Still, its incomparable advantages are bound to tell. Absolute freedom from tidal fluctuation and currents, freedom from the teredo and, therefore, assurance of permanence in subaqueous timber construction, the beneficial effect of fresh water on the hulls of vessels, and the access which the lakes give to all sections of this district, are advantages which will not go unused. The first and immediate effect will be on small-boat traffic, lighterage, and the like, and a complete readjustment of this class of traffic may surely be expected. Salmon Bay and Lake Union will become great docks in the very heart of the city, while Lake Washington will offer thousands of acres of shore lands adapted to manufacturing. Gradually, larger shipping will follow, particularly in quest of lumber cargoes. Already inquiries are being made for sites for the fishermen's fleet and the yachting and motor-boat fleets. The large number of vessels which ply these northern waters, but which lie idle in winter, will find ideal refuge here. It will be strange if even the Navy Department does not take advantage of these fresh,

sheltered waters to lay up such of its vessels on this Coast as remain for a time out of commission. The ship-building industry of the entire Northwest ought to center at Seattle. Therefore, in spite of the unrivaled attractions of Elliott Bay, Seattle's future fresh-water harbor seems bound to become a priceless adjunct to the city's growth.

The natural perfection of Seattle's outer harbor is in no way better shown than by the remarkable fact—probably unique among American harbors—that no Federal appropriation has ever been made for its improvement. The only expenditure, not by direct private initiative, has been the development of the East and West Waterways and Harbor Island, and this has cost, in round numbers, $3 000 000.

The development of the inner harbor will have cost, when completed, exclusive of bridges and other crossings, approximately $4 250 000, of which the Government will have contributed about $2 750 000, and local agencies (State and County) about $1 500 000.

On the west shore of the Sound, directly opposite Seattle, and concealed in a deep inlet, with narrow, tortuous approaches, yet safe for the heaviest ships and protected by strong defenses, is one of the most interesting spots in the city. It is the Naval Station of the North Pacific Coast, destined to expansion, because of its superior advantages, into one of the greatest, if not the greatest, in the United States. It is mentioned in this connection with particular reference to its dry-dock facilities, which are often utilized by commercial vessels. There are other dry docks on the Sound, particularly the Heffernan Dock on East Waterway, Seattle, but no others of a capacity for docking the largest vessels.

Tacoma, the second port in importance on the Sound, is 30 miles south of Seattle, on Commencement Bay, similar in form and position to Elliott Bay. The tide flats have been built up by deposits from the Puyallup River, as those of Elliott Bay were by the Duwamish. Two waterways have been laid out, and one of them, the City Waterway, has been excavated into these flats. An atiempt was made to excavate the other—the Puyallup Waterway—but the excessive deposits of silt brought down by the river (greatly augmented since 1906 by the bodily diversion to the Puyallup, through natural causes, of the White River from its former outlet into the Duwamish) made it impossible to secure or maintain the desired depth. The principal dockage facilities consist of a long quay dock on the west

side of the Bay, the City Waterway, and a slip excavated by the Chicago, Milwaukee and Puget Sound Railroad for its own use. The aggregate berthing space is 14 500 lin. ft. The business of the port has been greatly promoted by the location there of the principal shipping facilities of two important railway systems, and it now crowds closely on that of Seattle.

There are five other ports on the Sound worthy of particular note. These are Olympia, at the extreme southern end, and formerly important as the first point where travel from the Columbia touched the Sound—a very important circumstance before there were any good roads or railroads in the country. Everett is 30 miles north of Seattle, and is at the point where the Great Northern Railway reaches tidewater. It lies at the mouth of the Snohomish River, and is a port of considerable importance. Bellingham is another of the important secondary ports, and the farthest north of those considered in the paper. Anacortes is a flourishing port on Fidalgo Island, reached by a branch line of the Great Northern. Port Townsend is the chief port on the Olympic Peninsula, and has a peculiar importance quite apart from its commercial business, which is slight. It stands at the gateway to Puget Sound, where the great defenses are, it is the headquarters of the Customs District of the Sound, the location of the Quarantine Station and Marine Hospital, the base for nearly all marine reckonings pertaining to the Sound, and, in other respects, an artificially important port. Its location is such, however, that, despite its excellent harbor, there is no reason to expect that it will ever develop an important commerce of its own.

The expenditures, in round numbers, already made or authorized, by the Government in improving the several harbors of the Sound, are as follows. There have also been local expenditures in most of them, but these amounts, except in the case of Seattle, are difficult to determine.

Olympia	$160 000
Tacoma	320 000
Seattle (Canal)	2 750 000
Everett	700 000
Bellingham	60 000
Total	$3 990 000

The commercial statistics of the Sound ports are given in Table 5, the totals being as follows:

* Compiled from the Harbor Master's Report.
† Computed in part.

Vancouver, B. C.—The chief Canadian port, Vancouver, B. C., is in the vicinity of the mouth of the Great Fraser River, though actually not in the valley of that stream. More fortunate than Portland, Vancouver has been able to flank a troublesome river with its floods and shoals while still taking advantage of its valley on its rail route through the mountains. The port has been built in a land-locked bay called Burrard Inlet, surrounded on nearly all sides by towering hills which give the location a most beautiful setting. The area of the entire inlet inside the entrance is 23.6 miles, with a shore line of upward of 50 miles; but the port proper, as at present developed, utilizes only a small fraction of this. The shores are mainly of rock formation; the tidal range is 11 ft. mean and 16.4 ft. extreme. There is no ice, and the harbor is perfectly sheltered and has good anchorage.

The port facilities, as developed so far, are mainly on the south side of the east 5.5 miles of the Inlet. The portion of the Inlet comprising the harbor is about 1½ miles in width, connecting with the Gulf of Georgia on the west and the remainder of the Inlet on the east by two narrow channels designated First and Second Narrows, respectively. These Narrows were formed by the deposit of gravel, sand, and small boulders brought down by mountain streams on the north side of the Inlet and deposited in the shape of extensive bars. The Narrows are deep, but only about 500 ft. in width. Navigation through them is seriously handicapped by strong tidal currents, which, at the First Narrows, reach as high as 8 knots per hour at spring tide, and are such a menace to navigation that the Dominion Government has undertaken to widen the entrance by dredging to 1 200 ft. The improvement will not affect the current perceptibly, but will give more leeway for the navigation of ships. In most portions of the harbor the tidal currents interfere seriously with the berthing of ships.

New Westminster.—Ten miles south of Vancouver on the Fraser River, and 16 miles above its mouth, is the Town of New Westminster, which is taking active steps to develop port facilities for deep-sea shipping. The Fraser is a large river, not unlike the Columbia, but with a channel less difficult to improve and maintain. The ordinary tidal range at the port is only 5 ft., but the range between high and low water in the river is 14 ft. Reference will be made in another place to the steps being taken to develop this port.

Victoria.—This has been an important port in the past, and is so still, though its commercial business is not large. It is the chief port of Vancouver Island and on it is located the capital of British Columbia. The commercial port is on a small land-locked inlet with bald rocky shores. A few miles to the west is the celebrated Esquimault, an excellent port, strongly defended, and, prior to 1905, the headquarters of the British North Pacific Naval Squadron.

Prince Rupert.—This harbor is on an island within a well-sheltered inlet on the "inside passage" to Alaska, a little north of the mouth of Skeena River, the valley of which stream is the route of the western division of the railroad. The area of the entire inlet in front of and back of the island is about 27 sq. miles, and that of the shore line is about 80 miles. The tidal range is large, the maximum being 27 ft. and the mean about 14. The harbor is perfectly sheltered and is free from ice.

The port is very new, and its development has only begun. It now has about 2 700 ft. of berthing space, of which 600 ft. belongs to the Provincial Government and the rest to the Grand Trunk Pacific. It has a sectional dry dock 600 ft. long. The newness of the port and the fact that rail connection east is not yet opened, give little as yet for comparison with other ports. Its record lies all in the future.

The promoters of this important terminal enterprise adopted the almost unique course in civic growth of laying out their city before its occupancy by settlers began. It has been scientifically planned by artists of national reputation, and, if the plans are followed, it will be spared the disfiguration characteristic of most American cities.

III.—Notable Engineering Works.

The development of the ports of the Pacific has evolved a great range of engineering problems, some of which are of unusual magnitude, difficulty, and cost. A brief reference to the more important will be given. They include:

(1) Rock removal.
(2) Breakwater construction.
(3) Jetty construction.
(4) Lock construction.
(5) Dredging.
(6) Sea-wall and pier construction.

Rock Removal.—This class of work has been confined mainly to San Francisco Harbor and to ports north of the Strait of Juan de Fuca. In San Francisco the removals have been almost entirely of isolated rocks, some of which did not originally come to the surface. Another example of sunken rock removal is that in Roche Harbor, San Juan Island, Washington. Ledge rock removal has been and is being extensively carried on in British Columbia ports.

The various rock removals in the vicinity of San Francisco include the following: Blossom Rock, directly in the channel leading from Golden Gate into the harbor; Rincon Rock, now within the pier-head line and covered with a wharf; Arch Rock; the two Shag rocks; Centissima Rock, in the Bonita Channel just outside the Golden Gate; and Noonday Rock, 33 miles at sea opposite the harbor entrance. Of these removals, Blossom Rock was most important. The method of removal originated with General Alexander of the U. S. Corps of Engineers, and the plans were very carefully worked out. They included the building of a coffer-dam on top of the rock, which rose to within 6 ft. of low water, unwatering the coffer-dam, sinking a shaft into the bed of the rock, and then excavating an immense chamber into which was to be placed the explosive. It was expected that the strong tidal currents would remove most of the shattered rock, and that the remainder would be scraped into deep water. The contractor sank and securely fastened to the rock a timber crib which served the double purpose of a platform and a protection to an iron tube 6 ft. in diameter and 14 ft. high, which was placed through the center of the crib. A watertight connection was effected with the rock by the use of a liberal quantity of cement. The tube was then unwatered and a shaft sunk to Reference 30 ft. below low water. During the progress of sinking the shaft so much leakage occurred through the rock that it was found expedient at two different times to telescope smaller tubes into the shaft and secure water-tightness by cementing the annular space between the rock sides of the shaft and the tubes. At a depth of 14.5 ft. into the rock the leakage became nominal, and the chamber was then easily excavated. The floor of the chamber was at Reference 31.5 ft. below low tide, the axes being 135 and 55 ft., respectively. The roof conformed to the general shape of the surface of the rock and had a thickness varying between 14 and 18 ft. Four stone pillars were left at the shaft, and timber supports were distributed throughout the chamber.

The explosive used was nitrate of soda, of which 4 300 lb. was placed in 38 wooden, ale barrels and in 7 old, boiler-iron tanks. The barrels were distributed around the edge of the chamber, and the tanks were scattered at about equal intervals on the floor. The blast took place on April 23d, 1870. The explosion was a pronounced success, but the chamber had not been made large enough to engulf the broken-up roof, and the hope that the current would remove the débris was not realized. The subsequent removal of débris, by scraping the blasting, cost as much as all the previous operations, up to and including the blast.

A contract for removing an additional 6 ft. from Blossom Rock in order to give a 30-ft. depth at low water, was let in November, 1902, for $45 142. The quantity of rock to be moved was 4 630 cu. yd. The contractor drilled a few holes, but abandoned the process for surface blasting and dredging the broken-up rock into deep water. The official reports do not give the reasons for the adoption of this method, but it may be conjectured that at least one reason was the shattered state of the rock due to former operations.

On January 2d, 1863, the clipper ship, *Noonday*, was wrecked on an uncharted rock in the Pacific opposite Golden Gate, and a demand arose for its removal. A search for the rock was made by the U. S. Coast Survey, and a pinnacle 5 ft. square on top, with 19½ ft. of water over it at low tide, was found and buoyed. In 1874 a contract was awarded to Mr. Edward Moore, of Portland, Me., for removing the menace to navigation, at an upset price of $20 000. Being in the open sea and subject to adverse weather conditions, the work entailed more hazard than similar work in a sheltered harbor. At first it was proposed to sink an encircling chain to a depth of 50 or 55 ft., at low tide, to which were to be attached packages of nitro-glycerine, but when operations were commenced the diver discovered below the required depth a cavity 10 ft. deep in one side of the rock. The plan was altered immediately to put the entire charge of explosive in the cavity. The charge was fired May 7th, 1875, and proved an entire success.

The method of subaqueous rock removal known as "bulldozing" apparently had its origin in San Francisco. It consists simply in placing high explosives in contact with rock surface and exploding it there without drilling or tamping. The shattered surface is then scraped away and the process repeated. Although the use of explosives

by this method is excessive, the expense of drilling is saved. The results, so far, however, do not seem to commend the method on the score of either efficiency or cost. In 1907-08 a submerged rock at the entrance to Roche Harbor, Puget Sound, was removed by this method. The volume of the portion to be removed was 1 500 cu. yd., and the contract price was $23 460; but the work probably cost the contractor more than this. The official Government report says that "the method, as applied in this case, did not prove satisfactory, and the contractors state that if they had the work to do over they would drill the rock."

In the work in San Francisco Bay, where the masses to be removed were considerable, the contract price per cubic yard was less than $10; as, for example, the work on Rincon Rock, before it was abandoned, cost $9.06 per cu. yd. for the removal of 4 357 cu. yd.; and the cost of removing 32 000 cu. yd. on the Shag and Arch Rocks was $7.93 per cu. yd.

The subaqueous basaltic rock excavation at the eastern end of Victoria Harbor was performed by the drilling method. The single drill was mounted on a platform float that could be raised clear of high tide by steam power spuds. Steam was furnished from boilers on a barge. Thirty-two holes were drilled at one setting of the raised platform. The holes were 2.5 in. in diameter, drilled to a depth of 2.5 ft. below grade (20 ft. at low water), and spaced 3 by 3 ft. The actual cost for drilling and blasting only was $6.17 per cu. yd., without interest, depreciation, or plant renewal.

The blasting in Vancouver Harbor will be a more delicate operation, as it will be carried on in close proximity to constructed piers. Holes 3 in. in diameter, spaced 5 by 5½ ft. centers, will be drilled to a depth of 3 ft. below the required grade line (36 ft. at low tide), and shot off in series. It is expected that 1½ lb. of dynamite per foot of hole will be used. The estimated cost for drilling and blasting is $5.60 per cu. yd. Dredging the broken rock will approximate an additional $1 per cu. yd. The Vancouver rock is a sloping sandstone ledge overlaid with from 3 to 7 ft. of gravel, hardpan, and disintegrated sand rock.

Breakwater Construction.—As an example of breakwater construction strictly speaking—that is, work done for the primary purpose of protecting anchorage areas or harbor entrances from ocean storms—the San Pedro Breakwater at Port Los Angeles is the most important

on the Coast. As finally constructed, it has a length of 11 000 ft. and extends first on a curve and then in a straight line easterly from Point Fermin, thus giving shelter against south and southwest exposure and in particular completely protecting the entrance to the inner harbor which is behind the inner end of the structure. The breakwater is built entirely of rock, except a concrete block 40 ft. square and 20 ft. high at the outer end. The base of this block is 3 ft. below the low-water plane. The construction of the breakwater was effected from a double trestle carrying tracks of standard gauge. The substructure was built to the elevation of low water and consists of a central portion of stone weighing 1 ton or less, with larger stones on the side slopes. The superstructure is 38 ft. wide at the bottom and 20 ft. wide at the top (14 ft. above low water), with stepped sides of huge blocks of stone placed by cranes. On the ocean side the stones weigh 16 000 lb. or more; on the harbor side, 6 000 lb. or more. The space between the sides is compactly filled with rock of all sizes, and the top is finished with large stones. The side blocks have been placed with such care that they seldom depart more than 6 in. from exact position.

Jetty Construction.—As used in this connection, the term, jetty, applies to a structure designed to serve the primary purpose of concentrating and directing ocean currents to develop scouring effects over shoal bars, and the secondary purpose of protecting such crossing from storms, as far as their location for the first purpose will permit. They are, therefore, a combination of training dike and breakwater. There are four prominent examples on that portion of the Pacific Coast considered in this paper, all of which are north of San Francisco, namely, Humboldt Bay, Coos Bay, the Columbia River, and Grays Harbor. There are also numerous minor examples, as at San Diego, Los Angeles, and Oakland. The principles involved are essentially the same in all, though varied in application, of course, to suit the conditions of each case. The Columbia Jetty far exceeds any of the others in importance and in the magnitude of the work, and the description will be limited to this one example.

As originally projected, the jetty extends in a west-by-northwest direction 4½ miles from the east side of Point Adams across Clatsop Spit and out to deep water. The jetty was to be built of large size stone on a brush mattress and raised to the level of low tide. Later,

the project was changed to raise it to high tide, and four groins were to be built from the north side to arrest scour. Work was begun in 1885 under an estimate of $3 710 000, and was completed ten years later at half the estimate. The depth over the bar had increased, in the meanwhile, from 21 to 31 ft., and the work seemed to have accomplished its purpose perfectly.

Unfortunately, the bar began rebuilding itself, the depths shoaled, and several years later there was only the original depth of 21 ft., and it seemed to be necessary to start all over. A new project was adopted, extending the jetty 3 miles farther, or somewhat beyond the longitude of Cape Disappointment on the north shore. The work was to be supplemented by dredging over the bar. This extension is now nearing completion and has resulted in a present depth of from 25 to 27 ft. A permanent depth of 30 ft. is sought.

This work, it is scarcely necessary to remark, is probably the largest and most difficult of its kind ever attempted, and has evolved some of the most ingenious and elaborate methods for overcoming difficulties in the whole range of engineering. The two great obstacles to be overcome in the execution of the work are the storms and the teredo, and it is the fact of the storm that gives the teredo its "inning." The roughness of the sea precludes the use of barges for dumping rock, thus necessitating a trestle, and the trestle piling is the particular delight of the teredo, which puts it out of commission in from 10 to 20 months. The rebuilding of the trestle on the rock of the jetty, which has been repeatedly necessary, and the methods resorted to in order to arrest the work of the teredo, have taxed the resources of the engineers to the utmost.

The jetty itself, as now being built, consists of a bed course of small rock as a substitute for brush mattress, it being found impracticable to use the mattress beyond the shoal depths of Clatsop Spit. On the foundation so provided heavier rock is deposited, and the whole is covered on the seaward slope with very heavy rock ranging in weight from 6 to 16 tons per piece. Even these enormous masses are displaced by the storms, and the embankment is progressively shaken down during each winter season.

The long continuance of this work has evolved a very efficient system for its management—one which it would be difficult perhaps to improve on, because every feature is the result of actual experience.

The pile-driver is a study in itself. The support of the pile trestle on its bed of huge boulders, the arrangement of the movable car beds and of the cars themselves for the quick handling of the rock, the systematic organization of the work, which moves with the regularity of clockwork, and, finally, the rational division of the work between the contract and day-labor systems, assigning to each the share it is best adapted to carry out—all combine to make this great work well worthy the attention of the engineers of the United States.*

Lock Construction.—Locks are an important adjunct of port development in English ports, where they are applied to overcome the drawback of excessive tidal fluctuation. They are nowhere so used on the American Continent, but they are about to be used in the Port of Seattle for the purpose of effecting a very large extension of the harbor, as previously explained. The lock which separates the main harbor from the Sound is located at the outlet of Salmon Bay, 1 mile inland from deep water, at a sheltered and easily defended point called the Narrows.

The lock is really a double structure, comprising a large chamber for heavy shipping, log rafts, etc., and a small chamber for the use of the mosquito fleet. It is certain that small-boat traffic through the canal will be large, and the plans provide a small, quick-operating lock for its use so as to avoid the slower and more expensive operations of the larger lock. It is considered that this provision will prove one of the most useful features of the canal. A similar arrangement is provided on the Manchester Ship Canal, in England. It seems to the writer that if the Panama Canal plans are open to any important criticism it is in not providing a flight of smaller locks. To operate those immense locks for the passage of small boats cannot fail to prove a great waste of energy and time and possibly an interference with traffic.

Returning to the Lake Washington Canal lock: a description of that structure, which is now in process of erection, will be given. The larger lock will be 825 ft. long and 80 ft. wide, or large enough to admit without breaking the large log rafts which are certain to constitute an important part of the traffic. The sill of the lower gate will be at Reference 25 ft. below extreme low tide, 29 ft. below

* Those who desire a detailed description are referred to an article on page 109 of *Engineering News* of July 30th, 1908.

mean lower low tide, and 35.67 ft. below mean sea level. The sill to the upper gates will be 36 ft. below the low-water level of the canal and 38 ft. below the high-water level. The lock will be supplied with intermediate gates which may be used to divide the chamber into lengths of 350 and 475 ft., respectively, for convenience and economy of water in the passage of shorter vessels. There will be guard gates at the two entrances, and a movable dam at the upper end for emergencies arising from accidents. The small lock will be built on the south side of the large one, and will be 150 ft. by 30 ft. and 16 ft. deep over the miter sills.

The lock walls will be of mass concrete, gravity section, straight-front face, with a toe projecting into the lock chamber, and stepped back. The filling culverts will be of large elliptical section, running the full length of both walls, and connecting with the chamber by numerous side culverts at right angles to the axis of the lock. The controlling culvert gates will be of the Stoney type in the large lock and of some form of cylindrical balanced valves in the small one. It is expected to fill or empty the chamber of the big lock in 8 min.

The lock gates will be of steel, with parallel straight faces except near the front and back edges. All gates will be provided with air chambers to relieve the strain on anchorages and to permit of floating the guard gates out of position for repairs and painting. The main gates will be reached by closing the guard gates and pumping out the chamber.

The most interesting detail of the lock, and the one on which there will be most divergence of opinion, is the lock floor. The ever-recurring debatable question in lock construction arises here—shall the floor be made strong enough to resist an upward hydrostatic pressure, or shall it be a mere pavement to protect the underlying material from scour, reliance being placed on the cut-off walls to prevent leakage? The lock floor is not yet determined on, the decision being held in abeyance until an examination can be made of the foundation material, when the lock coffer-dam is unwatered.

The lock when completed will be exceeded in size, on the American Continent, by the Panama Lock only; it will be on a par with the new Sault Lock, greater in some particulars, but less in others, and will entail the solution of more difficult engineering problems than the one at the Sault. It will rank with the greatest European locks, and take

its place in shipping and engineering circles as one of the very prominent structures of its class.

The principal data relating to the canal are as follows:

Extreme low tide in Puget Sound	Reference	0
Mean lower low tide, " "	"	4
Mean low tide, " "	"	6.89
Mean sea level, " "	"	10.67
Mean high tide, " "	"	14.50
Mean higher high tide, " "	"	15.23
Extreme high tide, " "	"	18
Present level of Lake Union	"	25
" low-water level in Lake Washington	"	33
" high-water level in Lake Washington	"	38
Proposed low-water level in canal	"	24
" high- " " " "	"	26
Length of large lock between quoins	825	ft.
Width " " " " "	80	"
Depth on lower sill at extreme low tide	25	"
" " " " " mean sea level	35.67	"
" " upper " " low water	36.00	"
" " " " " high "	38.00	"
Lift of lock from extreme low tide to high water	26.00	"
" " " " " high " " low "	6.00	"
Depth of water in main body of Lake Union	40.00	"
" " " " Lake Washington	40.00 to 200.00	"
Length of canal from deep water in Puget Sound to deep water in Lake Washington	8.00	miles

Dredging.—Pacific Coast ports are no exception to the almost universal need of dredging operations to secure full navigable depths in channels and docks. Seattle and Tacoma come nearest to being exceptions, but even in these ports waterways have been created artificially by dredging. At Seattle, for example, a great deal of work has been done in reclaiming the tide flats of the Duwamish Delta, and creating artificial waterways there, while now extensive operations are in progress in excavating the Duwamish Waterway and the Lake

Washington Canal. None of these operations was necessary, however, in the main harbor, which everywhere had ample depth. At the other extreme is Los Angeles, where the harbor itself is being built almost entirely from excavation. Differing from either of these is Portland, where the channel of approach to the harbor requires very extensive and continuous dredging, not only for original deepening, but for maintenance of depth. San Diego, Oakland, San Pablo Bay, Grays Harbor, and several of the ports in Puget Sound, have been thus improved by excavation. As a rule, this work has been done with Government appropriations, though in some ports, such as Portland, and, more recently, Los Angeles and Seattle, local funds are being contributed to the work. Now that the reclamation of tide flats is becoming so profitable an enterprise, dredging will be resorted to more than ever, the operation serving the double purpose of excavating slips and channels and filling the abutting lands.

The plant used in this work embraces every practical variety of dredging machinery, from the heaviest sea-going hopper or suction dredge to ordinary steam shovels loaded on scows. The Pacific Coast dredging fleet, taken as a whole, both publicly and privately owned, is a formidable one. In the more localized operations electricity is sometimes used as the motive power. Oil is used extensively as fuel. All varieties of excavation are encountered, from the lightest alluvium to indurated clays that border closely on soft rock. In California great use is made of the clam-shell dredge, with enormously long booms, designed for levee building on the Lower Sacramento and San Joaquin Rivers, and on some tributaries of the larger stream great hydraulic dredges are used to glean out the particles of gold which the improvident miner wasted as he sluiced down the auriferous hillsides a generation and more ago.

It is needless to describe in any detail these dredging operations, for they present nothing sufficiently characteristic to mark them from those with which engineers are familiar in the East. It will be of interest, however, to refer briefly to two of the dredges. The latest sea-going hopper dredge built by the United States Government is the *Chinook*, for use on the Columbia River Bar. It is a converted transport, 445 ft. long, of 5 590 gross tonnage. The transformation was made in 1902, but many alterations and repairs have been made since that time. The dredge has two 20-in. pumps and two

bins of a total capacity of 3 600 cu. yd. Its performance during the fiscal year ending June 30th, 1911, was:

Days worked	160
Cubic yards excavated	722 431
Total operating cost	$58 943.15
Cost per cubic yard	$0.08159

Probably the most effective dredging plant for all purposes on the Pacific Coast is the *Frühling,* built in Germany in 1906 at a cost of $275 000, exclusive of duty and cost of steaming to British Columbia. It is the property of the Department of Public Works, of Canada, and operates on the Fraser River. It is of the "Frühling" scraper suction type, elevating material by a pair of 16-in. centrifugal pumps through pipes and delivering to hoppers inside the hull. It is a sea-going dredge, of steel construction throughout, and is self-propelled by twin screws. Its length between perpendiculars is 187 ft.; the extreme beam is 34.5 ft., the draft, loaded, about 14 ft., and the hopper capacity at this draft, 800 cu. yd. Its performance from April 1st, 1910, to March 31st, 1911, was as follows:

Hours worked	862.5
Cubic yards excavated	924 800
Average cubic yards per hour	1 072
Average cubic yards per day of 9 hours, including all delays	3 000
Maintenance cost	$37 948.10
Repairs cost	8 835.58
Total cost	46 783.68
Cost per cubic yard	0.0505

Sea-Wall and Pier Construction.—As stated elsewhere in this paper, there has been very little massive sea-wall construction in the ports of this Coast, San Francisco being the only considerable exception. The earlier type of cross-section adopted there consisted of a loose rock core faced with heavy stone paving. More recently, reinforced concrete on a rubble and pile foundation is being used. There have been some attempts to build vertical concrete walls in Seattle Harbor, but the excessive cost and the injurious effect of the sea-water on the concrete have not led to their repetition. Where the tidal range

is as great as it is at Seattle, a sea wall has to stand above the foundation fully 60 ft., and the cost of a wall built on any adequate plan is almost certain to exceed $300 per lin. ft. This condition has led to various schemes for supporting the land face without the cost of a wall. Creosote or concrete piling, concrete piers, or cylinders supporting a platform back for a distance of from 30 to 60 ft., afford an opportunity to carry the slope up at an angle which can be made stable at moderate expense with brush or rock paving or a combination of both. Much thought is now being given to this problem, and a type of construction will doubtless be evolved which will be a fair compromise between cost and durability.

The same difficulties enter the problem of pier construction. The method heretofore in force along the Coast has been mainly that of wooden piling and timber superstructures—in fact, the simplest form of practical construction. Latterly, there has been a strong wave of sentiment for "permanent" work, which means reinforced concrete substructures and fire-proof superstructures. Conservative considerations, however, are going to place a strict limit on the application of this method, and timber construction, with creosoted piling, where subject to the ravages of the teredo, will continue to be the rule. Any extensive adaptation of the costly masonry construction of European ports is not to be expected.

The serious problem, of course, is that of the substructure. Ordinary piling will not last a year in these waters. Creosoted piling, if of superior quality, is safe for fifteen years; but the lack of stability in very deep water, where depth necessary for draft is augmented by a high tidal range; the great cost of replacement, requiring, as it often does, the removal of shed roofs and the suspension of business; the increased danger from incendiarism, rats, theft, etc., and draft in conflagration, all due to the open work underneath, are very serious drawbacks which go far to offset the advantages of less cost. The most practical compromise with timber construction would seem to be creosoted piling under wharf platforms with protected slopes to bulkheads on line with the shed walls, thus giving solid fills under the sheds. Concrete piling or concrete cylindrical piers, such as are used in the splendid new Government piers at Fort Mason, San Francisco Bay, are, of course, more to be desired for this exterior work. A brief description will be given of two docks, one a fine example of

typical timber construction and the other an original plan of solving the difficulties referred to.

The Grand Trunk Pacific Dock, at the foot of Madison Street, Seattle, is a recent structure. It is 625 ft. long, 128 ft. wide, and is supported entirely on creosoted piles, the length of the bearing piles varying from 55 to 90 ft., with bracing piles as long as 110 ft. The bents are 10 ft. apart, and the piles in the bents are spaced from 6 ft. centers at the inner end to 3 ft. at the center. The capping and floor systems are of very thorough construction, and the dock appears to have thorough stability, notwithstanding the great depth of water in which it stands.

The main shed is 90 ft. wide, with a platform 8 ft. wide on the south side and 16 ft. on the north, the latter carrying a railroad track. There are five adjustable slips on each side and one at the outer end worked by worm gear. The fender piles are of tight-bark fir, and are driven two at every bent and fastened to 12 by 12-in. stringers with ¾-in. straps. At the outer end they are spaced 3 ft. apart, and clusters of seven piles are driven at the outer corners. The timber used in construction was 241 775 lin. ft. of creosoted piling, 71 000 ft. B. M. of creosoted bracing, and 1 113 000 ft. B. M. of other lumber. In its finish, offices, equipment, and general lay-out, it is the best example of dock construction on Puget Sound.

The second of the docks selected for a brief description here is the Great Northern Dock, at Vancouver, B. C. It was designed by A. W. Münster, M. Am. Soc. C. E. The pier is 450 ft. long and 293 ft. wide, with a berthing space of 30-ft. depth at low water on each side, and with two sheds, 403 by 102 ft. Between the buildings is a space 41 ft. wide. The distinctive feature of the structure is a cantilever platform supported on cylindrical concrete piers, which themselves rest on a sandstone ledge. These piers are 4.5 ft. in diameter, with a base enlarged to 10 ft. The foundation is carried down into the hardpan or sandstone ledge to a minimum depth of 3 ft. below the bottom of the slip. The piers will have an average height of 52 ft. On top of them will be placed a longitudinal concrete girder, 3 ft. wide and about 7 ft. in depth, which will carry the transverse girders forming the immediate support of the floor slab, which are placed 12.5 ft. center to center. The transverse girders are from 2 to 3 ft. wide, 6 ft. deep, and 51 ft. long. They will project 16.5 ft. beyond the line of

the piers and, acting as a cantilever, will carry corresponding parts of the front platform. The inner end of these girders will rest on a line of 16-in. concrete piles driven to refusal and stayed in position before the rock embankment is placed. The floor slab is to be 7 in. thick. The concrete platform and beams have been designed for a distributed load of 500 lb. per sq. ft. The railroad track running the length of the platform is placed centrally over the longitudinal girders. The reinforced concrete construction supporting the track is proportioned to carry a 100-ton switch engine. Tie-rods encased in concrete will anchor the concrete platform firmly to the embankment.

The warehouse buildings are of wooden construction covered with galvanized iron. The roof is to be carried on trusses spanning the whole width of the building, leaving an unobstructed floor space. The floor inside of the building will be paved with creosoted blocks on a concrete base. The concrete slabs on the outside platform are to be covered with an asphalt wearing surface. The cost of the completed dock and buildings will be approximately $1.50 per sq. ft.

IV.—Administrative Systems.

Public Ownership and Control.—In discussing the different systems of administrative control which obtain in the ports of the Pacific Coast, it is necessary to take cognizance of the present strong trend of public thought in favor of public ownership and control of port facilities. It would be interesting to examine the reasons which underlie this movement, but it must suffice for the present purpose to say that they are essentially the same as those that have substituted the free public highway for the toll road of former times. For the wharf is in reality the transfer point between a free public highway on the land and a free public highway on the water, and there is no more reason why this point of transfer should be made a subject of private monopoly than either highway. The transfer may not indeed be made wholly free, and the user may properly pay the actual cost of use, just as a user of the public highways pays another for hauling himself and goods along it when he does not perform that service himself. Moreover, a public wharf being built and maintained through the agency of only a limited portion of the community actually using it, the cost cannot be equitably charged to that portion alone, as it would be if absolutely free of tolls and maintained

solely by taxation. A strictly free port is not, therefore, one of the things to be expected or desired, and is not likely to be realized except as a result of cut-throat competition between rival ports. The writer will not go further into this extremely important matter of port control than to repeat a summary of the principles involved as stated by him in a recently published article.*

"The true policy for a great port to pursue in these matters would, therefore, seem in the light of present-day advanced practice, to be essentially as follows:

"The wharves with the buildings and appurtenances directly connected therewith should be built and owned by the port itself, and should be operated either directly or by short-term assignments in such way as to eliminate entirely the element of private monopoly, and to bring the cost of service to the lowest point consistent with maintenance, operation, and gradual recoupment of original outlay. Even when this return cannot be fully realized and the utilities have to be supported in part by taxation, public ownership may still be vastly advantageous through indirect benefits, just as are public highways which yield no direct revenue whatever.

"The system of railway tracks serving the wharves should be consolidated in the larger ports, under a single unified management, separate and distinct from the tributary railway systems, except as they form the connecting link between such railways and the wharves. These service tracks may be managed either by a private terminal company, subject to port supervision, or by the port authorities themselves. The latter method has definite advantages.

"So far as a port may directly or indirectly foster industrial development in connection with its own utilities, it should do so upon terms which will attract private capital and insure it a sufficient lease of life to enable it to work out its plans and enjoy the fruition thereof. The case is essentially different from that of public utilities, and so far as a port may be drawn into such enterprises it must necessarily be upon a different basis. There is no question that many industrial enterprises have so close a connection with water and rail transfer facilities as to make them quasi-public enterprises. While they are not of a character which a port will ordinarily take up as an original proposition, they are entitled to every practicable measure of cooperation and assistance which the port may give, and are to be considered as an essential element in its successful development."

In many European ports there is a close approach to this ideal, though with wide variations under different governments and customs.

* *Railway and Marine News*, Seattle, Wash., May 1st, 1912.

In America the ultra-democratic ideal of *laissez faire* and non-interference by Government led to an almost universal custom of private ownership of harbor frontages. Astute business foresight was not slow to appreciate the opportunity thus offered, and the important points of every important harbor, almost in its infancy, became private monopolies. When the railroad came, this evil assumed an aggravated form, and it would be a threadbare story to describe the extensive appropriation of water frontage by the railroads, particularly in the newer sections of the country.

As time has passed and the public has been brought face to face with a situation resulting from its own earlier indifference, a change in sentiment has taken place and is just now in full tide of progress. The people are determined to recover the birthright which they bartered away for a paltry mess of pottage. It is no paltry ransom, however, that they are being compelled to pay. Untold millions are being paid and will continue to be paid for what should never have been parted with at all; but the people are determined, cost what it may, to regain control of their water fronts. Private interests resist—it is the loss of a rich monopoly—but they cannot prevail, and the force of public sentiment should be brought to bear to make the struggle as brief as possible.

San Francisco.—Among the ports of the Pacific Coast, San Francisco is the one bright exception in the past to the rule of private ownership. The principle of public ownership and control has, indeed, been adopted in all three of the Coast States; but it has failed utterly in application except in the Port of San Francisco. A significant proof of the overshadowing importance of this port in the past history of the State of California is seen in the fact that early legislation on port matters was directed almost exclusively to San Francisco, and a system of government was established there which was not applied to any other port of the State. The statute which created the Board of State Harbor Commissioners (note, it is a State tribunal, perfectly general in its title) limits its jurisdiction to "possession and control of that portion of the Bay of San Francisco" (description by metes and bounds takes up three pages in the printed statute), extending in general terms from the Federal Reservation (the Presidio) near Golden Gate around into the Bay to the line between San Francisco and San Mateo Counties. Though a State body, its

activities are purely local and pertain exclusively to a portion of the water-front of a single city of the State. Its officers are appointed by the Governor and confirmed by the Senate, and are a regular part of the political machinery of the State. The first Board of Commissioners was appointed in 1863, and the Board has been in existence, therefore, for very nearly half a century.

Whatever may have been the failings of this body—and it has been accused of many things, particularly of being a subservient political organization—the fact that, through all these years, in a State where railroad influence was supreme, it has maintained the integrity of the water-front of San Francisco and has kept it in public control, must stand to its everlasting credit. To-day San Francisco, New Orleans, and Montreal are the only American ports in which the principle of public ownership is practically applied on a large scale, and though the system in force in San Francisco is not as perfect as that in New Orleans, it is a vast improvement over that which prevails generally in the ports of this country.

The vicissitudes of economic progress, however, have at last made the system of State control antiquated, and San Francisco is now ready to forego the pupilage of the State and take her future into her own hands. She wants home rule. She notes with anxious eye the prodigious strides of Los Angeles, San Diego, and particularly the cities across her own Bay. These ports are helping themselves, except that they are receiving from the State grants of tide lands amounting to many thousands of acres. They are organizing on the basis of their own needs. They issue their own bonds. They prepare their own plans. They fight their own battles. They are not tied down to legislative sanction for the measures they desire to adopt, and do not have to go to the electorate of the whole State for financial aid. They may be no longer willing to help pay San Francisco's bills, and it behooves San Francisco to get authority to pay them herself. She is waking up to the situation and is now earnestly agitating for complete home rule of her port. Undoubtedly it will come, and with it a more energetic and efficient working out of her destiny.

The small importance of the east side of the Bay in the early years made it an easy prey to private interests. Although the water-front of Oakland was granted to the town by the State as far back

as 1852, it immediately passed into private hands on a long-term lease, and finally fell into the control of the Southern Pacific, from which it has only recently been wrested by strenuous litigation. The port is fully alive to its opportunities, and the course of development from now on will unquestionably be in the direction of public ownership and control. As yet there is no port organization separate and distinct from the City Government. In time the east-side towns undoubtedly will consolidate, and a comprehensive port organization will be developed. Whether such an organization for the whole of San Francisco Bay will ever be adopted is doubtful. The jealousies of the two sides are too strong to make union practicable at present; but to the onlooker from the outside, a port commission for the whole of San Francisco Bay, with unified development of the entire port, would seem to be the best plan.

Los Angeles.—In Los Angeles there is no separate port organization distinct from the City, but the policy of public ownership is making great headway. Probably the bitterest struggle ever waged to rid a port of the incubus of private monopoly of its water-front is that of Los Angeles against the allied Southern Pacific and other interests. Of the final triumph of the people's cause there is no longer any doubt, though the delay and expense of litigation are a severe strain on the patience of the community. The administration of the port is divided on indefinite lines between a board of public works and a board of harbor commissioners. The method, of course, is unbusinesslike and has resulted, as might have been foreseen, in conflicts of authority which have seriously disturbed the orderly procedure of the work of port development. One of the first problems which Los Angeles should solve is the working out of an efficient system of port administration.

San Diego.—San Diego furnishes an interesting example of the prevalence of home-rule sentiment in Californian ports. In 1910 the State voted $1 500 000 in bonds for the development of the harbor; but the people preferred home rule, and the Legislature annulled the grant and ceded the tide lands within the city limits to the City on condition that the latter shall expend $1 000 000 in port development along specified lines and within a specified time. There is no separate port organization in San Diego, and the development work is carried out as an adjunct of the City Administration.

Portland.—The Oregon system of port management is admittedly not a satisfactory one, and, as exemplified by its application to the principal port of the State, it is in no sense an efficient one. It does not embrace any comprehensive scheme of port development and control, and, until quite recently, it contemplated nothing in the line of public ownership and control of dock facilities; it left the whole matter to private enterprise. The river front was originally deeded to the City, but has passed almost entirely into the hands of private interests—mainly that of the railroads. So strong was the hold of this system that, when the "Port of Portland" was created twenty years ago, its purpose was not at all to provide port facilities, much less acquire or control those in existence, but solely to secure and maintain a 25-ft. channel to the sea. It was simply an ally of the Government in its regular work of channel improvement. Certain specific functions have since been added, such as control of pilotage charges and the building of a floating dry dock; but in its essential purpose it is still an agency for channel improvement only. Its name, therefore, is a misnomer, and, when public sentiment became aroused recently to the necessity for some actual measures in port development, a new body was organized—the Portland Dock Commission—to take up this particular line of work. A bond issue of $2 500 000 was authorized, and plans are actively in progress for the construction of a system of public docks. On the face of it, the whole arrangement appears to be of an unsatisfactory and piecemeal order. Neither the original nor the new commission, nor even both together, has anything like a comprehensive jurisdiction; but their work has to be supplemented by co-operation with the City, and thus there is a sort of three-cornered jurisdiction of the port. It is scarcely to be expected that such a system can be permanently satisfactory. In all probability there will result a consolidated port organization, which will comprehend the present divided jurisdictions and proceed systematically with a unified upbuilding and administration of the port.

The Washington State Law.—The State of Washington has recently taken the most advanced position of any of the Pacific Coast States in this important matter of port administration. By Act of March 14th, 1911, it provided a system of comprehensive port development and control under an organization for that exclusive purpose. The organization is styled a Port Commission, and is composed of

three members elected for terms of one, two, and three years, respectively, in the first instance, and one Commissioner each year thereafter for the three-year term. The powers of the Commission are very comprehensive, embracing the whole range of port development and a large measure of port control. Certain powers are still lacking for the legal enforcement of rules, etc., and there is doubt as to the extent of the Commission's power in promoting industrial enterprises. There are, however, certain crude provisions which need modification to make the statute run smoothly; but on the whole it is the most elaborate, comprehensive, and effective measure of the kind ever passed. It will take time for it to gain full recognition, for it strikes at the root of private monopoly in communities where a large element of the so-called "business" interests is immovably committed to such monopoly; but, if it ever has half a chance to demonstrate its efficiency, it will command popular approval. Two districts have already been organized—one in King County, in which Seattle is located, and one in Chehalis County, which embraces Grays Harbor. In the Seattle District the law has been put into effect with great vigor, and a programme of $6 000 000 has been adopted by popular vote.

The development of the Port of Seattle prior to the passage of this law is a typical example of the complete miscarriage of a great purpose. In no State in the Union was a broader view taken of public questions of this character in framing the Constitution than in Washington. It was the purpose of the State to hold the tide lands in perpetuity for the use of the people, and the first Board of Harbor Line Commissioners was in earnest and determined to abide by the purpose of the Constitution. It would have been a great thing for Seattle if it had prevailed; but the time was not ripe. Public sentiment did not support it. It robbed private interests of too many opportunities for speculation. The false cry of business necessity prevailed, and in one way and another the Constitutional injunction was completely nullified, and the tide lands, now worth many millions, passed wholly into private hands at almost nominal rates. Streets were vacated, and even the harbor area, the phantom relic of a beneficent intention, was so tied up to abutting lands as to become a private monopoly. To-day the Port Commission, in trying to recover enough of this wasted heritage to build its first piers, is asked to pay, in some instances, as high as $86 000 per acre.

British Columbian Ports.—The British Columbian ports, particularly Vancouver, are wholly private-ownership ports, and the water-front development is almost exclusively in the hands of the railroads. It is a striking contrast to the great Canadian port of Montreal, which is one of the most progressive public-ownership ports in the world. Vancouver is passing through the boom experience of most new localities in the West, and is willing to make almost any concession to private interests for what promises most for the immediate present. Not until after the present period of expansion has passed, and public thought, now absorbed in speculation activities, has time to take stock of the situation, is it likely that the problems of port control will be given very serious consideration.

Port Charges.—The diversity of administrative method among the Coast ports is particularly manifest in port charges. The widest difference prevails, and in only one port is there a definite and uniform system. San Francisco has a well-defined schedule of charges, and, whether the best adapted to the purpose or not, it is carefully worked out and serves its purpose very well. In most other ports of the Coast, rates are a matter of private arrangement, although in each there is generally a voluntary agreement among shippers as to what they shall be. They vary greatly, and even in the same port different rates are often applied according to the exigencies of the case. Thus, in Seattle, the basing rate on foreign cargoes is 25 cents per ton, and on coast and local cargoes 50 cents per ton. In San Francisco the whole matter is strictly regulated by a public body, and there is complete uniformity and absence of discrimination. Heretofore in Seattle there has been no such regulation except the ineffectual regulation of the State Commission, and there are frequent complaints of discrimination and irregularity. The two systems, moreover, are essentially different. In San Francisco there is a substantial dockage charge against the vessel; in Seattle there is no such charge, the entire charge being against the cargo. It is this custom which has given Seattle the reputation of being a "free port", but the freedom refers only to the vessel itself. The system is not an equitable one, and will have to be changed as soon as an agreement among the Sound ports can be reached. The San Francisco system is the more rational one in this respect. It comprises three fundamental charges, which have been defined officially as follows:

Dockage.—The charge made for vessels occupying berths at the wharves or moored in any slip or channel.

Tolls.—The charge made for merchandise passing over State premises.

Wharfage.—The charge made for leaving merchandise on State premises longer than the time specified in the rules.

In the Puget Sound ports there are no dockage charges unless a vessel is lying alongside a dock unengaged. The "handling" of the cargo corresponds to "tolls" in San Francisco, though it is less definite in its application and sometimes has no application at all.

Although the San Francisco system appeals to the layman as the more rational and just, the ship operator is positive in his preference for the Puget Sound system (if it can be called such) and holds that it is decidedly the cheaper port. As far as the vessel is concerned, this is true, but there is no great difference in amount where the total cost to ship and cargo is considered. Labor conditions in San Francisco make stevedoring higher than on Puget Sound, but this is a matter entirely apart from the port regulations in themselves. Labor unions may at any time force wages in other ports to the San Francisco scale, and, therefore, a correct comparison of systems should assume uniformity of wages.

In Los Angeles the charges are classified under the heads of dockage handling, and wharfage, "handling" corresponding to "tolls" in the San Francisco schedule. The rates in San Francisco are fixed by the Board of State Harbor Commissioners, supplemented by several statutory enactments. In Los Angeles they are fixed by the Board of Harbor Commissioners, a branch of the City Government. The City charter gives this Board the same legal powers which the State Board enjoys in San Francisco in regard to the enforcement of its rates and regulations, and gives it the power to punish violations thereof. In San Diego there appears as yet to be no system of local public control of rates, all the docks being in the hands of private interests. As soon as the new municipal docks are completed, the control of rates will be reduced to a system.

In Portland, as in San Francisco, pilotage is compulsory, and is an important item of the vessel's expense while in port. The wharves being all private property, there is no public control of rates, and the

charges of various kinds are determined largely by the individual wharf owners, although, of course, there is general conformity to an agreed schedule. The new Dock Commission, by the erection of its own wharves, will naturally assume control of future charges.

In Seattle the newly created Port Commission has the power to fix rates, but has exercised that power for the present only as a matter of form to comply with certain requirements of the statute. Prior to the actual completion of the docks which it contemplates building, it will adopt a thoroughly considered rate schedule. Under the present law it has no legal machinery with which to enforce compliance with its rules, but this defect will doubtless be corrected by the next Legislature.

In Tacoma and other Sound ports, practically the same system and schedule of charges prevail as at Seattle, but it may be expected that, in the near future, an effort will be made to revise the whole system through some mutual agreement.

The British Columbian ports being still almost exclusively under railroad control and ownership, as far as port facilities are concerned, the rates are privately controlled, and the charges are absorbed largely by the railroads.

Co-operation among Ports.—The writer's study of this question has led him to believe that important results might follow a duly organized conference among the recognized authorities of the various ports on the Coast with a view to evolving a uniform system of port administration and of port charges.

V.—Plans for the Future.

Let us now take a brief survey of the ports of the Coast from the viewpoint of their plans for the future. In the first part of this paper it was stated that the Coast is putting its house in order for the reception of the trade which will come from the opening of the Panama Canal. It is a safe assumption that nine-tenths of the funds provided in the past three years, or that will be provided in the next three, for the development of the Coast ports, have been secured through the argument that they are necessary for the above purpose. Ambitious plans have been prepared by recognized experts looking to a future a hundred years ahead and involving expenditures which can only be guessed at. To a great extent these plans will slumber indefinitely, because of

TABLE 6.—COMPARATIVE COSTS TO SHIP AND CARGO IN PACIFIC COAST PORTS.

This table is the result of a comparative study of the rates in the different ports with a view of determining the relative tax on commerce in each. In order to arrive at a condensed approximation of the cost of terminal charges and a comparison of the principal Pacific Coast ports, a purely hypothetic case has been assumed of a 6 000 net ton register ship, 30-ft. draft, discharging and loading cargoes of 12 000 tons of miscellaneous freight, the ship remaining in port 12 days. It is admitted that the assumption is not typical of ordinary occurrences, but it is apparent that, because of the complex and diversified tariffs, as well as lack of uniformity in freight staples, it is well-nigh impossible to obtain averages except through an assumption that is somewhat strained. The cost of stevedoring has been taken at the uniform rate of 40 cents per short ton at all the ports. This is not strictly true, but the labor unions may be relied on to equalize the cost by dictating the labor wage and the length of a day's work. Small miscellaneous items like water, etc., are insignificant, and have been lumped in the table at $50 per voyage. The charge for handling is a variable sum. The attempt has been made to arrive at an equitable average for each port. The dock rental, in San Francisco, for lines having regular assignment, is 45 cents per month per linear foot of dock rental. A 500-ft. space will amount to $225 per month. A monthly sailing for the case docketer will make the rental $225 per voyage.

their very excess over any actual requirement; but nevertheless there will be an immense stride forward in definite development. How far it will extend in the near future will depend on the progress made before the tide of popular enthusiasm begins to ebb, as it may be expected to do within a few years after the opening of the Canal, and the shrewd promoters of port development and no less shrewd port engineering experts will doubtless make the most of the present opportunity and ride on the crest of the flood wave to a point which the normal depth of water would not permit them to reach.

San Francisco Bay.—San Francisco has a fund of $10 000 000 for port improvement, embracing sea-wall and dock construction and the acquisition of 64 blocks of submerged tide lands. A considerable portion of this sum will probably have to be used in replacing defective structures, but it is already decided to build twelve additional wharves of dimensions varying from 600 to 850 ft. in length by 140 to 200 ft. in width. Six additional ferry slips are to be provided, and the two sections of the belt railway are to be connected across Market Street. The approaching Exposition will doubtless stimulate to still greater exertion, particularly if San Francisco secures home rule in the management of her port.

Across the Bay, the City of Oakland has voted $2 503 000 in bonds, and is actively at work in developing her west water-front and her important interior harbor. Her west front development, or the Key Route Basin, is a promising scheme, involving the filling in of 400 acres of land out to the bulkhead line between the Oakland and Key Route Moles, and wharfing out beyond this, still between the moles, to the pier-head line, in such a way as to form an interior basin with numerous slips and quays.

The plans for the interior harbor are scarcely less ambitious, while Alameda, Berkeley, and Richmond have their own projects of development. These have not yet taken form, however, in actually adopted plans or funds for carrying them out.

Los Angeles.—While Los Angeles has fought and is still fighting an heroic battle for the right to build and control a port of her own, she has as yet made only a small expenditure on her own account. She has, however, voted $3 000 000 in bonds and has committed herself to an expenditure of $7 000 000 more. She has had various studies made for the future development of the port, and E. P. Goodrich, M. Am.

Soc. C. E., has presented plans both for the outer and inner harbor which, if correctly reported by the press, are better fitted for a population like that of New York City than anything which even so thriving a city as Los Angeles has any right to expect in the near future. Fortunately, those dazzling schemes are harmless, and doubtless do good by broadening the public vision to a larger horizon.

The Goodrich studies provide an outer harbor in front of Terminal Island protected by a 20 000-ft. extension of the breakwater, and furnishing ten long piers, 500 ft. wide, with intervening slips 400 ft. wide. The inner harbor studies are more immediately practical, though scarcely less ambitious; but, as they involve several alternative plans and have received no official action, it is scarcely worth while to discuss them here. It is enough to add that the actual realization of this plan for 82 miles of developed water-frontage will cost from $75 000 000 to $100 000 000.

According to the latest report of the U. S. Chief of Engineers, the City "is preparing to undertake immediately the improvement of 79 acres on the westerly side of the entrance channel * * * rendering available about 9 100 feet of deep-water frontage." This is in the outer harbor.

San Diego.—In San Diego no comprehensive scheme of development has yet been prepared, but the City has voted the sum of $1 000 000 for new docks and for sea-wall construction. The length of berthing space to be provided with this fund is 1 600 ft., and the length of the sea wall is to be 2 500 ft. This will make possible the reclamation of 50 acres of tide flats. No definite steps have as yet been adopted for a terminal belt railway. It is stated that the City intends to follow up its present plans with a $3 000 000 bond issue. Perhaps most important, as bearing on the future of the port, is the project, said to be in contemplation, of building a railroad directly east to Yuma.

Portland.—Portland, like San Francisco, is pursuing the sane course of "procuring her cloth before cutting out her garments." In 1910 a Commission of Public Docks was created by City Charter amendment, and the sum of $2 500 000 was voted for the construction of such docks as might be needed in the near future. This Commission employed a board of experts from New York City, consisting of E. P. Goodrich, M. Am. Soc. C. E.; W. J. Barney, Jun. Am. Soc. C. E., and Charles W. Staniford, M. Am. Soc. C. E. A complete de-

tailed plan has been prepared by the Board and has just been made public. Those features of the plan which are proposed for immediate adoption consist of two combination docks, sheds, and warehouses, one on each side of the river, a coal dock, a motor-boat landing, fireboat station, etc.

The West Side improvement will consist of a quay dock, 1 075 ft. long and 100 ft. wide, in the central section of the harbor below the city bridges. For two-thirds of its length it will be a single-level structure, and the rest two-level, the upper being at Elevation 32 and the lower at 18 ft. above low water. The dock will be provided with adjustable slips, escalators, and elevators, and will have space for storing 10 000 tons of freight. A six-story reinforced concrete warehouse provided with full equipment for handling goods will be erected in the rear of the dock. Its capacity will be about 40 000 tons. Three additional warehouses are planned as soon as funds are available. Dock autos will be the main reliance for handling freight.

The East Side improvement, conveniently located for the transaction of business, consists of a two-story quay structure, 500 ft. long by 100 ft. wide, capable of storing 6 000 tons on each level. A one-story reinforced concrete warehouse will be provided with a foundation for five additional stories. All structures in both improvements are to be of steel and concrete, and fire-proof throughout.

In addition to these improvements for immediate adoption, the plan of the Consulting Board provides for future development on the two sides of the river, 7 000 ft. of quay construction, pier and slip development affording 21 200 ft. of berthing space with piers 300 ft. wide, together with the necessary warehouses and other accessories. A large coal-handling plant, freight-assemblage and storage yard with a capacity of 1 500 cars, and a public belt line serving all the docks, are also to be provided. The total development gives more than 6 miles of berthing space, of which only about 1 750 ft. are as yet provided for. As to this initial programme, it is understood that it is acceptable to the Dock Commission, and that steps will be taken immediately to carry it into effect. In connection with the Dock Commission projects, reference may again be made to the joint projects of the Government and the Port of Portland Commission to secure a 30-ft. channel to the sea.

Puget Sound and Grays Harbor.—North of the Columbia River, port-development work will doubtless always be associated with the name of Virgil G. Bogue, M. Am. Soc. C. E. Pursuant to a charter amendment of the City of Seattle, adopted March 8th, 1910, a Civic Plans Commission was created for the purpose of forming a plan for the future development of that city. This Commission employed Mr. Bogue as its Engineer, and his very elaborate report, submitted August 24th, 1911, includes a complete scheme of development of Seattle's harbor. Following immediately on the submission of this report came the creation of the Port Commission of Seattle, specifically charged with the duty, among others, of preparing a "comprehensive scheme" of port development. While Mr. Bogue's plans as a whole have not been adopted by a vote of the people, their essential harbor features will be given close study in the preparation of any plans that the Port Commission may adopt. Mr. Bogue, after the completion of his Seattle work, made a similar study for Tacoma and also for Grays Harbor, and he is now engaged on a plan for Prince Rupert. As already stated, whatever action may be taken as to the immediate adoption of his work in these ports, it is certain to have a profound influence on their future development.

The Seattle plan embraces elaborate suggestions for every part of the harbor, with especial emphasis laid on the Harbor Island and Smith's Cove sections. The mosquito fleet and industrial features of the inner harbor are likewise fully elaborated. No effort was made to form an estimate of costs, for the plan is one for long-continued development; but it certainly represents an outlay of not less than $25 000 000.

The Port Commission has definitely adopted an initial programme involving an expenditure of $6 000 000. This includes a slip with two wharves on the east side of East Waterway, giving berthing space for four large ships; a solid filled pier on the central water-front, with an 1 100-ft. berthing space of deep-sea depth, and a floating landing stage for small boats with 800 ft. of landing space, and also a large fruit cold-storage plant; a lumber, coal, grain, and general transhipment dock at Smith's Cove; a small dock for general use on Salmon Bay; and a new ferry across Lake Washington. The Port Commission is taking initial steps looking to the establishment of a terminal railway system for the port.

In addition to the Commission's original programme, there is being considered, at the earnest request of certain business interests, a very ambitious project for Harbor Island, patterned after the Bush Terminals of New York. The pier development proposed comprises six new piers with an aggregate berthing space of 16 800 lin. ft., or enough for the simultaneous berthing of 42 ships of an average length of 400 ft. Back of the piers is to be an extensive industrial development. The whole project is to be a co-operative one between the Port District and a private terminal company.

It is conservative to state that expenditures of all classes—Federal, State, County, City, Port District, and private—actually authorized or in definite contemplation, for the development of Seattle Harbor, aggregate approximately $20 000 000.

The study made by Mr. Bogue of the possibilities of Tacoma Harbor may best be told in his own words, as summarized in his report on Grays Harbor:

"At Tacoma, a great movement is on foot to keep the city well to the fore in all port extension matters. The plans contemplate a canal system with an aggregate length of 6 miles, to say nothing of spurs and laterals which may be built in future years in connection with large industrial enterprises. The cost of this canal system is estimated at about $4 000 000. It will develop a vast area of tideflats and present unexcelled opportunities for industrial development with convenient access from both sea and land. Beside the canal system a number of waterways are to be built and various slips and piers which will provide the best accommodations for vessels engaged in ordinary commerce. When these improvements shall have been made, the wharf frontage of Tacoma between Point Defiance and Brown's Point will aggregate 42.6 miles, all of which is well protected and easy of ingress or egress."

Olympia, Everett, and Bellingham are not as yet taking positive action in the development of their ports, but they will probably do so in the near future.

Grays Harbor.—The Port Commission of Grays Harbor, through Mr. Bogue, has prepared an elaborate scheme of development, but the report does not furnish an estimate of its probable cost, and no provision is yet made for carrying it into effect.

Vancouver, B. C.—As already stated, no comprehensive scheme of development of this port has been adopted. Special studies have been

and are being made of different parts of the harbor, and there are rumors of gigantic development plans by private interests. The Great Northern Railway has a fine new pier under construction, and other private improvements are in progress; but there is as yet no general plan, no distinctive scheme of port administration, and no provision of public funds.

The conformation of the harbor and the handicap of tidal fluctuation and currents have suggested an improvement which, though costly, would seem to possess great merit. That is to place a lock and dam across the throat of the harbor at the second Narrows, thus holding the upper part of the Inlet at high tide and making it a fixed-level fresh-water harbor. This would restrict the tidal area to one-third its present extent and would reduce tidal currents in the lower harbor so much as greatly to improve conditions there. It would seem on the face of it that this would be an improvement of great importance to the future of the port.

New Westminster.—The fresh-water port of New Westminster is taking active steps in harbor development. It has recently expended $15 000 on the study of a plan and its presentation, and is about to put into effect the one prepared for it by A. O. Powell, M. Am. Soc. C. E. It comprises wide marginal streets, routes for railways, the extension of the city quay, and a long waterway in a slough parallel to the river, from which the river is to be excluded at the upper end. A succession of parallel slips, oblique to the axis of the waterway, will develop a berthing space of 7½ miles.

Victoria.—Even that sometime staid and delightful provincial town of Victoria, more distinctly British than any other port of the Pacific, has become infected with the Panama *bacillus,* and is cogitating what it may do to be prepared for the changes which it has been told are about to ensue. No definite plans have as yet been evolved, but among the tentative suggestions are an outer harbor to be protected by a breakwater in front of the present entrance to the inner harbor, and also a development in Oak Bay on the opposite side of the town fronting to the eastward.

Prince Rupert.—Studies for the Port of Prince Rupert are now in progress under the direction of Mr. Bogue, but are not yet far enough along for incorporation in this paper. A suggestion that has been made of possible future development in this port, however, may be

properly mentioned. Prince Rupert City is on an elliptically shaped island about 6 miles long north to south by 4 miles east and west. The "lakes" which separate the island from the mainland in the rear have an area north of the railroad crossing of about 40 sq. miles. It is not unlikely that the north and south passages will be dammed off and provided with locks, thus converting the lakes into a tideless, fresh-water harbor just at the level of high tide. While this development is still some distance off, it has such great advantages, in view of the extreme tidal fluctuation in Prince Rupert Harbor, that it will probably be realized eventually.

Outlay on Pacific Coast Ports.—From the statistics of obligations actually assumed to date, and by the aid of the most reliable forecasts obtainable of port planning for the near future, it will be a conservative estimate to place the cost of port development along the Coast during the next five years at $50 000 000.

VI.—Influence of the Panama Canal.

The writer will close with a brief statement of the influence of the Panama Canal on the commerce of the Pacific Coast. The aggregate effect will be a summation of the following:

(1) Effect on consumption and production among the existing population;
(2) Effect on consumption and production through increase of population—chiefly immigration;
(3) Effect on rail commerce between the Pacific and Atlantic Coasts;
(4) Effect on industrial development;
(5) Effect on Oriental traffic to the east coast of America now transhipped to rail at Pacific Coast Ports;
(6) Adverse effect of Canal tolls.

Consumption and Production.—Under the first heading, it may be assumed that there will be some increase of consumption due to a reduction of prices resulting from lower freight rates *via* the Canal. For example, anthracite coal may possibly find considerable use along the northern coast, where now it finds very little, if any at all. As to production, the effect ought to be extensive and immediate on lumber products, for the Canal will open to Coast lumber the market of both shores of the Atlantic, and the production can be instantly increased

to any desired extent by putting existing mills now closed into operation or speeding up others to their full capacity. In the matter of fruit and cereal products, no radical effect on production should be expected as an immediate result of opening the Canal. The conditions are not the same as with lumber, and any material increase of production must await an increase of population and general development.

Immigration.—This consideration brings up the second heading specified—the influence of the Canal on the increase of population on the Pacific Coast. It is an influence which, in the long run, may prove the most important of all; for it is not so much additional port facilities that are needed to develop a country as increased numbers of those who do the work of development. Many other factors, of course, contribute; but in a new country increase of population is the main thing, and this must come in large part through accessions from the outside. There is a general consensus of opinion that the opening of the Canal will have more immediate effect on immigration than on any other class of traffic. In this fact lies a great hope and a great peril for the Coast. What kind of immigrants will be brought here? What reception will they meet? Will they prove a blessing or a curse to our communities? The writer will consider these matters no further than to quote a paragraph from a bulletin recently published by the Seattle Port Commission:

"In this connection the commission may be justified in digressing so far as to observe that the real preparation for this influx of immigration rests with the people of the State rather than with the Port Commission or the Government. If intelligent and organized effort is made through agents in Europe to secure a good quality of immigrants, and if similar effort is made here to start them in their new career without too much hindrance and discouragement and without being victimized by those whose only desire is to fleece them of their meager belongings and leave them stranded in a country where the problems of successful agriculture are so different from what they are accustomed to, this immigration may be of inestimable value to the State and indirectly to its metropolis and chief port. But if this matter is allowed to drift along without organization or sympathetic effort in aid of the new arrival, the result may be to crowd this port with an indigent population and to justify the effort which is said to be already under way here to resist the whole immigration movement."

Diversion of Rail Traffic.—In reference to the third consideration, a degree of uncertainty exists which completely nonplusses the ablest

traffic authorities of the country. The rail traffic between the Pacific Coast and points far enough east to be affected materially by the Canal is smaller than is popularly supposed. A high railroad authority has estimated that not more than 600 000 tons of traffic goes to the Northwest Coast from east of "Missouri River common points", and that only about 20% of this originates east of Buffalo or Pittsburgh where the influence of the Canal would be effective. On traffic from the Great Lakes and from the Mississippi, Ohio, and Missouri Basins, it is not likely that the Canal will have much effect. The railroads will hold it, except for the possibility that it may cease to originate in those sections. All but about 7½% of this traffic, it has been estimated, might originate on the Atlantic and Gulf Coasts, where it would fall directly within the Canal influence. Is it not likely that the ultimate result of the Canal will be to transfer to the Atlantic Coast much of the Pacific Coast traffic which now originates in the central sections, thus cutting off from both the railroads and the producer of the Central West an important business? And is it not a perception of this probable result which accounts for the lukewarmness, if not active opposition, of certain sections of the country to free tolls for coastwise trade through the Canal? In any event, it seems to be reasonably certain that the Canal (particularly with free tolls) will transfer from rail to ship a large part of the traffic which now crosses the country to the westward by rail. This will operate to increase the business of ports on both coasts and of the railroads from the coast inland for uncertain distances.

As to east-bound traffic originating on the Coast, lumber shipments will increase very largely, but rather through the opening of new markets than the diversion of existing rail shipments. The present eastern market for Coast lumber is mainly in the tramontane region eastward as far as the Mississippi. The market farther east cannot stand the heavy freight charge, except for shingles and the finer grades of lumber. The market of the Central West will continue to get its supply by rail, and only consignments farther east are likely to be diverted to the water route.

With fruit products of all kinds along the Coast, there is every reason to believe that the Canal will effect a marked change in the method of shipment. Refrigerator ships will carry this product to both shores of the Atlantic in better condition and at cheaper rates

than can be done under present conditions. It is estimated that within 10 years the fruit shipments from Central Washington and Oregon will approach 100 000 carloads, while the shipment of all classes of fruit from California will exceed that figure. The problem of handling those prodigious quantities by rail in the short periods and over the long distances necessary may prove an impossible one; and the water route will come in as a great relief in addition to its normal advantages. It seems to be one of the certainties of the near future that cold-storage plants of immense capacity will be built in all the principal ports in order that the fruit crop can be stored in part, awaiting shipment.

In regard to wheat and other grain, and fish products, the Canal will not make much change, because these products already go largely by water; but considerable change in the method of water shipment is likely to result. Wheat, for example, is now shipped mainly in sacks in order to avoid the alleged danger of heating if shipped in bulk on the long voyages *via* the Horn, Good Hope, or Suez. The shorter voyage *via* Panama will obviate this difficulty, and we may expect to see elevators in greater numbers provided in our ports, as they are on the Great Lakes, at Montreal, and in other Eastern ports.

Industrial Development.—It is a much disputed question as to what the effect the Canal will have in promoting industrial development on the Coast, particularly manufactures. Some hold that the lower freight cost will bring raw materials here at rates which will make manufacturing practicable where it is not at present. On the other hand, it is argued that the lower rates will bring manufactured products from the East more cheaply than at present, and that this will offset the tendency just noted. Where the balance of these conflicting forces will fall is wholly problematical, but it is certain, from the uniform experience of the older sections of the country, that increasing growth in population and wealth of itself will bring increased development of manufactures. It will become a part of the development of every port, and will operate to increase its business.

Oriental Traffic.—As to Oriental traffic transhipped to or from Atlantic or Gulf points, it is clear that the effect of the Canal must be to draw it away from Pacific Coast ports. It will not draw it away altogether, because, with certain commodities, like silk, of high value in proportion to freight charge, the interest on purchase cost may amount to more, through the longer time required to receive the goods *via* the

Canal, than the saving in freight. Most of the manufacturers consulted are agreed that silk shipments will continue to go by rail. With other articles, however, such as hemp bound East and cotton bound West, it would seem that, if through lines are established direct to the Orient, *via* Panama, they must absorb this class of traffic.

Canal Tolls.—It is a matter of profound satisfaction to be able to state in this discussion of the ports of the Pacific Coast that a question vital to their welfare and one but yesterday of doubtful issue has been settled and settled right. Our coastwise trade will pass through the Canal without paying any toll. The great principle of the free public highway, and of the free use of public improvements of rivers and harbors, has triumphed over the narrow vision and selfish interest that threatened to defeat it. It is one of the greatest victories of an enlightened national citizenship, which illumines the record of this generation.

The victory, however, great as it is, is not as great as it should be. The Canal should be free to all commerce. The highway toll system on this great thoroughfare should be abolished for all nations and forever. The same system on the public roads became its own executioner, because it defeated its own end. It prevented the use for which the road was built, and while it was an improvement on no road at all, it never performed its full service. So likewise, tolls on commerce through the Panama Canal will restrict the rightful use of that great work. This is a demonstrable certainty. Take a table of distances and look up, for example, the routes from New York to Valparaiso *via* Panama and Magellan. The Panama route is 3 500 nautical miles shorter. Yet it is a fact that the delay in passing the Canal plus the toll cost at a dollar a ton commuted into cost of running the vessel will make it cheaper for large fast vessels to take the longer route. To vessels between Valparaiso and European ports, the disparity against the Canal route will be still greater, and, of course, the same principle applies in varying degrees to all routes. Tolls will inevitably restrict the use of the Canal, and thus deprive the United States and the rest of the world of its full benefit.

It is one of the most powerful illusions that public thought is subject to, that a work like this, in order to justify itself, must be made to pay its own cost in direct revenue. It is easy to overlook the fact that every dollar collected in this way has to be paid by the people in

some other form. At the very best, it is taking out of one pocket to put into another, and meanwhile the utility of the work is being curtailed by restriction of use. Happily the true principle has been grasped by our legislators and applied to the Canal, as far as our own trade is concerned, and that is the utmost which it was in their present power to do. It is only just that foreign nations which have borne no portion of the cost of the Canal should pay something for its use. No one can question the correctness of that position, but this end should be attained by payment for this use, without imposing a toll, by the discovery of some method which will not restrict the use of the Canal. Is such an achievement possible? The writer believes that it is.

It can come, of course, only through international agreement; but it is conceivably practical to form a convention by which each nation shall pay into the Treasury of the United States a proportion of the rightful charge based on the actual use of the Canal by its own subjects, or under its own flag, or on the tonnage to and from its own ports. The charge would be computed on cost of maintenance and operation and such an additional sum annually as would retire the indebtedness within a determinate period. The question is surely worthy of highest consideration, and few subjects more vital to the interests of the world at large could engage the attention of the Third Hague Conference in 1915 than this of mutual co-operation to make the greatest public work of the ages free to all users. Let the police jurisdiction, direct control and operation, and questions of use in time of war be left to the United States; but otherwise let it be free. As the writer has elsewhere said, a "way must be found for making Panama and Suez as free to the world's commerce as if Nature herself had excavated their channels—as free as are the Straits of Gibraltar and Magellan."

DISCUSSION

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—On page 180 the authors speak in glowing terms of the future possibilities of the Lake Washington Ship Canal scheme, now well under way. As a matter of historical interest, it may be stated that, in October, 1871, the late Gen. B. S. Alexander, accompanied by Lieut. (now Col.) Thomas H. Handbury, M. Am. Soc. C. E. (both of the Corps of Engineers, U. S. A.), and the writer, as Assistant Engineer, went to Puget Sound with the view of making extensive "current observations" for the purpose of determining the practicability of harbor defense by torpedoes. While on this mission, Mr. Briar Brown and Dr. Whitworth, two estimable citizens of Seattle, took the party to the proposed ship canal site, and explained the scheme. Orders were received to make the survey, and called for plans, estimates of quantities, and probable cost of making a ship canal, Mr. Le Conte.

"with the view of ascertaining the adaptability of this lake for a naval depot, and the proper route for a ship canal to connect it with Admiralty Inlet, and the cost of such canal.*"

The field work was done by Lieut. Handbury and the writer. The report of the results of this survey will not be found in the River and Harbor Index, because the expenses came out of "Surveys for Military Defense"; consequently, it will appear only among the Senate Executive Documents for the fiscal year ending June 30th, 1872.

At the time this survey was made, it was claimed that the main object of the fresh-water depot was to enable the naval fleet to go up into Lake Washington, and, while taking on stores and supplies, all barnacles, sea-grasses, etc., befouling their bottoms would naturally drop off, leaving them clean when they proceeded to sea. In ordinary cases, of course, ships would have to go into dry dock to have their bottoms cleaned. For large vessels, this would be a matter of $2 000 per day in dock expenses, hence the great saving to be naturally expected. The writer has no doubt whatever of the great future possibilities of the Lake Washington Ship Canal, and will watch its growth in usefulness with interest.

Speaking of the Sound waters in general, the writer was greatly impressed by the bold shores everywhere. In fact, a 3 000-ton ship can go up to the shore, make fast to the trees, and lay there as long as necessary. This same feature was also noted in Lake Washington, and the writer is firmly of the opinion that it is due to vertical stratification; thus, whenever one stratum drops off, it always leaves a new vertical face standing. This natural feature makes trouble for

* Report, Chief of Engineers, U. S. A., 1872, p. 26.

Mr. Le Conte.

the commercial wharves along the shore, but, nevertheless, it has its advantages in some cases.

The removal of Blossom Rock, in San Francisco Harbor, was a most interesting piece of work, and the fact that it ended disastrously was due, as usual, to unexpected contingencies. The writer had the pleasure of visiting the work several times during its progress, and just after the blast, in April, 1870, was told by the late Col. A. W. von Schmidt, the contractor, that he was compelled to set it off some time before he really intended, because of the exceedingly shaky condition of the rocky shell overhead, which had to be propped up with timbers. The tremor due to the working of the hoisting engine at the main shaft would start up leaks everywhere, and he was dreadfully afraid of a general collapse; hence the blast was premature. The subsequent quantity of dredging and scraping necessary to get the required depth of 24 ft. at low water ate up all the profits on the contract.

The draft of vessels entering the harbor gradually increased to 28 ft., and in November, 1902, a second contract was let for increasing the depth over the rock to 30 ft. at low water. The extra 6 ft. to be removed being largely loose broken stone, the contractor resorted to surface blasting, and excavating with a clam-shell dredge and a 10-ton bucket of the grapple type with long lever arms. The results were highly satisfactory.

The same system and dredge were also used in the removal of Shag Rock No. 2, and the results were equally satisfactory. The whole secret of success in surface blasts lies in the use of small charges, exclusively. The writer had local charge of the removal of Rincon Rock, in San Francisco Harbor, and the contractor engineer, Mr. Albert Boschke, made the great mistake of using 40-lb. charges for surface blasting before dredging the broken rock. Such large blasts simply expend their force in making a fine fountain, and the mechanical effect on the bottom, where it is needed, is practically nothing.

The quantity of powder required for each blast is that which will just begin to make a fountain. In most cases this is about 6 lb. of, say, 90% nitro-gelatine. These small blasts, judiciously distributed and followed immediately by clam-shell dredging, are by far the cheapest and most effective, where applicable.

A few remarks about the great jetty at the mouth of the Columbia River may not be out of place. The prodigious movement of sand mentioned in the early reports on this work proved to be a myth, and later experience showed that the sand simply traveled in an orbit of limited diameters. When the Point Adams Jetty was well extended, the sand movement practically disappeared, because it was "bottled-up." The depth of 31 ft. was obtained over the bar, and everybody rejoiced. Peacock Spit, on the north side, next to Cape Disappoint-

ment, was practically the natural north jetty. Unfortunately, Peacock Spit was cut away by subsequent heavy storms and strong currents, and as a result the bar shoaled up to its original depth of 21 ft. at low water. It is very evident that the only thing to do is to build another jetty from Cape Disappointment out along the crest of Peacock Spit, and thus maintain the spit and hold the tidal currents up to their work along and against the south jetty. The writer is of the opinion that a 31-ft. channel cannot be maintained unless Peacock Spit is fixed on the north side. Mr. Le Conte.

Dredging has grown to be a most important adjunct to every type of harbor work. The great advances made in machinery have cheapened the cost of dredging to such an extent that all schemes for proposed harbor work are now materially affected thereby. It may be stated that the day for extending jetties out into deep water in order to maintain the depth on the bar is gone forever. The annual interest on the cost of deep-water extensions will pay for the necessary dredging five times over.

The improvement of tidal flats for commercial purposes is looming up everywhere. When the fact is considered that the new property, after full improvement, can be readily sold for $30 000 per acre, one can see how easy it is to pay for proposed schemes.

Everywhere in Europe it is customary for the government to condemn and purchase all property contiguous to a proposed harbor work, and, after improvements are completed, sell the property to the highest bidder. As a result, it not only gets all its money back, but in addition a handsome profit. The writer fails to see why the same cannot be done in the United States.

The work for bar dredges is growing more important every day. Where the entrance is largely under good shelter, the work can be done for 4 or 5 cents per cu. yd.; but where the bar is exposed to heavy deep-sea swells a large part of the time, the working period is cut down fully one-half, and the cost naturally goes up to 8 and 10 cents per cu. yd. These results are so flattering that harbors of any importance cannot afford to get along without a good bar dredge for general use, as it will pay back its first costs in one year's operation.

E. P. Goodrich, M. Am. Soc. C. E.—Having been a student of port problems for some years, and being intimately connected with some of the work described in this paper, the speaker has studied it with considerable attention. Concerning several points, his interest has been specially aroused. The general problem of the Panama Canal and its effect on the commerce of the world is of great interest, and, together with the various physical problems discussed by the authors, has been of professional interest to the speaker. On these matters, however, he does not care to make any comments. Mr. Goodrich.

Concerning several non-professional points, the speaker's interest

Mr. Goodrich.

has been similarly aroused. Among these is the fact that, in a professional paper before the American Society of Civil Engineers, nothing but an obviously exaggerated newspaper report has been used in describing the port conditions at Los Angeles, Cal. The speaker may lay himself open to criticism for possessing unprofessional curiosity, but he must confess that had it been possible, he would have liked to await the authors' final discussion in order to ascertain whether or not they would correct the descriptions of the projected Los Angeles work, by making use of modified but obviously more accurate subsequent newspaper articles, to the files of which they evidently have access. The speaker is in entire accord with the opinion expressed in the paper, that it is possible that the popular enthusiasm which is now working such wonders on the Pacific slope may go too far, and that the pendulum may eventually start on a reverse swing. Thus, both in Portland, Ore., and in Los Angeles, Cal., he has laid himself open to the possibility of becoming unpopular by sounding a strong note of conservatism. It may not be out of place to state that the newspapers in both cities reported such fact, which might have been discovered by the authors had they read the local papers carefully. Because of the juxtaposition of the speaker's name, coupled with certain comments about the Los Angeles work, with the authors' reference to "shrewd promoters of port development and no less shrewd port engineering experts," who "will doubtless make the most of the present opportunity and ride on the crest of the flood wave to a point which the normal depth of water would not permit them to reach," he is afraid that casual readers will obtain an erroneous conception of the Los Angeles work and of his connection with it. Even the qualifications inserted by the authors are considered inadequate to meet the exactions of truth, and, therefore, the following facts are presented to the Society in an effort to secure justice for a city which the authors themselves have characterized as "incontestably the center of activity of Southern California" and destined to "become a great port, not because Nature made it so, but because her own virile people have said so."

The facts (which might have been ascertained by correspondence or by perusal of public prints) are as follows: The City of Los Angeles owns about 200 acres in the outer harbor, comprised in two tracts of about 150 and 50 acres, respectively. The outer harbor works now contemplate the immediate improvement of only one of these tracts, work on the 50-acre tract being practically under contract to the extent of bulkheading and filling, while plans for the 150-acre tract are in process of evolution, the detailed design being made subject to the determination of certain physical conditions with regard to currents, the occurrence of rock in the foundations, and the securing of certain real estate to provide rights of way for means of access.

Mr. Goodrich.

In a professional paper* published nearly a year ago by Amos A. Fries, M. Am. Soc. C. E., Captain, Corps of Engineers, U. S. A., a suggestion was made with regard to the possibility of further improvement of the outer harbor, proposing a tremendous breakwater and certain long piers similar to those described by the authors and ascribed to the speaker:

"* * * due to the fact that the ocean bottom becomes flatter as you go east from Point Fermin, the breakwater can be extended to inclose any amount of anchorage that may be desired. Indeed, a 25 000-foot extension, should that much ever be required, could be made on almost the same line as the outer arm of the present breakwater, and while keeping in depths averaging barely 48 feet would inclose 10 square miles of water, half of which would average more than 36 feet.

* * * * * *

"Not only can the breakwater be greatly extended, but if fifty or one hundred years hence a long extension becomes necessary, the harbor frontage itself can be increased at least 17 miles by the construction of nine slips between Deadmans Island and the entrance to the Long Beach Harbor. The slips beginning at the present 18-foot curve could be made in lengths varying from 6 500 to 2 100 feet, with a tongue of land 1 000 feet in width between each two slips.

"It would seem advisable, whenever any considerable extension of a breakwater is made, to leave a gap 2 000 feet in width between the present breakwater and the beginning of the extension."

While the authors state that great reliance is being placed on the inner harbor in the development of port facilities, they also say that:

"A great saving fact in the enormous labor of building the Harbor of Los Angeles is its close relation to the industrial development of the city. The lands into which the waterways are being dredged are admirably adapted for factory locations, and the material of excavation is being used in making the necessary fills. The whole development goes hand in hand in a way to produce the best results."

It is the speaker's firm opinion that the inner harbor will be developed almost exclusively for industrial plants and the outer harbor for deep-sea tonnage. At the wharves of the inner harbor, vessels with full cargoes for special manufacturing plants will berth. In order to make the best use of certain dredging which has already been completed, the speaker recommended, and it is understood that the contracts have now been let for, certain temporary wharves located on one of the arms of the inner harbor as now laid out. Only a portion of this wharf will be shedded, and this whole improvement will be carefully studied in an effort to determine what is likely to be the future of that portion of the port. It is further believed that the authors should have put their qualification with regard to the profitableness of reclaiming tide flats, noted under the head of "Dredging,"

* "Los Angeles Harbor," *Professional Memoirs*, Corps of Engineers, U. S. A., and Engineer Department at Large, Vol. IV, No. 13 (Jan.-Feb., 1912), p. 1.

Mr. Goodrich.

in closer proximity to the point they endeavor to make of the great cost of doing the harbor work in Los Angeles. They say:

"Now that the reclamation of tide flats is becoming so profitable an enterprise, dredging will be resorted to more than ever, the operation serving the double purpose of excavating slips and channels and filling the abutting lands."

Increased real estate values will be much greater in Los Angeles in comparison than in many other locations, so that moneys expended will produce larger returns for self-supporting enterprises, such as harbor propositions have generally shown themselves to be, and the criticism of the costly nature of the work at Los Angeles Harbor submitted by the authors becomes largely nullified. In reference to this, it may be well to call further attention to what the authors say with regard to San Francisco Bay:

"The shoaling of San Francisco Bay is one of those great natural blessings which the unthinking are so accustomed to look on as a curse. One-tenth of its natural area, with deep connecting channels, would serve every possible need of commerce, while the other nine-tenths would be of immeasurably greater benefit reclaimed and turned to industrial or agricultural use. Every cubic yard of earth washed down from the rugged slopes of the mountains is worth a thousand times more in those low areas, where it is turned to efficient use in the service of Man."

As to the inner harbor at Los Angeles, the speaker has recommended certain alterations in the harbor lines, a portion of which proposed changes has been presented to the War Department for consideration, and it is hoped will receive its approval. Again, with regard to the inner harbor, such changes in harbor lines are in close accord with the recommendations contained in the paper by Capt. Fries, who writes as follows:

"Between Deadmans Island and the turning basin in the inner harbor there are 18 000 feet of bulkhead lines and 500 acres of land, most of which is now reclaimed. The frontage there may be increased a few thousand feet by slips. Above the turning basin, in the east and west basins combined, there are 750 acres of reclaimed land and 52 000 feet of frontage exclusive of the Salt Lake Railroad Company's land on the south and east. This frontage may be increased economically by slips to the extent of 13 000 feet.

"The above is along present approved harbor lines, and while the total—including the slips suggested by the writer and the 12 000 feet along the Salt Lake Railroad Company's property—amounts to 132 000 feet, or 25 miles, it does not represent half the frontage that can be developed if the future shall show that more is needed.

"Bounded by the bluffs of San Pedro on the west, the Anaheim Road and the city of Wilmington on the north, the City of Long Beach on the east, and San Pedro Bay on the south, there are some 8 square miles (about 5 000 acres) of swamp, tide, and submerged

lands capable of being practically improved as part of the inner harbor. Before this is all developed it is evident that the present anchorage area will be too small. Mr. Goodrich.

* * * * * * *

"* * * the land owned by the Salt Lake Railroad Company between the Long Beach Harbor and the east basin can probably best be developed by slips opening into the east basin and the Cerritos Channel between it and the Long Beach Harbor, giving a frontage of 12½ miles. On Plate V the channels are shown 500 feet wide on the north side of Cerritos Channel, where they are about 1 mile in length, and 300 feet wide on the south side where the lengths are 2 000 feet."

The authors are entirely wrong with regard to their criticism of the possibilities of the inner harbor of Los Angeles becoming silted by material carried in the floods of the Los Angeles and San Gabriel Rivers. The speaker cannot do better than quote again from the report of Capt. Fries:

"The question of maintenance of depths is always a very important one when considering the future of a harbor. In this matter Los Angeles Harbor is exceedingly fortunate. Indeed, it is hard to conceive of an ocean harbor that will cost less to maintain. The two causes of the deterioration of a harbor are silt carried down by rivers flowing into the harbor and sand piled up at the entrance by cross-currents and wave action.

"Ordinarily, the Los Angeles River is the only one whose waters reach the harbor during the rainy season. During the greater part of the year the river goes entirely dry before reaching the sea, due to irrigation and the great quantities of water used in the city of Los Angeles. It is noted, however, that during the winter of 1910-1911 the San Gabriel River, which ordinarily flows into Alamitos Bay, about 10 miles east of Los Angeles Harbor, broke from its regular channel into one known as New River at a point about 20 miles from the harbor and, following the New River, united with the Los Angeles River at a point about 5 miles north of the harbor. This was one of the worst floods known in many years and carried into the Los Angeles Harbor possibly 350 000 cubic yards of material. Efforts are now being made by railroad companies and agricultural interests in the vicinity of the break to make such improvements in the bank of the river as will confine it in the future to its regular channel, emptying into Alamitos Bay.

"The Government has been asked to aid in this as a measure of protection to the harbor, and steps are being taken in that direction. Unquestionably this improvement will be made, but even if the San Gabriel River should regularly flow into the Los Angeles Harbor, the cost for dredging would still be comparatively small, as the records for nearly fifty years show only five serious floods. These occurred in 1867, 1873, 1884, 1891, and 1911. The Los Angeles River itself carries down some material in smaller floods at lesser intervals, but the amount is so small as to be scarcely noticeable, except just where the river first enters the deep water of the harbor."

Mr. Goodrich.

Another point described by Capt. Fries, and now being actively pushed by the local authorities, is the widening of the channel between the inner and outer harbors to a minimum of 750 ft. A request for this improvement has been formally filed with the War Department, and it is believed that the Washington authorities look favorably on the suggestion.

In discussing the administrative systems of the ports, the authors criticize the conditions in Los Angeles, where there was originally and is now technically a divided responsibility. The trouble described by them, however, has been entirely overcome by the Mayor, who appointed what is called an "Advisory Harbor Commission," consisting of the two boards meeting jointly, with the Mayor as Chairman. During the meetings of this joint board all matters relating to harbor affairs are talked out, and differences of opinion are eliminated. The Mayor's solution of the small difficulty described by the authors has proven highly advantageous to the community.

With reference to the table of comparative costs to ship and to cargo in Pacific Coast ports, the fact should be pointed out that, with the exception of San Francisco, the table shows Los Angeles to have the lowest total cost. It should be noted further that the handling rate of 41.8 cents has been taken from an average which might be vastly different in an actual case. The dropping of the 0.8 cent would reduce the cost by nearly $200.

The speaker is extremely sorry that the authors were not more accurate in their statements with regard to Los Angeles Harbor, and believes that it throws grave doubt on the accuracy of the paper in other points.

Mr. Haupt.

LEWIS M. HAUPT, M. AM. SOC. C. E. (by letter).—This is a very comprehensive paper, not only on the engineering problems of Pacific Coast harbors, but also on their commercial relations; and, in view of interesting discussions previously published in the *Transactions* of this Society,* the present contribution is one of great value to the Profession as a guide to and aid in the early solution of these intricate questions.

History and experience are the foundations of theory on which the engineer must rely to shape his course in order that he may best serve his Profession and his country by removing these obstacles to international commerce, hence it is that this paper is peculiarly appropriate on the eve of the completion of the Panama Canal. As it

covers all the important ports from San Diego to Vancouver, no detailed discussion is possible, nor are the maps appended sufficient for such purpose; the text, however, supplements them in large part by stating local conditions and results, and several extracts therefrom are submitted as pointing to such modifications of practice and policy as to give promise of much greater certainty of securing early results. Mr. Haupt.

As it is not possible to review all the cases cited, that of the typical and important Columbia Bar is taken as an example, because, as the authors very justly state:

"This work * * * is probably the largest and most difficult of its kind ever attempted * * *. The two great obstacles to be overcome * * * are the storms and the teredo * * *. The roughness of the sea precludes the use of barges for dumping rock, thus necessitating a trestle, and the trestle piling is the particular delight of the teredo, which puts it out of commission in from 10 to 20 months. * * * the embankment is progressively shaken down during each winter season."

Specifically, the work is described as follows:

"The jetty was to be built of large size stone on a brush mattress and raised to the level of low tide. Later, the project was changed to raise it to high tide, and four groins were to be built from the north side to arrest scour. Work was begun in 1885 * * *, and was completed ten years later at half the estimate. The depth over the bar had increased, in the meanwhile, from 21 to 31 ft., and the work seemed to have accomplished its purpose perfectly.

* * * * * *

"Several years later there was only the original depth of 21 ft. * * *. A new project was adopted, extending the jetty 3 miles farther, * * * to be supplemented by dredging over the bar. * * * a permanent depth of 30 ft. is sought.

"The jetty itself, as now being built, consists of a bed course of small rock as a substitute for brush mattress, it being found impracticable to use the mattress beyond the shoal depths, * * * and the whole is covered on the seaward slope with very heavy rock ranging in weight from 6 to 16 tons per piece."

These extracts indicate that the usual resources of jetties built out from the shore by the aid of trestles and laid on mattresses, supplemented by dredging, are at least very unsatisfactory, if not impractical, at this locality, because of the activity of the teredo and the waves, so that the method has been modified to conform more closely to that proposed in the recent paper* by H. C. Ripley, M. Am. Soc. C. E.

Notwithstanding the great skill and ingenuity expended in the construction and maintenance of this trestle, more than 6 miles in length, and the excellent system of operation, the physical conditions are such as to retard its advance to such an extent that it seems

* "How to Build a Stone Jetty on a Sand Bottom in the Open Sea," *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 1040.

Mr. Haupt.

impossible to overtake the deposits of littoral drift which constitute the bar; for the last official report available at this writing, states the following facts: The estimated cost to secure a depth of 40 ft. was $3 715 000. This project was revised to raise the jetty to mid-tide level, in 1909, at a cost of $3 529 300, and to make it 25 ft. wide at that level. In some places it is in 39-ft. depths, thus requiring an enormous increase in the amount of rock. Between September 20th, 1910, and June 30th, 1911, the dredge worked on the bar 62 days, removing 212 080 cu. yd. The project is 85% completed.

"The survey of June shows the channel to have shifted about 2 500 ft. to the northwest, and the depths vary from 25 to 27½ ft., an increase of 1 ft. over last year.

"The life of the trestle is very uncertain. * * * It is believed that the contraction of the entrance by the north jetty may be followed by scouring along the north side of the south jetty (2 miles distant), and that for its maintenance two more groins should be provided, each about 500 ft. long. The total appropriations since 1902 aggregate $7 901 852.25. The outer 24-ft. contour has advanced some 3 000 ft. since 1902, and the outer depths of 50 ft. in that year had shoaled to 24 ft. by 1909. On the southerly side of the jetty the 24-ft. curve had advanced about 4 000 ft. within 2 years, or about twice the length of the jetty extension in the same time, and large deposits had been made in the throat of the entrance between the jetty and Peacock Spit."

The deductions from these statements are that the extension of the jetty has caused deep erosion at its outer end, requiring enormous quantities of rock to fill voids formerly occupied by sand in place; the rapid advance of the outer slope, accompanied by a shoaling of 26 ft. at the 4-fathom contour; the inability to overtake this advance by the jetty; the shifting of the channel some ½ mile to the northwest by the deposits of drift; the great excess of cost, amounting to more than $1 000 000 per ft. of depth gained; and the proposal to erect the second jetty extending out from Cape Disappointment for a distance of 2 miles, and at this same distance from the present jetty, but neither of them reaching to the crest of the bar by nearly a mile. The result of this must be to aggravate the seaward movement of the bar, while affording little or no protection for dredging.

It is also apparent that the report of 85% completion does not apply to the north jetty, nor to the ultimate extension of both, if this method is to be the main reliance for the improvement of this bar. The purpose of the south jetty, slightly convex to the channel, 4¼ miles in length, was to extend the protecting spit to a point abreast of Cape Disappointment and thus secure the co-operation of that headland, as a second jetty. This has resulted in disappointment, and any extensions of two jetties, it would seem, would give no promise of any different result, because there is no change in the general regimen

of the entrance, affecting the relative equilibrium of the flood and ebb currents. Mr. Haupt.

If the life of the piling, due to the teredo, is taken at the maximum limit of 20 months, then the entire structure subject to their attacks, must be rebuilt in that brief time, necessitating constant repairs and heavy expenses for maintenance. Moreover, the statement from actual experience that the dredge was able to work 62 days out of 283, or 22% of the time, covering the winter season, would give a reasonable assurance that it may be quite possible to work on the bar by creating an insular barrier on its outer slope, as a nucleus, sufficient to serve as a breakwater to protect a floating plant. From this a rock jetty could be extended shoreward to connect the deep-water areas on its outer and inner slopes, and to protect the crest from the littoral drift, as well as create a reaction from the impingement of the ample discharge on its concave face which would cut a channel more than 40 ft. deep automatically, as is shown by the existing channel at the base of the Point Ellice headland just within the throat of the entrance, which channel is about 8 miles long and more than 40 ft. deep, having a radius of 5 miles.

So confident is the writer that such a permanent, navigable channel could be readily obtained that, on June 9th, 1902, at the instance of the Senator from Oregon, he filed with the Secretary of War a proposal to guarantee such a channel for the sum of $2 500 000, which proposal was referred to a Special Board of Engineers for consideration and report. On October 14th, the Board gave a hearing to the officials of the Reaction Jetty Company (organized with a capital of $1 000 000 to execute the work), at which time a full discussion was submitted to the Board, all the members being present. On November 10th, 1902, the Board requested further information, and submitted twenty-three queries which were categorically answered on the 17th, and after several months of consideration, the report was filed with the Secretary of War, but its contents were not disclosed, and the Reaction Jetty Company was advised that it could ascertain the findings when the annual report of the Chief of Engineers was published. As that report has expunged all reference to the special provisions of the tender then submitted, and as 10 years have elapsed since it was made, and the recommendations of the Board, which were estimated to cost $2 260 000 for the extensions of the south jetty, at mid-tide level, a distance of 2½ miles, have been executed and for which appropriations approximating $8 000 000 have been set aside, it would seem appropriate that the terms of that proposal should be reviewed, as a matter of interest to the parties concerned, merely as an index to the early solution of this difficult but important problem of securing an open channel of ample capacity at reasonable cost without bar advance.

Mr. Haupt.

The principles involved have been tested on a practical scale at a condemned inlet on the Texas Coast, and notwithstanding the most serious physical as well as "metaphysical" obstacles, a detached jetty actually secured the full predicted depth of 20 ft. before the work was connected with the shores. Then it was seriously impaired, and the channel shoaled to 9 ft., requiring several years before equilibrium was restored. Thus assurance becomes doubly sure.

Briefly, the reaction jetty proposal reviewed the physical condition of the bar and its changes, as shown from official charts, stating that to obtain the 40-ft. channel would require the removal of some 30 000 000 cu. yd. which would be impracticable by dredging in the open sea with no protection works, as it would require some 30 years, if there were no littoral drift to maintain the supply, and would cost more than $6 000 000.

To control this drift and create an automatic channel, the company designed a permanent structure to create a zone of local activity across the bar, to arrest the drift on its convex face, being on the windward or "weather" side of the proposed crossing, and, at the same time, to cause a continuous reaction, with erosion and deepening on its concave face, by utilizing the forces and agencies of impact, head, reaction, concentration, gravity, and continuous deflection, whereby a sufficient amount of the potential energy of the affluent water is developed locally to produce deep scour and lateral transportation.

The old jetty, completed in 1895, which created the temporary 30-ft. depth, had caused the bar to shoal up at the rate of 3 500 000 cu. yd. per annum, and pushed it seaward about 1 mile, reducing depths of 60 ft. to 30 ft., and less.

To avoid this advance, the company proposed to make its work discontinuous, leaving a gap of about 2 miles between the outer end of the existing jetty and the inner end of the breakwater. The company also proposed to reverse the direction of the curvature of the breakwater, so as to place its cutting face toward the ebb currents and to receive them at first tangentially and, by gradual but continuous deflections, cause a constantly increasing pressure on the most vital part of the ebb for a distance of about 2 miles across the bar. Thus, too, the ingress of the flood tide would not be impaired, and the conditions of equilibrium would be changed in favor of the ebb stream.

Numerous other advantages, not incidental to straight jetties, were pointed out, time and expense were to be saved, and no risk was to be incurred by the Government, which was to be fully safeguarded by bonds, and pay only for work in place and depths secured.

Plans and cross-sections of the existing and proposed channels were submitted, with the form and dimensions of the proposed structure, closing with these words:

Mr. Haupt.

"As the proposed plan is novel and the location one of exceptional difficulty, this Company desires, if permitted, to accept all the responsibility for the success or failure of its plan, and will furnish such security as the Secretary of War may require to protect the United States from loss by reason of its failure. It will also satisfy the Secretary of its ability to carry out the contract to execute these plans as rapidly as the physical conditions will permit * * *. We believe that this proposition will be found to be 'the most economical and advantageous to the Government,'* since it is based upon the utilization of a part of the enormous energy now going to waste over the bar."

After summing up the special advantage to be secured by the acceptance of the proposal, the Company pledged its good faith for its execution in the following words:

"If this Board, therefore, can see its way to recommend to the War Department the acceptance of this proposition for the relief of the Columbia River Basin, it is believed that it will perform a public service of great value to the country, and the Company will accept the trust and the responsibility of its execution in good faith, and will release the Government from any or all claims for royalties incidental to the use of its patents at this place."

The sequel to this, and similar tenders with like guaranties, indicated so plainly that the policy of past administrations was not to encourage the letting of contracts to extrinsic parties, however guaranteed, that the Reaction Jetty Company was dissolved.

The changes on the bar during the past 10 years have served to confirm the predictions made to the Board of 1902 as to the probable effects of the Government plan, and the elaborate report submitted at that time only alluded to the offer of the Company in a single paragraph as follows:†

"The Board knows of no plan for the improvement of this entrance that has not contemplated one or two jetties extending continuously seaward from the points of the entrance that are fixed in position naturally or artificially. The turbulence of the bar is such that operations from floating plant have never been seriously considered as practicable, and any work must be executed from a structure built out from the shore. Even the structure proposed by the Reaction Jetty Company, while nominally a detached breakwater, is in effect an extension of the old jetty, * * *."

This was the only reference, and the extension of the south jetty, as since constructed, was recommended, notwithstanding the following statements in the report:

"The Board cannot expect that an advance of the bar at this point will not follow the construction of the jetties and the removal of the large quantity of sand necessary to secure a 40-ft. channel. Such advances have invariably been found in all jetty harbors."

* Terms of the law authorizing the Secretary to make such contracts.

† Report, Chief of Engineers, U. S. A., 1902, p. 2305.

Mr. Haupt.

But it is expected that:

"The waves and strong littoral currents have at this point their maximum effect, in retarding and counteracting the bar advance, and, unless the history of the past 60 years is misleading, that advance will be speedily checked and probably reversed with a return of the outer bar slope toward its present location."

These hopes do not appear to have been justified by the results in the later reports, and the question arises as to whether or not there may ever be a better solution than the two-jetty plan, which, it is conceded, "invariably" advances the bars in "all" cases. The answer may be suggested by the experience at Aransas Pass during the operation of the partial reaction breakwater, which not only prevented bar advance but caused a recession of the outer contours until the channel was cut entirely through, without injury to the structure, by a feeble diurnal tide. There are many other elements in this report of the Board of 1902-03 which are worthy of consideration, but space and time prevent the writer from mentioning them.

It is hoped that these suggestions may open the door to a broader consideration of the policies and possibilities of this nation for removing physical obstacles to international trade, and be of greater economic advantage to all people.

Some light is thrown on the status of the two-jetty system of surmounting ocean bars by the following extracts from a letter by Col. E. H. Ropes, a layman of New York, who was endeavoring to effect an entrance from the Gulf of Mexico to the bluffs across Corpus Christi Bay, Texas, addressed to Mr. Brewster Cameron, also a layman, interested in promoting the opening of the near-by entrance at Aransas Pass where three previous efforts had failed.*

As this letter expresses the opinion of one who had given his time and means to a project on which he was willing to stake his fortune, after careful investigation, it has a direct bearing on the subject as a practical demonstration of the futility of undertaking a maritime work without consideration of all the elements affecting the problem.

"The Plea for 'Ropes' Pass.'

"NEW YORK CITY, May 24th, 1894.

"MR. BREWSTER CAMERON,
"Baltimore, Md.

"DEAR SIR:— * * * If you are in a position to go ahead with Aransas Pass, I have no proposition to make. If you are not, or if you had considered the outcome of your efforts there so dubious as to incline you to consider a proposition from me I should make one.

* This letter is a part of the posthumous correspondence left by Mr. Cameron who lost his life by slipping into the Niagara Rapids above the Falls after he had successfully reorganized the Aransas Pass Harbor Company and inaugurated the work on the plans of the reaction jetty which secured the requisite depths before the second jetty was built.

The whole thing turns upon the condition of your prospects for Aransas. Mr. Haupt.

"You are right in thinking I will be benefited by deep water at Aransas. It will be far more to me than the public supposes. I have, therefore, the best of reasons for wishing you success. * * *

"The objections you cite to Ropes' Pass are based upon wholly erroneous ideas concerning the scientific project, the commercial plan, and the financial methods. Of this I could satisfy you in a brief interview.

"1. The channel across Mustang Island, no where goes through land 30 feet high. Half the distance is through flats covered at high tide; the rest has an average height of 3 to 10 feet, * * * while a vast amount of dredging will be required at Aransas for dockage in any depth exceeding 12 feet. At Ropes' Pass the dredging for channel makes the dockage, and by reason of the shorter passage and greater depths the currents will be immensely more powerful to scour, thus saving much excavation.

"2. The dockage, being on both sides of the channel, is now completely land-locked. No harbor could be more so.

"3. We can also make it a free port * * * while Aransas will doubtless charge tolls.

"4. But the jetty work is the big item, as has been shown at every Texas point. Dredging in smooth water is child's play in comparison. Do you know that more than $9 000 000 has been spent on Texas jetties, and with no important permanent results? Ropes' Pass requires less jetty work than any proposed harbor on that coast.

"5. * * * I know more now than I did five years ago about Texas sand-bars. The official reports show that every prophecy concerning the results of work on each of the Texas bars has been negatived by experience. Latterly the Reviewing Boards have been denouncing such predictions as the product of 'ignorance' and as attempts to impose upon 'the credulity of mankind'! Engineers of the highest rank declare that no prediction can possibly be made of the effect of operations on those bars. All the strong language occurs in the official reports. Galveston was the immediate theme, but the principles apply equally well to all the Texas bars. The facts sicken me of all bar work on that coast. Why, they have been at work 24 years at Galveston, and at other points nearly as long. You know the results. Every bar, as soon as it is touched, commences to move seaward. That is the real trouble at the Brazos. The existing jetties end where deep water was when they were begun. The bar has been racing with the jetties, just as at Galveston.

"6. Ropes' Pass has great advantage over others in length of jetties, in size, depth, and nearness of internal basin, and in other important matters, but none counts as much as the fact that we have no bar to deal with. It is a steady slope all the way from beach to 90-ft. depth. We can figure exactly how much rock will be required to build our jetties to any given depth. No living man can do this at any other point.

"If the bars had only stood still at Galveston and Brazos, the jetties would now stand in deep water. Not only this, but no bar can form at Ropes' Pass until the whole shape of the coast has changed, because

Mr. Haupt.

our jetties will shut away the bar building forces from the channel, and it will take hundreds of years for the whole island to build out to these ends.

"Your impression that the conditions are 'more favorable' at Aransas than at Ropes' is natural, but erroneous."

(The remainder of the communication refers to financing the project, and asks for a conference.)

The sequel is well known, for the effort to dredge a cut across Mustang Island into Corpus Christi Bay merely made an indent in the beach, destroying the continuity of the littoral drift, which was driven into this artificial bight, and closed up the channel in the wake of the dredge which was imprisoned in its own grave. Had the leeward jetty been built, in advance, to a sufficient distance to intercept the drift, there might have been a fair chance of opening the cut through to the bay, and, with proper work, of maintaining it.

This work, therefore, was abandoned, while that at Aransas Pass, due to the new order of construction by building in from the outer end by a floating plant and on a concave trace, has automatically scoured out its own channel, more than 20 ft. in depth and 300 ft. in width, without bar advance, at a cost to the Government of less than one-fourth of its original estimate, and with a 14-in. diurnal tide. It is true that subsequently a second straight jetty was built, at a cost, including other superfluous works, of more than $1 000 000, but the immediate effect of connecting the "Haupt breakwater" with the shore of St. Joseph's Island was to shoal the 20-ft. channel to about 9 ft. and reduce the tidal energy to such an extent that nearly 4 years elapsed before the former 20-ft. channel was recovered. This experience, therefore, furnishes an excellent practical example of the removal of an ocean bar by a portion of a single barrier placed across its crest, without aid from dredging and without bar advance, at a very great economy in cost, and should commend itself to the Profession as worthy of acceptation in many other cases, notably at the mouth of the Columbia River, Grays Harbor, Coos Bay, etc., on the Pacific Coast, where the conditions are exceptionally favorable.

Gen. Chittenden.

H. M. CHITTENDEN, M. AM. SOC. C. E. (by letter).—Mr. Goodrich has permitted an unnecessary sensitiveness to the writer's rather jocular commentary on his ambitious vision of the future port of Los Angeles to give a false color to his estimate of what the writer said about that port. A careful perusal of the treatment of that subject, mainly in Section II of the paper, will show it to be substantially accurate, though lacking in detail, as was necessarily the case. Particularly inexcusable is the following remark by Mr. Goodrich: "Nothing but an obviously exaggerated newspaper report has been used in describing the port conditions at Los Angeles." The most superficial examination of the paper would show the absurdity of that

statement. As a matter of fact, all available literature, including Major Fries' admirable report, was used, and this was supplemented by a long list of questions sent to an official of the Port of Los Angeles asking for data on all phases of the question. Gen. Chittenden.

As to the newspaper report, which is what really annoys Mr. Goodrich, it came to hand just before the paper was finished. It fitted in so perfectly with the writer's treatment of "plans for the future" and seemed to be so much in detail and to bear so unmistakably Mr. Goodrich's authority, that the writer ventured, with some misgiving, it is true, to make use of it. If it committed him to any erroneous suggestions as to the future of Los Angeles which later data would have modified, he is, of course, only too glad to accept corrections.

The writer will not comment on Mr. Goodrich's references to estimates of cost of Los Angeles work, nor to administrative control, for they are so manifestly unjust that Mr. Goodrich must himself realize the fact if he will but compare his criticism with what the writer really said.

The comment on the writer's parenthetical reference to the Los Angeles and San Gabriel Rivers is a case of assuming that something was meant which was not said, and then criticising that something. The writer's description of the natural state of those streams is literally correct; but he did not anywhere say, or even imply, that these streams were a menace to the integrity of the harbor. The writer has carefully looked over his paper to see if it contains any hint of danger "of the inner harbor of Los Angeles becoming silted up by material carried in the floods" of these streams, and he can find none. All this, and the careful refutation of it, are purely the result of Mr. Goodrich's imagining what the writer did not say.

In short, Mr. Goodrich has permitted himself, most mistakenly, to class the writer as a "knocker" of the Port of Los Angeles. Yet a perusal of the paper will show it to be, not only wholly sympathetic in tone, but full of admiration for the wonderful work which the people of Los Angeles are doing.

The impartial reader of the paper cannot fail to observe that it endeavors to draw a just comparison among the leading ports of the coast as to their respective advantages and drawbacks. The partisans of each will naturally take exception as to their particular port, magnifying the advantages and minimizing the drawbacks; but, when all is said and done, the case for the principal United States ports on the Pacific Coast will stand substantially as summarized below:

San Diego.—Advantages: A magnificent natural harbor which, with a moderate degree of development, would accommodate the shipping of the world.

Drawbacks: A sharp restriction of hinterland (tributary commer-

Gen. Chittenden.

cial territory) by the national frontier immediately to the south and a mountain range on the east. The first natural outlet to the eastward is in the vicinity of Los Angeles.

Los Angeles.—Advantages: Commercially located where the great southern transcontinental routes, and also one from the interior, debouch from the mountains to the coast plain; strategic location for ocean terminal; extensive and productive near-by hinterland; good connection with the hinterland farther back; climate an asset of enormous value in development of country.

Drawbacks: Entire absence of an adequate natural port, and consequent necessity of creating one almost wholly by artificial means; cost of port development greatly enhanced by this fact.

San Francisco Bay.—Advantages: A perfect natural harbor of great magnitude, close to the sea; a hinterland which embraces the heart of California's agricultural and mineral producing regions—one of the richest in the world; on the line of the great routes north and south; in direct rail connection with all the region to the eastward; a commerce and development half a century old, with the immense force of customs and established lines of trade in its favor; most centrally located of all the ports for the commerce of the Pacific; important naval and military bases.

Portland.—Advantages: Unexcelled strategic location at great crossroads of north and south, and east and west routes; a productive local hinterland (agricultural) in the Willamette and other near-by valleys; immense timber resources; a water-grade route to the eastward—the only one from the Pacific Coast of the United States; consequently a vast natural interior hinterland.

Drawbacks: Long distance and defective natural channel to sea which discourages entrance of largest vessels—a drawback as yet only partly overcome.

Puget Sound.—Advantages: Almost perfect natural harbors, the principal defect being excess of depth; center of great timber producing region; center of great fish producing region; limited local agricultural hinterland; extensive agricultural hinterland back of the mountains; the natural emporium for the Alaska trade; well located for Oriental trade; important naval and military base.

Drawbacks: Walled off from natural hinterland to eastward by an immense range of mountains, the main passes being less than 75 miles from tide-water and more than 3 000 ft. high; crossed, however, by three railways, which give same terminal rates as to Portland.

A most striking illustration of the drawbacks above described of both the Lower Columbia and of Puget Sound was seen in the conditions which prevailed on January 7th and 8th, 1913. A fierce storm was causing wrecks and great loss of life at the mouth of the Columbia, while deep snow, avalanches, and (soon after) floods from melting

snow completely paralyzed rail traffic over the mountains back of Puget Sound, and caused considerable loss of life. Permanently to remove either the handicap of the Columbia Bar or the handicap of the Cascade Mountains will cost an enormous sum, yet both ends must be classed as within the range of practical engineering. Gen. Chittenden.

In the foregoing comparative estimate of advantages and drawbacks of Pacific Coast ports it will be noted that San Francisco stands first; and it seems to the writer that she will long continue to stand first, because of her unexcelled advantages. It has also become more and more apparent to him that, unless ports are close competitors in the same field—not distant competitors like Puget Sound and California ports—a mere superiority of port facilities cuts little figure in the matter of competition. Vessels are bound to go where the trade is, even if docks are inferior and charges high, and the writer does not believe that San Francisco or Seattle will take much trade from each other by reason of superior expenditures on docks and wharves; but, with two nearby ports like Seattle and Tacoma, both of which are equally well located, as far as local trade is concerned, and between which the vessel owner sees no choice except in the matter of conveniences and charges, a superior equipment in either might be decisive in its favor.

The writer will refer to one other point, that of port administration. Mr. Goodrich says that Los Angeles has corrected the undesirable condition in port administration prevailing at the time this paper was written. That is fortunate, but the writer does not believe that anything approaching an ideal system will ever be worked out as long as port administration is a function of city government and is thereby necessarily involved in city politics and subject to the vicissitudes of changing administration. That this is the view of sagacious observers on the ground is evident from the following extract,* received after the foregoing statement was written:

"Inefficiency and delay, bickering, obstruction, and even deadlocks will unquestionably be the rule rather than the exception so long as the present machinery for harbor development is relied on by the city. The concentration of power, authority and responsibility in one board, under which the legal, engineering and administrative departments would be placed, will probably have to come before much satisfactory progress is made on this all-important municipal project—the development of Los Angeles harbor."

In a most instructive pamphlet recently issued by the Commonwealth Club of California, Professor C. T. Wright, of the University of California, made some pertinent observations on port administration. The following are some of his conclusions:

"The organization of the harbor governing body should be simple and efficient. Its members should be few in number, with a tenure of

* From the *Los Angeles Tribune*, January 17th, 1913.

Gen. Chittenden.

office sufficiently long to permit of the formation and inauguration of a consistent policy.

"The appointment of a full new board almost always results in an entirely new policy. A new board usually rejects a great part of the programme outlined by its predecessors, and spends a large part of its time in preparatory work before it begins or pursues any real constructive programme; and this in turn is superseded by the plan of a succeeding board. The harbor governing body, if ideally constituted, would be a perpetual body, a certain proportion of whose members would retire each year. In other words, it ought not to be possible, or at least it ought not regularly to occur, that the entire board should retire at one time, or even that a majority of the board should do so.

"The harbor governing body should have full authority to carry out the work which it exists to do, subject of course to review by the courts or other higher authority. This power of the governing board should extend to all activities which directly concern shipping.

"A harbor governing body should represent a constituency of ample financial ability."

These are sound fundamental principles. While it is perfectly true as a rule that "What'er is best administered is best," and that a very efficient law inefficiently administered may give poor results while a defective law efficiently administered may give good results, still, in the long run, the best law will give the best results. The writer believes that the Washington State statute comes nearer to satisfying the above fundamentals laid down by Professor Wright than any other. The port organization is simple, consisting of three members, entirely free of State, county, or city politics, and responsible directly to the people of the Port District.

The harbor governing body (Port Commission) is a continuing body, the term of office being three years, and only one member being elected each year. No sudden change of policy, with its disturbing features, is possible, as is the case with the San Francisco Board, which is liable to change bodily with every change of State administration.

The powers of the Port Commission are extensive; its activities are directed to the single purpose of port development; it is almost supreme within its restricted sphere, and its authority satisfies perfectly Professor Wright's requirement that it be "both extensive and intensive."

The territorial extent of the constituency and also its financial ability are determined in the original organization of the district. The Port of Seattle, for example, was made co-terminous with King County, in which the City of Seattle is located. "Ample financial ability" does not necessarily mean large financial ability. A small port may have an organization and a financial ability "ample" for itself, which might be quite inadequate for a great port. The system is thoroughly elastic, and is applicable to all conditions, and the writer would commend a study of it by port authorities wherever changes are contemplated in port organizations.

Paper No. 1247

NOTES ON BRIDGEWORK.

By S. Vilar y Boy, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. J. C. Howalt, William P. Parker, and S. Vilar y Boy.

In submitting the following, the writer does not pretend to have solved any special points in engineering science. The paper contains only a re-statement of some of the problems which every-day practice has made of interest to him in the construction and maintenance of the Guatemala Railway, and this is the only reason for thinking that they may be of interest to those engaged in similar work.

For instance, the increase of the reaction on the intermediate support of a continuous beam for a double span is generally disregarded when computing trestlework; but, at the same time, and for the sake of stiffness, the stringers for trestlework are generally made continuous over two spans; therefore, the writer has considered it worth while to undertake the solution of this problem, in order to ascertain whether or not the general practice is approximate enough.

Of course, if such stringers are laid with broken joints, the total load on each bent is the same, but the partial reaction due to the stringer which is continuous on the bent considered is higher than that due to its fellow, therefore the load on such a bent is not symmetrical, and, in consequence, the foundations, whether mud-sills or piles, are likely to settle unevenly.

It is stated in the textbooks on applied mechanics that a continuous beam on three supports can be dealt with as two separate beams fixed at the intermediate point and simply supported at the ends.

In this assumption the writer has considered a concentrated load on a beam supported at one end and fixed at the other, and has worked out the solution of this problem in accordance with the general principles of the elastic theory, as follows:

If the beam be simply supported at the two ends, the reaction on A should be: $\frac{W b}{a+b}$, and the reaction on $B = \frac{W a}{a+b}$; but the effect

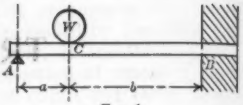

FIG. 1.

of the embedding or fixed support at B (Fig. 1) increases the reaction at this point and diminishes it at A, so that the reactions are:

$$\text{On } A \ldots\ldots\ldots\ldots\ldots\ldots X = \frac{W b}{a+b} - Z$$

$$\text{On } B \ldots\ldots\ldots\ldots\ldots\ldots Y = \frac{W a}{a+b} + Z.$$

Note that the increase and decrease of the reactions on the two ends must be equal, so as to fulfill the condition, $X + Y = W$; that is to say, the sum of the two reactions must be equal to the total load.

The bending moment at C, referred to the support, A, is:

$$m = \left(\frac{W b}{a+b} - Z\right) a$$

and the bending moment, referred to B, is:

$$m' = \left(\frac{W a}{a+b} + Z\right) b - M,$$

M being the bending moment at the fixed end, B.

These two moments must be equal, as corresponding to the same section, C, so that:

$$\left(\frac{W b}{a+b} - Z\right) a = \left(\frac{W a}{a+b} + Z\right) b - M; \text{ from which,}$$

$$(a+b)\, Z = M \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Otherwise, the general equations of the neutral fiber applied on the segment, $A\ C$, should be:

$$E I \frac{d^2 y}{d x^2} = \frac{W b}{a+b} x - Z x$$

$$E I \frac{d y}{d x} = \frac{W b}{a+b} \frac{x^2}{2} - Z \frac{x^2}{2} + C$$

$$E I y = \frac{W b}{a+b} \frac{x^3}{6} - Z \frac{x^3}{6} + C x$$

C being the unknown value of the constant in the first integral, the constant of the second integral being $= 0$, as representing the value of the deflection at the support, A.

The neutral fiber equations between C and B are:

$$E\,I\,\frac{d^2\,y'}{d\,x'^2} = \frac{W\,a}{a+b}\,x' + Z\,x' - M$$

$$E\,I\,\frac{d\,y'}{d\,x'} = \frac{W\,a}{a+b}\,\frac{x'^2}{2} + Z\,\frac{x'^2}{2} - M\,x'$$

$$E\,I\,y' = \frac{W\,a}{a+b}\,\frac{x'^3}{6} + Z\,\frac{x'^3}{6} - M\,\frac{x'^2}{2}$$

the constants in the two integrals being $= 0$ because B is a fixed end.

At the point, C, the two segments, $A\,C$ and $B\,C$, must be tangent to each other, and, therefore if $x = a$ in the first system of equations, and $x' = b$ in the second one, the two following conditions must be fulfilled:

$$y = y';\ \frac{d\,y}{d\,x} = -\frac{d\,y'}{d\,x'}$$

Therefore, the two conditions wanted are:

$$\frac{W\,b}{a+b}\,\frac{a^2}{2} - Z\,\frac{a^2}{2} + C = -\left(\frac{W\,a}{a+b}\,\frac{b^2}{2} + Z\,\frac{b^2}{2} - M\,b\right)$$

$$\frac{W\,b}{a+b}\,\frac{a^3}{6} - Z\,\frac{a^3}{6} + C\,a = \frac{W\,a}{a+b}\,\frac{b^3}{6} + Z\,\frac{b^3}{6} - M\,\frac{b^2}{2}$$

which can be reduced to:

$$\frac{W\,a\,b}{2} - Z\,\frac{a^2-b^2}{2} = M\,b - C$$

$$\frac{W\,a\,b}{6}(a-b) - Z\,\frac{a^3+b^3}{6} = -M\,b^2 - C\,a$$

The foregoing equations, together with Equation 1, will give the system:

$$(a+b)\,Z = M$$

$$\frac{W\,a\,b}{2} - Z\,\frac{a^2-b^2}{2} = M\,b - C$$

$$\frac{W\,a\,b}{6}(a-b) - Z\,\frac{a^3+b^3}{6} = -M\,\frac{b^2}{2} - C\,a$$

from which, after substituting for M its value as in Equation 1, and eliminating C, results:

$$Z = \frac{W\,a\,b\,(2\,a + b)}{2\,(a + b)^3},$$

and therefore $$M = \frac{W\,a\,b\,(2\,a + b)}{2\,(a + b)^2}.$$

Call the total span l, and:

$$Z = \frac{W\,a\,b\,(l + a)}{2\,l^3};\ M = \frac{W\,a\,b\,(l + a)}{2\,l^2}.$$

The following is an application of the foregoing theory to the "Mogul" engines of the Guatemala Railway (3-ft. gauge) on the pile bridges of that road:

According to the actual conditions, the loading diagram for the maximum reaction on the intermediate support is as shown in Fig. 2.

The total load on B is equal to the sum of the two reactions due to the two 11-ton driver axles plus the 12-ton axle which bears directly on the support.

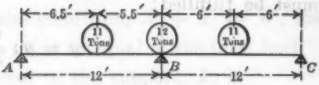

FIG. 2.

The reaction on B due to the left-hand span

$$= \frac{W\,a}{l} + \frac{W\,a\,b\,(l + a)}{2\,l^3} = 5.96 + 2.10 = \ldots 8.06 \text{ tons.}$$

The reaction on B due to the right-hand span

$$= \frac{W'\,a'}{l} + \frac{W'\,a'\,b'\,(l + a')}{2\,l^3} = 5.5 + 2.06 = 7.56 \text{ "}$$

Total.....	15.62 tons.
Axle bearing directly on B.....	12.00 "
Total reaction on B.....	27.62 tons.

Whereas, disregarding the continuity of the beam, the total reaction on the same point should be 23.46 tons.

Therefore, the increase due to the continuity is 18 per cent.

As for the bending moment, it is not worth while to take into consideration the continuity of stringers in order to calculate their size, because their strength is governed somewhat by the horizontal shearing along the neutral fiber, and the equation of moments for

the continuous beams would give too small a size to resist the horizontal shearing.

The following example will illustrate this:

With the same "Mogul" engine, the loading diagram for the maximum bending moment is as shown by Fig. 3.

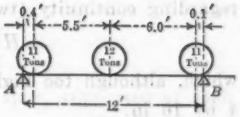

FIG. 3.

Disregarding the continuity:

The reaction at A ..... = 16.8 tons.
The reaction at B ..... = 17.2 tons.
The maximum bending moment ..... = 38.7 ft-tons.
The maximum bending moment under each rail .... = 19.3 ft-tons.
" " " " " " " .... = 232 in-tons.
The maximum shear under each rail ..... = 8.60 tons.

Assuming the cross-bending stress = 1 000 lb. per sq. in., that is, 0.5 tons, $\frac{I}{Z}$ (section modulus) = 464, which practically corresponds to two 6 by 16-in. pieces.

Continuous Beam.—

Left-hand axle	$Z = 0.18$ tons;	$M = 2.16$ ft-tons.
Middle axle	$Z = 2.23$ "	$M = 26.76$ "
Right-hand axle	$Z = 0.09$ "	$M = 1.08$ "
Totals	$Z = 2.50$ tons;	$M = 30.00$ ft-tons.

Therefore, the total reaction at $B = 17.2 + 2.5 = 19.7$ tons.

The maximum shear under each rail = 9.85 tons.

The maximum bending moment under each rail = 15.00 ft-tons = 180 in-tons.

If the cross-bending stress = 0.5 tons, $\frac{I}{Z} = 360$, which corresponds to two 4 by 16-in. pieces.

Longitudinal Shearing Strain.—

$$H = \frac{3}{2}\,\frac{\text{Maximum vertical shear}}{\text{Cross-section of beam}}$$

For two pieces 6 by 16 in. (disregarding continuity)

$$H = \frac{3}{2}\,\frac{8.6}{12 \times 16} = 0.067 \text{ tons} = 134 \text{ lb. per sq. in.}$$

For two pieces 4 by 16 in. (continuous beam)

$$H = \frac{3}{2}\,\frac{9.85}{8 \times 16} = 0.115 \text{ tons} = 230 \text{ lb. per sq. in.}$$

Whereas, the actual reaction, 9.85 tons, due to the continuous beam, applied to the size deduced from the bending moment, disregarding continuity (two pieces, 6 by 16 in.), would give:

$$H = 154 \text{ lb. per sq. in.}$$

which, although too high, is much more reasonable than two pieces, 4 by 16 in.

In the foregoing calculations, for the sake of simplicity, the writer has not included the dead loads; and, as he has referred to longitudinal shearing, he will point out the discrepancy between the safe shearing stress with the grain, as recommended by the Association of Railway Superintendents of Bridges and Buildings and the safe uniform loads on beams as per the tables reprinted from the *Proceedings* of the same Association.

These tables are computed, as explained in the preface of the pamphlet, assuming that: "the working stress in shearing is one-twentieth of that in cross-breaking."

To realize this, take for instance the tabular figures for a short-leaf yellow pine beam, 1 in. wide, 16 in. deep, on a 12-ft. span.

The foregoing formula, $S = \frac{3}{2}\frac{V}{b\,d}$, or $V = \frac{2}{3}\,b\,d\,S$, if $S = \frac{1\,000}{20}$ $= 50$, $b = 1$ in., $d = 16$ in., and noting that the total load is equal to twice the end reaction for uniform loads, gives:

$$W = \frac{4\,d\,s}{3} = \frac{4 \times 16 \times 50}{3} = 1\,070 \text{ lb.}$$

Therefore the tabular values correspond to a safe shearing stress of 50 lb. per sq. in., whereas the value generally accepted in ordinary practice is 100 lb. per sq. in., and therefore the safe load on the foregoing beam should be 2 140 lb. or, say, twice as much as shown in the table.

Therefore the assumption of "working shearing stress = one-twentieth of allowable extreme fiber stress" does not agree with actual practice. Doubtless this error came through overlooking these two facts:

The working cross-breaking stresses recommended by the Association of Railway Superintendents refer to the ultimate extreme fiber strain as an average between the ultimate endwise compressive and tensile strengths.

The ultimate cross-bending strains, as shown in the United States Forestry Department tables, agree fairly well with the values of R deduced from the well-known formula:

$$\text{Bending moment} = R\,\frac{I}{Z}$$

applied to a beam, 1 in. square, and of 1 ft. span, supported at each end, loaded with a center breaking load, W, given by actual tests.

The writer has not at hand the center breaking loads from the Forestry Department tests, but has come to this conclusion by using the values given in Trautwine's "Pocket-Book."

In the latter case it is a matter of fact that, for white pine and similar material, the ratio between shearing with the grain and cross-bending (ultimate) is about one-twentieth.

Another important point in bridge building is the depth to be given to a girder to stand a certain strain, which, as far as the writer knows, has never had a definite solution. Experience shows it to be from one-ninth to one-twelfth of the span, which is not definite. At the same time, experience shows the maximum allowable deflection of girders under good conditions, and from this the depth can be deduced as follows:

The value of the bending moment due to the actual axle loads being nearer to the value for the equivalent uniform load than to the moment due to a single concentrated load, we may refer the actual deflection of the girder to the formula for uniform loads.

For the sake of accuracy, however, the total uniformly distributed load must be computed so that the maximum bending moment it produces shall be equal to the maximum bending moment due to the actual loading diagram.

Call M the actual maximum bending moment, l the span, and W the total uniform load:

$$M = \frac{W\,l}{8}, \text{ and therefore } W = \frac{8\,M}{l} \quad \ldots\ldots\ldots\ldots (2)$$

The deflection is given by the formula:

$$f = \frac{W\,l^3}{77 \times E \times I}, \text{ and } \frac{1}{77} = \frac{5}{384}$$

From which,

$$I = \frac{W\,l^3}{77 \times E \times f} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Otherwise, call S the permissible unit stress, F the flange area, and d the depth of the girder:

$$M = S \times F \times d.$$

At the same time, assuming, as in regular practice, that the bending moment is entirely resisted by the flange area:

$$I = \frac{F \times d^2}{2}, \text{ and } F = \frac{2\,I}{d^2}, \text{ and therefore:}$$

$$M = \frac{S \times 2 \times I}{d^2} \times d = \frac{2\,S\,I}{d}, \text{ and } d = \frac{2\,S\,I}{M} \ldots\ldots\ldots\ldots (4)$$

From Equations 2 and 3,

$$I = \frac{\frac{8\,M}{l} \times l^3}{77 \times E \times f} = \frac{8\,M\,l^2}{77\,E \times f}, \text{ and substituting this value in Equation 4,}$$

$$d = \frac{2\,S \times 8\,M\,l^2}{77 \times E\,f\,M} = \frac{2 \times 8 \times S\,l^2}{77 \times E \times f}, \text{ in which, of course, the span, } l, \text{ is expressed in inches; but, if the span be measured in feet:}$$

$$d \text{ (inches)} = \frac{2 \times 8 \times 144 \times S \times l^2 \text{ (feet)}}{77 \times E \times f \text{ (inches)}}.$$

Assuming $E = 29\,500\,000$ lb., and $S = 10\,000$ lb.,

$$d = \frac{2 \times 8 \times 144 \times 10 \times l^2 \text{ (feet)}}{77 \times 295 \times 100 \times f} = 1.014 \frac{l^2 \text{ (feet)}}{100 \times f}.$$

As for the value of f, although it might go up to the limit of 1 in. in a 100-ft. span, the writer finds, after working out the depths of the plate-girder spans on this road from 25 to 85 ft., that the results of the foregoing formula (assuming a deflection of $\frac{7}{8}$ in. in a 100-ft. span) agree with the actual dimensions within 2 or 3 in. in most cases.

The following is an example: In the 80-ft. girder span over "Los Andes" River on the Guatemala Railway, $l = 80$ ft. The deflection should be $0.875 \times 0.8 = 0.7$ in. in order to keep the standard of $\frac{7}{8} = 0.875$ in. per 100 ft. of span.

In this case

$$d = 1.014 \frac{6\,400}{100 \times 0.7} = \frac{1.014 \times 6\,400}{70} = 92.7 \text{ in.}$$

The actual depth of the girder as built by the Baltimore Bridge Company = 90 in.

DISCUSSION

W. J. C. HOWALT, ASSOC. M. AM. SOC. C. E. (by letter).—The author says: Mr. Howalt.

"It is stated in the textbooks on applied mechanics that a continuous beam on three supports can be dealt with as two separate beams fixed at the intermediate point and simply supported at the ends."

The foregoing statement holds good only when the following conditions are fulfilled:

1. The two spaces must be equal.
2. All three supports must be on a straight line.
3. Cross-sections of the beam symmetrical around the center support must be equal.
4. The loads must be arranged symmetrically around the center support.

Conditions 1 and 3 are fulfilled in the author's case. Condition 2 is assumed to exist, but, when settlement is feared, it is quite advisable to consider what effect this may have. Condition 4 is not fulfilled at all, and renders the whole deduction void.

Apply a load, as in Fig. 1, and call the supports A, B, and C, as indicated in Fig. 2. The reaction at B, as found by the author, happens to be correct. The reaction at A will be $\frac{W b}{a+b} - \frac{1}{2} Z$, and at C $= -\frac{1}{2} Z$; this, being an uplift, must be counteracted by anchorage.

On page 242 the author accounts for the total external load in the reactions at A and B (his equation, $X + Y = W$). It must be assumed, therefore, that no anchorage is applied at the C end of the beam, but this, in turn, will change the continuous beam to a simple one supported at A and B, with an overhanging end on which no load acts, and for which the formulas are not applicable.

Now look at Fig. 3, which is supposed to be a diagram showing the loading for maximum bending moment for both simple and continuous beams; in neither case is this diagram correct.

In the first case assume the train coming in at B and stopped when the 12-ton axle is 4.69 ft. from B. We will then get a maximum moment of 42.07 ft.-tons against the author's "maximum" moment of 38.7 ft.-tons.

Regarding the second case: The writer will only refer to Fig. 2. This position of the load gives a moment at $B = 49.92$ ft-tons against the author's "maximum moment of 30.00 ft-tons. In both cases the

Mr. Howalt. formula for moment, M, on page 244, was used, which formula, by the way, is wrong.

The author makes no distinction between reaction and shear. With loadings as in Fig. 3 and with continuous beams, the maximum reaction is 19.7 tons, but the maximum shear is only 18.55 tons. He should explain why he uses the same position of the load for finding both maximum moment and maximum shear.

Mr. Parker. WILLIAM P. PARKER, M. AM. SOC. C. E. (by letter).—The author's treatment is on the assumption that a continuous beam on three points of support can be dealt with as two separate beams fixed at the middle point and simply supported at the ends.

This assumption is incorrect, as a load on either span affects the reactions on all three supports.

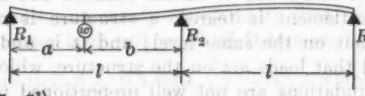
For any load, W (Fig. 4), the sum of the reactions at 1 and 2 is greater than W, while the reaction at 3 is negative. The three reactions, $R_1 + R_2 + R_3$, of course, are equal to W.

The purpose of the investigation seems to be primarily to find the reactions at R_2, the intermediate support, for any load or series of loads. By the method in the paper, the results give a much less reaction than the correct one. The writer, for his work in reinforced concrete design, uses the curves in Fig. 4, which give directly the reaction at all three points of support for a concentrated load in any position and the results from a series of loads can be combined arithmetically to give the resultant reactions. With the reactions found, it is easy to ascertain the bending moment and shear at any point on the beam, and locate points of contraflexure.

Using the notation on Fig. 4: From the theorem of three moments, for any load in the span, 1-2, W produces:

$$\text{Moment } M_1 = 0$$
$$\text{Moment } M_2 = -\tfrac{1}{4}\, wl\,(a - a^3)$$
$$\text{Moment } M_3 = 0$$

Taking the center of moments at the different supports, and expressing the given moment, the algebraic sum of the reaction and loads multiplied by the arms gives three equations. These, together with the equation, $R_1 + R_2 + R_3 = W$, make it possible to solve for the values of the reaction, as follows:



$$R_1 = +\, wb - \tfrac{1}{4}\, w\,(a - a^3)$$
$$R_2 = +\, wa + \tfrac{1}{2}\, w\,(a - a^3)$$
$$R_3 = -\tfrac{1}{4}\, w\,(a - a^3)$$

These three equations were used in laying out the curves in Fig. 4. The results from the use of the curves are readily checked, for, having found the reactions for a given W,

$$R_1 + R_2 + R_3 = W.$$

Mr. Parker.

CONTINUOUS GIRDER OVER 3 POINTS OF SUPPORT

$M_2 = -\frac{1}{4}\, wl\,(a - a^3)$

$R_1 = +wb - \frac{1}{4}\, w(a - a^3)$, $R_2 = +wa + \frac{1}{2}w\,(a - a^3)$, $R_3 = -\frac{1}{4}\, w(a - a^3)$

Diagram gives reactions at Supports R_1, R_2 & R_3 for a Load "w" at distance "a" from Support R_1. Lower horizontal line represents different values of "a". Where vertical from given value intersects the different curves will give directly % of "w" which goes to each of the Supports.

For check $R_1 + R_2 + R_3 = 100\%$

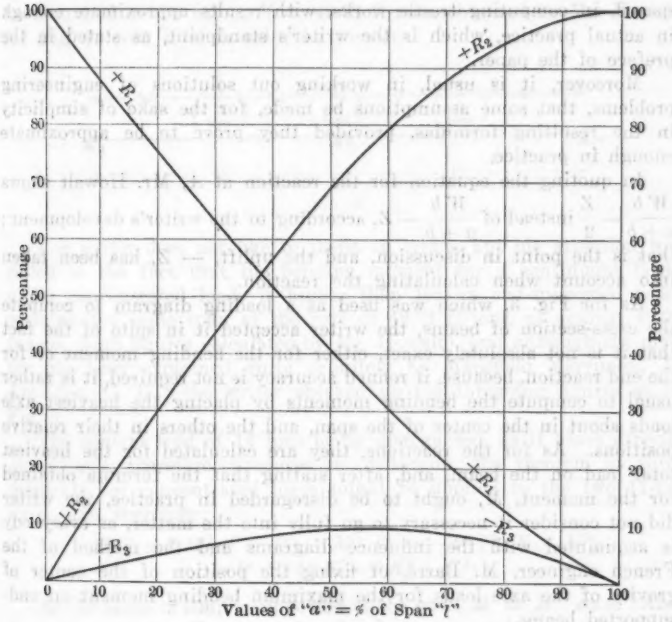


FIG. 4.

Mr. Vilar y Boy.

S. VILAR Y BOY, ASSOC. M. AM. SOC. C. E. (by letter).—Regarding the four conditions required to deal with a continuous beam as though it were two independent beams fixed at the intermediate support, Conditions 1 and 3 are of course fulfilled and also Condition 2, because, when settlement is feared, a structure is not supported at different levels, but on the same level; and it is under the condition of the same level that loads act on the structure, which will settle unevenly if the foundations are not well proportioned to the loads they are to sustain. This is what must be avoided; therefore, it cannot be considered as an actual working condition.

As for Condition 4, it is not mathematically fulfilled, but might be accepted as approximate enough, because the position of the engine for the maximum reaction on the intermediate support agrees very nearly with it, for which the writer refers to Fig. 2 and to Article 15 of "Railroad Construction," by W. L. Webb, M. Am. Soc. C. E., in regard to the possibility of assuming uniform axle loads, uniformly spaced, in computing trestle works, with results approximate enough in actual practice, which is the writer's standpoint, as stated in the preface of the paper.

Moreover, it is usual, in working out solutions of engineering problems, that some assumptions be made, for the sake of simplicity in the resulting formulas, provided they prove to be approximate enough in practice.

In quoting the equation for the reaction at A, Mr. Howalt shows $\frac{W b}{a+b} - \frac{Z}{2}$ instead of $\frac{W b}{a+b} - Z$, according to the writer's development; that is the point in discussion, and the uplift, $-Z$, has been taken into account when calculating the reaction.

As for Fig. 3, which was used as a loading diagram to compute the cross-section of beams, the writer accepted it in spite of the fact that it is not absolutely exact, either for the bending moment or for the end reaction, because, if refined accuracy is not required, it is rather usual to compute the bending moments by placing the heaviest axle loads about in the center of the span, and the others in their relative positions. As for the reactions, they are calculated for the heaviest total load on the beam, and, after stating that the formula obtained for the moment, M, ought to be disregarded in practice, the writer did not consider it necessary to go fully into the matter, as everybody is acquainted with the influence diagrams and the method of the French engineer, M. Barré, of fixing the position of the center of gravity of the axle loads for the maximum bending moment on end-supported beams.

The foregoing assumption might be checked as follows:

Let $M = 38.7$ tons, as accepted in the writer's calculations, so that $M = 19.3$ tons under each rail $= 232$ in-tons $= 0.5$ tons (permissible

stress) $\times \frac{I}{Z}$ (section modulus). Therefore, $\frac{I}{Z} = 464$, which practically corresponds to two 6 by 16-in. pieces, the section modulus of which is 512. Mr. Vilar y Boy.

Using the bending moment, $M = 42.07$ tons, as worked out by Mr. Howalt, M, under each rail $= 21.03$ ft-tons $= 252.36$ in-tons, and assuming as before that $S = 0.5$ tons, $\frac{I}{Z} = 504.72$, which also corresponds to two 6 by 16-in. pieces.

Therefore, the writer's purpose being only the comparison of the resulting cross-sections for the same loading diagram, both in the case of the end-supported beam and of the one fixed-end beam, the use of Fig. 3 does not appear to be unreasonable.

The value of $M = 30$ ft-tons does not apply to Fig. 2, as Mr. Howalt appears to think, but to Fig. 3, which might be ascertained by checking up the arithmetical calculations, so that really it cannot be compared to the value, $M = 49.92$ ft-tons, obtained by Mr. Howalt for Fig. 2, even if such value be correct.

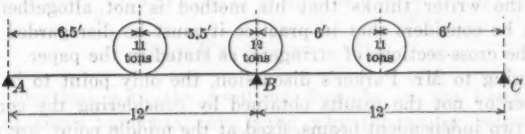

FIG. 5.

The writer does not like to insist on trifles, but his attention was called to the fact that the bending moment for a continuous beam under concentrated loads is higher than for an end-supported beam covering the same span at the rate of 49.92 ft-tons, as against 42.07 ft-tons (both figures calculated by Mr. Howalt), and although the matter has been explained quite definitely by Mansfield Merriman, M. Am. Soc. C. E.,* the writer checked up the foregoing figures as in Fig. 5.

The central load of 12 tons being disregarded, as it bears directly on B, and, therefore, produces no deflection, the theorem of three moments for concentrated loads might be applied to the two 11-ton axles, and therefore:

$$M' l' + 2 M'' (l' + l'') + M''' l'' = -P' l'^2 (K - K^3) - P'' l''^2 (2 K - 3 K^2 + K^3).$$

As the beam is simply supported at the ends, $M' = M''' = 0$. Also, $l' = l'' = 12$ ft., $K = 0.54$ for the first span, and $K = 0.5$ for the second span.

* "Mechanics of Materials," Chapter on "Comparison of Beams."

Mr. Vilar y Boy.

Then:

$$48\,M'' = -11 \times 144\,(0.54 - 0.16) - 11 \times 144\,(1 - 0.75 + 0.125)$$

$$48\,M'' = -11 \times 144\,(0.54 - 0.16 + 1 - 0.75 + 0.125)$$

$$= -11 \times 144 \times 0.755 = -1\,195.92\text{; and } M'' = -\frac{1\,195.92}{48}$$

$$= -24.91 \text{ ft-tons, as against 49.92 given by Mr. Howalt.}$$

Dealing with the continuous beam as though it were two separate beams fixed at the intermediate support, and applying the writer's formula for M, the results are as follows:

For the first span = 25.2 ft-tons;
For the second span = 24.7 ft-tons;

as against the 24.91 ft-tons given by the theorem of three moments, whereas Mr. Howalt's figures are about twice as great.

As the obtained value for the reaction at B "happens to be correct," and the value of M, according to the same method, also happens to be very close to the exact figures, and, moreover, as the whole deduction is in accordance with the general principles of the theory of flexure, the writer thinks that his method is not altogether wrong, although he considers that in practice it must be disregarded in computing the cross-sections of stringers, as stated in the paper.

Referring to Mr. Parker's discussion, the only point to be decided is whether or not the results obtained by considering the continuous beam as two independent beams, fixed at the middle point, are approximate enough in practice. Of course, the deduction on the basis of the theorem of three moments is mathematically exact and excludes any assumption, and, furthermore, Mr. Parker's formulas are so handy that had the writer known of them, he would have accepted and used them instead of working out the solution of the same problem in a different way.

At the same time, Mr. Parker's conclusion as to the method in the paper giving a much less reaction at R_2 than the correct one, is probably due to the fact that the percentage shown by the curves in Fig. 4 refers to the actual load on the beam, whereas the percentage shown in the paper refers to the calculated reaction without regard to the continuity of the beam.

The figures obtained by applying Mr. Parker's formulas to Fig. 2 will prove it:

$R_2 = wa + \frac{1}{2} w\,(a - a^3)$ gives the following results:

For the left-hand load,	$R_2 =$	8.03 as against	8.06 shown in the paper.
For the right-hand "	$R'_2 =$	7.59 " "	7.56 " " " "
Load resting on B,	$R''_2 =$	12.00 =	12.00 " " " "
Total reaction at B,		27.62 =	27.62 shown in the paper.

Mr. Vilar y Boy.

In order to prove that the foregoing result is not a mere coincidence, the writer tried to compare both formulas (Mr. Parker's and his own) from a theoretical and abstract standpoint, as follows:

To avoid any misunderstanding, the symbols, a and b, in the writer's formula will be expressed in Greek letters, α and β, because in such formula a and b represent the actual dimensions, in feet, whereas in Mr. Parker's they are fractional factors, so that the actual lengths of the two stretches of beam are al and bl, respectively, that is to say, $\alpha = al$ and $\beta = bl$, and as $\alpha + \beta$ must be equal to the total span, l, it follows that $a + b = 1$.

Therefore, the writer's formula:

$$R_2 = \frac{W\alpha}{l} + \frac{W\alpha\beta\,(l+\alpha)}{2\,l^3}, \text{ will be easily reduced to:}$$

$$R_2 = W\,a + \frac{W \times al \times bl\,(l+al)}{2\,l^3} = W\,a + \frac{W\,l^3 \times ab\,(1+a)}{2\,l^3}, \text{ or,}$$

$$R_2 = W\,a + \frac{W}{2} \times ab\,(1+a), \text{ but } b = 1 - a, \text{ so that}$$

$$R_2 = W\,a + \frac{W}{2} \times a\,(1-a)\,(1+a) = W\,a + \frac{W}{2} \times a\,(1-a^2)$$

$$R_2 = W\,a + \frac{W}{2}\,(a - a^3)$$

which is identical with the resulting formula on the basis of the theorem of three moments, this being why the writer believes that Mr. Parker's assertion, about the different results obtained from his and the writer's formula, is due to a misunderstanding.

Similarly, the writer's formula for R_1 might be reduced to:

$$R_1 = w\,b - \frac{1}{2}\,w\,(a - a^3) \qquad (4)$$

against $R_1 = wb - \frac{1}{4}\,w\,(a - a^3)$ from the theorem of three moments, the difference between these two values being $-\frac{1}{4}\,w\,(a - a^3)$, the maximum of the absolute value of which (for a constant load, w) corresponds to the maximum value of $(a - a^3)$, the first derivative of which:

$1 - 3\,a^2$ equalized to 0, that is to say, $1 - 3\,a^2 = 0$, solved for a leads to $a = \sqrt{\frac{1}{3}} = \sqrt{0.3333} = 0.58$, which corresponds to a maximum of the function, as the second derivative is a negative expression.

Therefore, the maximum absolute value of $\frac{1}{4}\,w\,(a - a^3)$ should be:

$\frac{1}{4}\,w\,(0.58 - 0.20) = \frac{1}{4}\,w \times 0.38 = 0.095\,w$, or, in other words, the

Mr. Vilar y Boy.

maximum error in the value of R_1, due to the writer's assumption, should be 9½% of the load, w, in case only one span is loaded, as shown in Fig. 4.

If the two spans are loaded, as in Fig. 6, the reaction at A should be as follows:

On account of the load, W, $r_1 = W\,b - \frac{1}{4}\,W\,(a - a^3)$

" " " " " , W', $r_1' = (\quad) - \frac{1}{4}\,W'\,(a' - a'^3)$

and, therefore, the total reaction at A would be:

$$R_1 = W\,b - \frac{1}{4}\,W\,(a - a^3) - \frac{1}{4}\,W'\,(a' - a'^3)$$

and, if $W = W'$, $a = a'$, $b = b'$, or, in other words, if the spans be symmetrically loaded: $R_1 = w\,b - \frac{1}{2}\,w\,(a - a^3)$, which is identical with Equation (4), so that if the axle loads are uniform and uniformly spaced, which is the case of the engine drivers in the standard loading diagram, both formulas (Mr. Parker's and the writer's) should lead to exactly the same values.

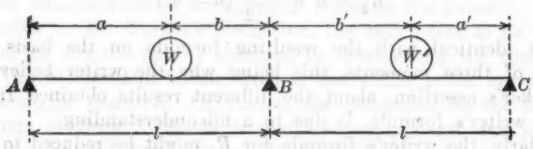

FIG. 6.

As for the actual axle loads, the conditions prove to be so close to symmetry that the difference between the results of both formulas may be disregarded in practice.

Referring again to Fig. 2:

$a = 0.54$, $b = 0.46$, $a' = 0.5$, $b' = 0.5$, $W = W' = 11$ tons, so that by using Mr. Parker's method:

$$R_1 = 11 \times 0.46 - \frac{1}{4}\,11\,(0.54 - 0.16) - \frac{1}{4}\,11\,(0.5 - 0.125)$$

$= 11\,(0.46 - 0.095 - 0.094) = 11 \times 0.271 = 2.981$ tons.

Whereas, the writer's method gives:

$$R_1 = \frac{11 \times 5.5}{12} - \frac{11 \times 6.5 \times 5.5 \times 18.5}{3\,456} = 11 \times 0.46 - 11 \times 0.191$$

$= 11 \times 0.269 = 2.959$ tons.

The error is $2.981 - 2.959 = 0.022$ tons, that is to say, less than 1% of the exact value, which is within the error of the slide-rule, the use of which is generally accepted.

Mr. Vilar y Boy.

Reviewing the whole discussion, the following conclusions might be obtained:

First.—As for the value of the reaction at the intermediate support (which was the writer's primary purpose), the assumption of a continuous beam being equivalent to two separate beams fixed at the intermediate support proves to be absolutely exact in any case.

Second.—As for the reaction at the ends and the bending moment, the above assumption is absolutely correct in the case of the two spans being symmetrically loaded, and approximate enough in practice for the actual loading diagrams.

Third.—As for the reaction at the ends and the bending moments, the assumption should be incorrect in the case of only one span being loaded, which is not the actual loading diagram in the problem submitted by the writer.

Paper No. 1248

THE STRENGTH OF COLUMNS.

By W. E. Lilly, Esq.*

With Discussion by Messrs. Edward Godfrey, J. O. Eckersley, Henry S. Prichard, J. S. Branne, and W. E. Lilly.

Of recent years many data have been accumulated from the published results of tests of the strength of columns and struts. The application of these tests to the various cases that occur in the design of columns, however, gives rise to some difficulties, owing principally to a want of some general method by which the experimental data may be co-ordinated. For instance, from the individual tests on braced struts, the proportions to be adopted for bracing can be approximately determined, but no rules based on these tests have been formulated which are generally applicable.

In this paper it is proposed to consider briefly the derivation of the Rankine-Gordon formula and the writer's formula for columns, and then compare some of the values obtained from tests on columns with those derived from the formulas applicable to the particular cases considered. Some criticism on column formulas and their application to the design of struts will then be given, and some suggestions offered as to the lines on which the co-ordination of experimental work in this direction should proceed.

A bibliography of the literature of the subject is given in the appendix, together with titles of papers by the writer referred to in the text.

At different times various formulas have been put forward to determine the strength of columns; of these, the writer considers the

* Lecturer in Engineering, University of Dublin.

Rankine-Gordon formula to be the best. The following quotation from Mansfield Merriman,* M. Am. Soc. C. E., also supports the writer's opinion:

"The theoretic basis of Rankine's formula seems far more satisfactory than that of any other which has been proposed for the discussion of such columns as are used in engineering practice."

This formula is of a form proposed by Tredgold and afterward revised by Gordon, who determined the approximate value of the constants; it was then modified by Rankine, who substituted the value of the radius of gyration for the diameter of the cross-section. The formula only applies to solid columns, and requires modification when used for hollow or irregular forms of cross-section. It may be derived as follows: Consider the column of uniform cross-section shown by Fig. 1, and assume that it is slightly bent by the load, P; then the bending moment at the middle is

$$M = P\,d = p\,A\,d \quad \ldots\ldots (1)$$

Where P = the load on the column,
d = the central deflection,
p = the load per unit area,
and A = the area of the cross-section.

From the theory of flexure,

$$\frac{M}{I} = \frac{p_1}{y} \quad \ldots\ldots (2)$$

Where I = the moment of inertia of the cross-section about a diameter,
y = the distance of the outer fiber from the neutral axis,
and p_1 = the intensity of the outer fiber stress due to bending.

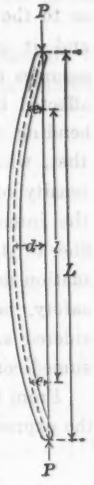

FIG. 1.

From Equations 1 and 2 the following relation obtains:

$$p\,A\,d = \frac{p_1\,I}{y}; \text{ or } \frac{p_1}{p} = \frac{dy}{\rho^2} \quad \ldots\ldots (3)$$

since $I = A\,\rho^2$, where ρ is the radius of gyration of the cross-section.

If the cross-section of the column is considered as being made up of two areas, as shown by Fig. 2, one of which, A_1, transmits the direct stress and the other, A_2, transmits the bending stress; then, if the outer

* "Mechanics of Materials."

fiber stress due to bending is equal to the direct stress, $P = p\,A$ may be put equal to $p_1\,A_1$; also, $I = A_2\rho^2$, giving

$$\frac{p_1}{p} = \frac{A_2}{A_1} = \frac{dy}{\rho^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (4)$$

This relation obtains because any alteration of the breadth of a given cross-section does not alter the value of ρ. Adding unity to both sides of Equation 3 and putting $p + p_1 = f$, the strength to compression of the material, gives

$$p = \frac{f}{1 + \dfrac{dy}{\rho^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (5)$$

In applying Equation 5 to columns and struts, the difficulty arises as to the determination of what function of the length applies to d, and it can only be approximated. The Rankine-Gordon formula assumes that the area, A_1, transmits only the direct stress and is not affected by the bending stress, and that the area, A_2, transmits the bending stress and is not affected by the direct stress; and further, that, when the column is about to break, the intensity of the direct stress on A_1 is then equal to the intensity of the bending stress on the outer fiber of A_2. This assumption gives the first approximation derived from theory, and errs on the side of safety, because the strength of the column, considered as a whole, is greater than that of the assumed compound column.

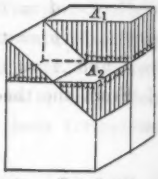

FIG. 2.

From the theory of flexure, the deflection of the column is given by the expression

$$d = \frac{f\,L^2}{\pi^2\,E\,y} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (6)$$

where E = Young's modulus of elasticity, L = the length of the column, and the other terms have the signification already given. This expression is the same as that obtained for a uniform beam supported at its extremities and carrying a load proportional to the ordinates of a sine curve; the deflection curve is then also a sine curve. Substituting for d in Equation 5 from Equation 6 gives

$$p = \frac{P}{A} = \frac{f}{1 + \dfrac{f\,L^2}{\pi^2\,E\,\rho^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (7)$$

which is the form of the Rankine-Gordon formula for centrally loaded, round-ended columns. In order to modify it to include eccentrically loaded columns, assume that the sinusoidal deflection curve closely approximates to the parabola; then, from Fig. 1,

$$d = e + \frac{f\,l^2}{\pi^2\,E\,y^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

where e = the eccentricity of loading.

Substituting for d in Equation 5 from Equation 8 gives

$$p = \frac{P}{A} = \frac{f}{1 + \frac{e\,y}{\rho^2} + \frac{f\,l^2}{\pi^2\,E\,\rho^2}} \quad \ldots\ldots\ldots\ldots\ldots \quad (9)$$

which is the modified form of the Rankine-Gordon formula for eccentrically loaded columns.

The writer has given the further modification of the formula to include transversely loaded columns, which can be derived as follows: From Equations 9 and 4,

$$\frac{A_1}{A_2}\left(\frac{e\,y}{\rho^2} + \frac{f\,l^2}{\pi^2\,E\,\rho^2}\right) = 1$$

but

$$\frac{P\,e}{I} = \frac{f\,A_1\,e}{A_2\,\rho^2} = \frac{p_o}{y}$$

hence

$$\frac{p_o}{f} + \frac{f\,l^2}{\pi^2\,E\,\rho^2}\,\frac{A_1}{A_2} = 1$$

or

$$\frac{f}{f - p_o}\,\frac{f\,l^2}{\pi^2\,E\,\rho^2} = \frac{A_2}{A_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (10)$$

giving, from Equation 4,

$$p = \frac{P}{A} = \frac{f}{1 + \frac{f\,l^2}{\pi^2\,E\,\rho^2}\,\frac{f}{f - p_o}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (11)$$

To apply the formula given in Equation 10, a supplementary calculation is necessary in order to determine the load required to produce a given fiber stress, p_o. Writing Equation 10 in the form,

$$A_2 = \frac{A}{1 + \frac{\pi^2\,E\,\rho^2}{f\,l^2}\,\frac{f - p_o}{f}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (12)$$

Now

$$\frac{p_o}{y} = \frac{M}{A_2\,\rho^2}, \text{ or } A_2 = \frac{M\,y}{p_o\,\rho^2},$$

and substituting for A_2 in Equation 12 gives

$$M = \frac{p_o \rho^2}{y} \frac{A}{1 + \frac{\pi^2 E \rho^2}{f l^2} \frac{f - p_o}{f}} \quad \ldots\ldots\ldots\ldots (13)$$

To determine M, the kind of normal loading must be specified; for a uniform load, $M = \frac{w l^2}{8}$, where w is the intensity of the load per unit length on the column; hence, for a given column, when M is given, p_o can be determined from Equation 13, and conversely.

For the uniform load, the shear stress, S, is $\frac{w l}{2}$, and this is taken up by the supports at the ends of the column; there is also the internal shear stress of the column to be considered. Usually, in a beam or girder, it is the shearing stresses which give rise to the bending moments; in columns, however, it is the variations of the bending moments which give rise to the shearing stresses. If, then, a column is bent to its proof deflection, so also should the web (if properly designed) come to its proof stress. Now consider the column as a beam supported at its extremities and bent to a sinusoidal curve. If w is the intensity of the load per unit area, and d is the central deflection, the bending moment

$$M = \frac{w d l^2}{\pi^2}, \text{ and } S = \frac{w d l}{\pi}$$

where S is the shearing force at one support. Hence,

$$S \frac{l}{\pi} = M = \frac{f I}{y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Now $M = Pd$ for the column, and substituting for P and d from Equations 6 and 7 gives

$$S \frac{l}{\pi} = \frac{f A}{1 + \frac{f l^2}{\pi^2 E \rho^2}} \frac{f l^2}{\pi^2 E y}$$

$$\text{or } S = \frac{f I}{y} \frac{1}{\frac{l}{\pi} + \frac{\pi E \rho^2}{f l}} \quad \ldots\ldots\ldots\ldots\ldots (15)$$

From this equation the thickness of the web for box-columns can be determined; for braced columns, the area of the cross-section of the bracing is given by the equation, $a = \frac{S}{f}$ sec. θ, where θ is the angle of the bracing with the direction of the shearing force. It follows,

then, from Equations 13 and 15, that in designing columns the external and internal shear stresses must be considered together.

The formulas given in Equations 7, 9, and 11 can be written in the generalized form

$$p = \frac{P}{A} = \frac{f}{1 + \frac{f}{f - p_o}\left(\frac{e\,y}{\rho^2} + \frac{f\,l^2}{\pi^2\,E\,\rho^2}\right)} \quad \ldots\ldots\ldots (16)$$

which may be regarded as the modified form of the Rankine-Gordon formula extended to include eccentric and transversely loaded columns. The formula only applies to solid columns, and requires modification when applied to columns of irregular or hollow forms of cross-section.

If a short, hollow, cylindrical tube be tested under direct compression in the testing machine, it fails by secondary flexure or wrinkling, and the tube breaks up into a series of waves. From a comparison of the results obtained from a large number of tests by the writer, it was shown that, as the tube becomes larger in diameter and the thickness less, the load producing failure becomes smaller, and it is not until the length of the tube is less than a wave length that the load producing failure approaches the resistance to compression of the material. Hence the true strength to compression of the tube is the load which produces the wave formation. From the experiments, and also from the analysis, it was found that the wave length varied as the square root of the area of the cross-section. This result leads to the following equation for the limiting load:

$$f_c = \frac{f}{1 + k\frac{\rho}{t}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

where f_c = the limiting load per unit of area on a column of one wave length,

f = the strength to compression of the material,

k = a constant,

ρ = the radius of gyration of the circular cross-section about a diameter,

t = the thickness of the circular cross-section.

Further experiments on columns of square, triangular, and H sections showed that the above formula applied, not only to circular sections, but to these sections as well, the coefficient, k, having a particular value for each cross-section.

Referring now to the Rankine-Gordon formula given in Equation 7: The value of f, the strength to compression, was assumed as constant, whereas the experiments show that it is a variable which involves the phenomena of secondary flexure, and therefore should be replaced by the value, f_c, given in Equation 17. The following formula is then obtained:

$$p = \frac{P}{A} = \frac{f}{1 + k\frac{\rho}{t} + \frac{f\,l^2}{\pi^2\,E\,\rho^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

This formula takes into consideration both primary and secondary flexure, and its solution involves the length and the figure and thickness of the cross-section of the column. Also, by giving values to k pertaining to the different figures of the cross-section, it can be applied generally to all forms of struts.

When eccentric and transverse loading require to be taken into consideration, the formula, by substitution from Equation 17 in Equation 16, becomes

$$p = \frac{P}{A} = \frac{f}{\left(1 + k\frac{\rho}{t}\right)\left(1 + \frac{e\,y}{\rho^2}\frac{f}{f - p_o}\right) + \frac{f\,l^2}{\pi^2\,E\,\rho^2}\frac{f}{f - p_o}} \quad \ldots\ldots (19)$$

Table 1 gives the constants to be used in the foregoing formulas for different materials; these have been deduced from a critical examination of the tests on columns and from the writer's experiments. The value of the constant, c, is $\frac{f}{\pi^2\,E}$ for round-ended columns and $\frac{f}{4\,\pi^2\,E}$ for fixed-ended columns.

TABLE 1.

Material.	Strength to compression, f, in pounds per square inch.	Modulus of elasticity, E.	Round-ended columns, c.	Fixed-ended columns.
Nickel steel.....	120 000	31 000 000	$\frac{1}{2\,800}$	$\frac{1}{11\,200}$
Bessemer steel.....	110 000	31 000 000	$\frac{1}{2\,600}$	$\frac{1}{10\,400}$
Mild steel.....	80 000	30 000 000	$\frac{1}{4\,000}$	$\frac{1}{16\,000}$
Mild steel, annealed.....	60 000	30 000 000	$\frac{1}{5\,000}$	$\frac{1}{20\,000}$
Wrought iron, annealed...	55 000	26 000 000	$\frac{1}{4\,500}$	$\frac{1}{18\,000}$
Cast iron.....	110 000	14 000 000	$\frac{1}{1\,300}$	$\frac{1}{5\,200}$

The coefficient, k, is of the form $\frac{Nf}{E}$, where N represents the tabular number of the figure of the cross-section of the column. On Fig. 3 are shown the numbers obtained for a few types of cross-section; these have been obtained from tests on small specimens, for which reason they can only be considered as approximate.

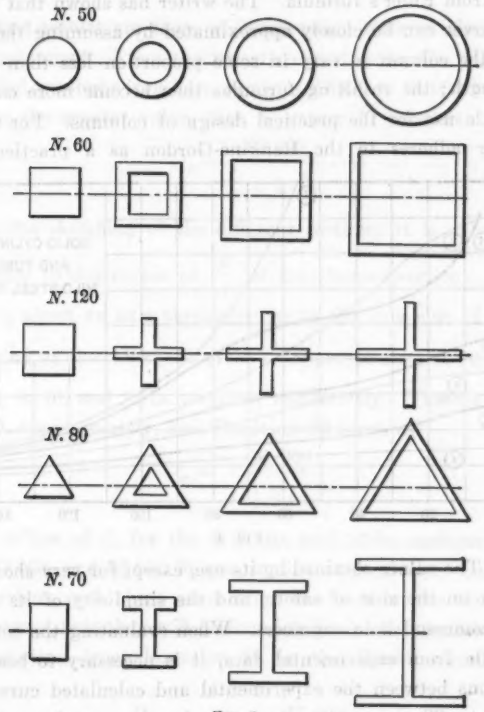

FIG. 3.

On Fig. 4 are shown the results of some tests by the writer on mild-steel columns, $\frac{1}{2}$ in. in diameter. The values obtained for the solid, round-ended columns under central loading are shown by Curve *A*, and the plotted values from the Rankine-Gordon formula by Curve *2*. It will be noticed that these curves intersect at the value of $\frac{l}{\rho}$ = about 40 to 45. For values of $\frac{l}{\rho}$ less than 45 the values given by the formula

are slightly higher than the experimental ones, and for values of $\frac{l}{\rho}$ between 45 and 120 those given by the formula are somewhat less than those obtained from the experiments. For values of $\frac{l}{\rho}$ greater than 120 the calculated and experimental values sensibly agree with Curve *1*, obtained from Euler's formula. The writer has shown that the experimental curves can be closely approximated by assuming the deflection curve of the column to vary in some proportion less than the square of the length; the resulting formulas then become more complex and are of little use for the practical design of columns. For this reason the writer adheres to the Rankine-Gordon as a practical working

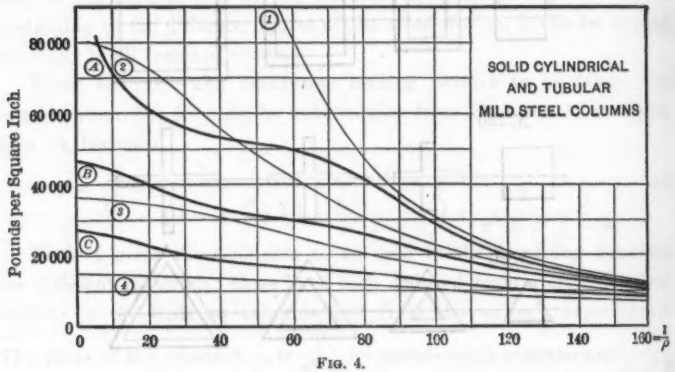

FIG. 4.

formula. The values obtained by its use, except for very short columns, always err on the side of safety, and the simplicity of its form must always recommend it to engineers. When evaluating the constants for the formula from experimental data, it is necessary to bear in mind the relations between the experimental and calculated curves, as just pointed out. The same remarks apply, but in a much smaller degree, when allowing for secondary flexure in the writer's formulas. Curves *B* and *3* show this. Curve *B* relates to a series of tests on centrally loaded, mild-steel tubes, $\frac{3}{4}$ in. in diameter and 18 S.W.G thick. These have been selected to show the influence of secondary flexure on the strength of such columns. Curve *3* shows the calculated values from the formula. Curves *C* and *4* relate to the same tubes but having an eccentricity of loading of $\frac{1}{4}$ in. In these experiments there is little

variation in the loads producing failure for a large range of the length, owing to the small deflection of the column under the applied load compared with the eccentricity of loading.

The values obtained by the use of the foregoing formulas will now be compared with the results obtained from some experimental tests on columns.*

The first results are those of compression tests on channel bars of latticed columns.† From the writer's experiments, the value of f, for solid, rolled, wrought-iron bars, is about 60 000 to 65 000 lb. per sq. in. Assuming the greater value, then Equation 17 becomes

$$f_c = \frac{65\,000}{1 + k\frac{\rho}{t}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (20)$$

From the sketches‡ of the different sections, it is only possible to approximate to the values of $\frac{\rho}{t}$ of the channel sections. Taking the value of ρ about an axis perpendicular to the long side of the section, and dividing by the thickness, gives $\frac{\rho}{t}$ approximately 9, 10, 11, and 12, for the 6, 8, 10, and 12-in. sections, respectively. These numbers give $k = 0.06$, approximately, and Equation 20 becomes

$$f_c = \frac{65\,000}{1 + 0.06\frac{\rho}{t}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (21)$$

and the values of f_c for the 6, 8, 10, and 12-in. sections are 42 000, 40 500, 39 000, and 37 800 lb. per sq. in., respectively. On comparing these numbers with those given from the tests on the shorter lengths of the channel bars they will be found to be in close agreement.

Substituting from Equation 21 in the Rankine-Gordon formula gives

$$p = \frac{P}{A} = \frac{65\,000}{1 + 0.06\frac{\rho}{t} + \frac{1}{4\,300}\frac{l^2}{\rho^2}}$$

E being taken at 28 000 000. The data in the sketches and tables are not sufficiently precise to allow of any great accuracy in determining

*Some of the tables showing the results of these tests are contained in Professor Lanza's "Applied Mechanics" (Ninth edition), and some are in the *Transactions* of this Society.

†Lanza, "Applied Mechanics," pp. 422-423.

‡Lanza, "Applied Mechanics," pp. 427-428.

the values of ρ, of which two are to be considered, one in a plane parallel to the lacing and the other in a plane perpendicular thereto. Using the smaller values in the formula gives numerical results which approximate to the experimental values in the tables.* The constant, $\frac{1}{4\,300}$, has been deduced for round-ended columns. For the tests given in the tables the friction of the pins prevents this condition from being satisfied, and therefore the constant requires to be modified for these tests; a value of about $\frac{1}{5\,000}$ should be used.

The manner of failure, as stated in the tables, gives but little information as to the way in which the lacing was affected when failure of the column took place. As already pointed out, in a laced column the proportions of the lacing depend on the shear stresses due to primary flexure of the column. Reverting to Equation 15, and applying it to the test column, No. 463,† gives the thrust in the lacing as about 1 750 lb. For this column, the following are the approximate data: From Equation 21, $f = 42\,000$ lb. per sq. in., $A = 4.68$, $\rho = 3$ in. (nearly), $l = 240$ in., and $y = 4.5$. Substituting these values in Equation 15 gives

$$S = \frac{42\,000 \times 4.68}{4.5} \times \frac{3}{\frac{80}{\pi} + \frac{670\,\pi}{80}} = 2\,500 \text{ lb.}$$

The lacing slopes at 45° (nearly), giving

$$P = S \sec. \theta = 2\,500 \times \sqrt{2} = 3\,500 \text{ lb. (nearly).}$$

This thrust is taken up on two bars of the lacing, giving 1 750 lb. on each.

The size adopted for the lacing was 1.95 by $\frac{1}{4}$ in. in cross-section and 11.3 in. long between rivet centers. Assuming the bar to have been hinged at the ends, the safe thrust it would carry, by Equation 7, would be

$$P = \frac{65\,000 \times 1.95 \times \frac{1}{4}}{1 + \frac{24\,500}{4\,300}} = 4\,850 \text{ lb., approximately.}$$

As the calculated thrust was only 1 750 lb., the bracing was of ample strength. This seems to have been the case with nearly all the experi-

* Lanza, "Applied Mechanics," pp. 422, 423, 425.

† Lanza, "Applied Mechanics," p. 425.

ments given in these tables,* more especially as no particular failures of the lacing were recorded.

In addition to the shear stress due to primary flexure, there also arises the question of the proportions to be adopted for the lacing when secondary flexure is considered. If the lacing is made uniform throughout the column, and is of sufficient strength to transmit the shear stresses, it is also of ample strength to resist deformation due to secondary flexure. The writer has shown that, in the case of the usual box- and H-sections, the wave length of the wave formation is less than the breadth or width of the section. In a laced column, the channel bars are forced by the lacing to take up a wave length of twice the length of the lattice spacing, and this quantity is always greater than the size of the section. Under these conditions the stresses set up in the lacing due to secondary flexure are small compared with the shear stress at the ends of the column.

In a few tests of Phœnix columns,† the constants deduced therefrom, on substitution in Equation 18, give

$$p = \frac{P}{A} = \frac{70\,000}{1 + 0.04\,\frac{\rho}{t} + \frac{1}{4\,000}\,\frac{l^2}{\rho^2}}$$

In using the formula, it is to be noted that the columns were tested with flat ends, and therefore the ends of the column were sensibly fixed. For these columns, the constant, $\frac{1}{4\,000}$, is multiplied by $\frac{1}{4}$. The coefficient, $k = 0.04$, for these sections, has the smallest value yet obtained from tests on columns. Therefore, they give the column of maximum strength for a given quantity of material. The writer has previously drawn attention to the advantage of stiffened and cellular forms of cross-sections for columns.

The results of a number of tests on wrought-iron pipe columns at the Massachusetts Institute of Technology‡ will be considered next. The deduced value of the constants, on substitution in Equation 18, gives

$$p = \frac{P}{A} = \frac{65\,000}{1 + \frac{1}{10}\,\frac{\rho}{t} + \frac{1}{4\,000}\,\frac{l^2}{\rho^2}}.$$

* Lanza, "Applied Mechanics," pp. 422, 423, 425.
† Lanza, "Applied Mechanics," p. 425.
‡ Lanza, "Applied Mechanics," p. 440.

This formula agrees closely with the writer's experiments, on tubes of much smaller diameters, in the laboratory of Trinity College, Dublin.

Now examine some tests on wrought-iron Z-bar columns by C. L. Strobel, M. Am. Soc. C. E.* The Z-irons used in making the columns were $2\frac{1}{2}$ by 3 by $2\frac{1}{2}$-in. and $\frac{5}{16}$ in. thick. The constants deduced from these tests, on substitution in Equation 18, give

$$p = \frac{P}{A} = \frac{65\,000}{1 + 0.4 + \frac{1}{4\,000}\frac{l^2}{\rho^2}}.$$

The columns were tested with fixed ends, and therefore the constant, $\frac{1}{4\,000}$, is to be multiplied by $\frac{1}{4}$. The value of $k\frac{\rho}{t}$, for the section of these columns, cannot be given until further experimental data have been obtained.

In some tests on eight full-sized Bessemer steel bridge columns by the late J. G. Dagron, M. Am. Soc. C. E.,† the deduced value of the constants, on substitution in Equation 18, gives

$$p = \frac{P}{A} = \frac{80\,000}{1 + 0.5 + \frac{1}{4\,000}\frac{l^2}{\rho^2}}.$$

These were latticed columns, and were tested with pin ends. It is necessary to make a slight allowance for the friction of the pins, which increases the value of the constant from $\frac{1}{4\,000}$ to about $\frac{1}{6\,000}$. The lattice bars were $1\frac{3}{4}$ by $\frac{1}{4}$ by $14\frac{1}{2}$ in., center spaced, and 18 in. apart. Reverting to Equation 15, and substituting the data from the table, the thrust in the lattice bars at the ends is approximately 3 500 lb., and the breaking load on the lattice bars, calculated from Equation 7, gives 3 300 lb., showing that the proportions for the bracing were closely correct. The columns invariably failed by crippling, the lattice bars at the ends of the columns remaining intact.

The data, details, and results of some tests on mild-steel and wrought-iron columns, by Professors Talbot and Moore‡ will now be

* *Transactions*, Am. Soc. C. E., Vol. XVIII, 1888, p. 103; also Lanza, "Applied Mechanics," p. 439.

† *Transactions*, Am. Soc. C. E., Vol. XX, 1889, p. 254; also Lanza, "Applied Mechanics," p. 495.

‡ *Transactions*, Am. Soc. C. E., Vol. LXV, 1909, p. 202; also, *Bulletin No. 44*, University of Illinois, June, 1910.

examined. The deduced value of the constants from Test 17 on the mild-steel column, No. 1, on substitution in Equation 18, gives

$$p = \frac{P}{A} = \frac{60\,000}{1 + 1.4 + \frac{1}{4\,600}\frac{l^2}{\rho^2}}.$$

The tension tests show that the steel was of a very mild quality, and for this reason the value of $f = 60\,000$ has been adopted. The value of the coefficient, k, is approximately 0.09. The column failed by the sudden buckling of the flange between adjacent lattice bars, and therefore the ends of the column may be regarded as having been partly fixed. Reverting to Equation 15, and substituting the values from the data the shear stress is determined as being approximately 3 800 lb., and the thrust in two lattice bars about 4 250 lb. The lattice bars were $1\frac{1}{4}$ by $\frac{7}{16}$ by 18 in., and the breaking load on these bars, calculated by Equation 5, gives 6 500 lb., and for two bars 13 000 lb., showing that they were of ample strength. It will be noted that the column failed by crippling. In Test No. 1* the lattice bars were 1 by $\frac{1}{4}$ in. The breaking load on these bars, calculated by Equation 7, gives 1 000 lb. (nearly), and 2 000 lb. for two bars, showing that they had only half the required strength. In this test the column failed by the buckling of the lacing.

The deduced value of the constants, from the tests on wrought-iron columns, on substitution in Equation 18, gives

$$p = \frac{P}{A} = \frac{55\,000}{1 + 0.6 + \frac{1}{5\,000}\frac{l^2}{\rho^2}}$$

and the value of the coefficient, k, approximately 0.08. These columns failed by crippling, no failure of the lacing being recorded. Calculating the value of the shear stress from Equation 15 shows that the lacing was of ample strength.

The object of this paper is to draw attention to the merits of the Rankine-Gordon formula, and of the writer's formula for co-ordinating the experimental data obtained from tests on columns. The formula takes into consideration eccentric and normal loading and secondary flexure, which covers most of the factors that arise in considering problems on columns; moreover, the formula is derived in a logical way, which theory shows to be a first and true approximation of the problem,

* *Bulletin No. 44*, University of Illinois, Table 7, p. 35.

a merit which, as far as the writer is aware, is not possessed by any other column formula. From the standpoint of the engineer, the use of theory, for the purposes of design, is to act as a guide, and it is essential to know within what limits it may be safely relied upon. In this respect, the derivation of the formula, as already pointed out, errs on the side of safety, and this is also true when applying it to evaluate the shear stresses set up in the column. Other formulas in use for the design of columns, such as the straight-line formula, can be modified to allow for secondary flexure. For instance, the straight-line formula can be put in the form,

$$p = f - a\frac{\rho}{t} - b\frac{l}{\rho}$$

where a and b are constants.

This formula, although useful within a limited range of $\frac{l}{\rho}$, for purposes of rapid design, can only be roughly modified to include eccentric and transverse loading; and, as a formula for co-ordinating the results of experimental tests, is of little value.

The writer does not claim that any great accuracy has been obtained in deducing the constants from the experimental data in the paper. The data given with the tests are not sufficient, and the range of the experiments is too limited to allow of more than first approximations being obtained. To dissect and co-ordinate the mass of experimental data now in existence is beyond the powers of any one man, and the work can only be carried through by a body such as the American Society of Civil Engineers, who, the writer understands, has formed a Special Committee to deal with the subject. A co-ordination of the experimental data on column tests would be of great value to the Engineering Profession, and the American Society of Civil Engineers is to be congratulated on being the first to take the matter in hand.

DISCUSSION

Mr. Godfrey.

EDWARD GODFREY, M. AM. SOC. C. E. (by letter).—This paper is timely and important, not so much because it adds complexity to the already overburdened subject of the theoretical strength of columns, but because it affords an opportunity for a skeptical examination of the basis of all these column formulas, and particularly because any adverse criticism of the basic formulas will no doubt find a worthy champion in the able author.

In the technical press, the writer has repeatedly assailed both the Gordon-Rankine and the Euler formulas for columns. A paper on this subject, which if not denied ought to have revolutionized the subject, he had difficulty in finding a publisher to accept. It was not controverted when published, and it has not revolutionized the subject; the writer expected nothing of the sort; "what ought to be" and "what is" are separate and distinct things. It takes many years to pry accepted standards loose from a body of professional men, even though these standards are clearly proven false. In the meantime the writer has observed and demonstrated in his practice and reading that confidence in the Euler and Gordon-Rankine formulas has resulted in failure, as the error is so great.

When the writer was a student he swallowed the arguments of his textbooks largely because of the authority behind them. Since he has "put away childish things" he appreciates the fact that the highest authorities may err, and that error may be in the very subject that they know best. He accepted the apparent logic of the derivation of these formulas in those days, just as he would now probably accept what the textbooks state regarding the supposed strength of presumably reinforced concrete columns, which are constantly proving, by failing under a fraction of that strength, that such textbooks are wrong. Now, in reviewing his textbooks, he fails to discover any logical basis for either the Euler or the Gordon-Rankine formulas. If there is such basis, it is not stated in these books.

Textbooks say of the Euler load that "under this load the column just begins to deflect, and will under a constant load retain any deflection which may be given to it, within the elastic limit of the material." The writer can find no logical proof of this in the derivation of the Euler formula in these same books. It happens that the Euler load is one that will double any initial bow in a column. If an end load adds 100% to the initial bow of a round-ended column (more properly, one with knife-edge bearings), it will, by reason of this added bow, add another like amount because of that added deflection, and again another and another, and so on *ad infinitum*, or until the column fails. So that, whatever initial bow the column has to start

Mr. Godfrey.

with, it will fail at the Euler load. A column may be perfectly straight, that is, have an initial bow of infinitesimal amount: it will fail at the Euler load, and will not carry any more load than at its first measurable deflection. A similar column may have an initial bow of, say, $\frac{1}{8}$ in.; it will continue to deflect, but will not fail until the load is twice that which gives a total deflection of $\frac{1}{4}$ in. Both columns will sustain the same ultimate load (assuming that they are slender columns), though the originally imperfect one will deflect much more before reaching its ultimate capacity. These facts can be proven by the theory of flexure. They show one of the anomalies of the theory of columns. The writer believes that one would have to search through engineering literature a long time before he would find any statement of these facts, and yet they have a tremendously important bearing on the subject of the strength of columns.

The Euler load is independent of the tensile or compressive strength of the steel, depending only on the modulus of elasticity, which is practically the same for all grades of steel. The Euler load is the absolute maximum that any column can take, no matter how high the elastic limit or the ultimate strength of the steel may be, and two slender columns, of the hardest and of the softest steel, respectively, will have practically the same ultimate strength. These are also anomalies, and are very difficult to find in engineering literature. They also have an important bearing on the subject of the strength of columns.

While the Euler load is the greatest that any column could take, it has practical application only to slender columns. Short columns, by reason of the limiting compressive strength of the metal, cannot sustain loads approaching the Euler load, but will fail by crushing or buckling. Hence some other formula must be used for shorter columns. None can be correct, however, that shows greater ultimate strength for any column than that shown by the Euler formula, and herein is where the Gordon-Rankine formula is in error, at least, in its application in American books. Rankine does not point out this limitation in his derivation of the formula.* His statement: "The greatest deflection [of a rectangular column] consistent with safety is directly as the square of the length, and inversely as the thickness," is not sufficiently full. The deflection which counts is not the initial bow, which might be conceded to be constant for similar columns, but the resulting bow after the load is applied and equilibrium is established. There is no relation between this deflection and the dimensions of the column, for it is a function of the load itself. Any treatment that fails to recognize this is incomplete and is likely to result in error.

* "Applied Mechanics," p. 361.

Mr. Godfrey.

Dr. Lilly, in effect, ties up his Gordon-Rankine formula with the Euler formula when he recognizes that the deflection or curvature in the column will limit its carrying capacity. His values of p cannot exceed the Euler unit stress. The constant of his Gordon-Rankine formula is thus deduced from purely theoretical reasoning. This is eminently better than empirical determination of the constant as the latter has worked out.

A common value for the constant of the Gordon-Rankine formula for round-ended columns is $\frac{1}{18\,000}$. This, with a value of 50 000 for f, gives, for the ultimate strength of a column having a ratio of slenderness of 240, a unit stress of 11 910 lb. per sq. in. (Handbooks work this out for the busy user.) The Euler load for this column is only 5 140 lb. per sq. in. This is the absolute maximum load that any column could take, and yet a formula in general use appears to show that it can take 132% more than this. Here is the count which the writer would urge against the Gordon-Rankine formula, and he has known failure to result from confidence in this same formula with the constants commonly used.

The writer believes that the Gordon-Rankine formula fails to meet the needs of the practical design of columns, and that a straight-line formula is far superior. It gives results closer to those obtained from experiments, and there are several reasons why it should.

Columns, as commercially manufactured, are imperfect, of necessity, and a formula for their design should take into account this fact. They are not in true alignment, and their end connections are not always central. The writer has shown* that, if proportionate imperfections are assumed in columns, a purely theoretical formula can be deduced, which, though very complex, gives a locus which is almost straight for a large part of its length and agrees closely with the commonly used straight-line column formulas.

The ultimate strengths of test columns fall away rapidly after the range of very short columns is passed. This is probably because of local crimping or buckling of the metal, but it is a fact which must be dealt with in the treatment of columns. The Gordon-Rankine curve does not take this shape, hence it fails to meet this condition. The straight-line formula does meet this condition, for the locus falls away from the start.

The straight-line formula has the further advantage that it discourages the use of slender columns. Slender compression members may be weak by reason of their own weight, or, if in a vertical position, an accidental blow may cause them to fail.

* *Railway Age Gazette*, July 2d, 1909.

Mr. Godfrey.

In the writer's opinion, the whole subject of columns in engineering textbooks should be re-written, and its theoretical treatment simplified, instead of being rendered more complex. A large part of the engineering literature on this subject could be expunged with resulting benefit.

It is manifestly impossible to evolve a formula which will show close agreement with any comprehensive series of tests, for the reason that similar columns show discordant results. The exact strength of structural steel columns cannot be predicted, because imperfections of manufacture enter so largely in the results. Approximate results are all that can be expected, and simple theory answers this purpose just as well as the most complex theory ever devised.

In this re-casting of column literature, the importance of the Euler load should be emphasized, not as a load which the column can hold in equilibrium, conveying the idea that there is surplus strength in the column, but as the extreme limit of its carrying capacity.

Another fact of great importance which should be emphasized is that slender columns of all grades of steel are of practically equal strength. Working formulas should recognize this, and values should converge for long columns in low and high steels. Nickel steel struts of light dimensions are not economical, because their strength is practically the same as for soft steel, though they cost much more.

The converging of the strengths of columns of different grades of steel as the lengths increase has been illustrated by some tests* made by J. A. L. Waddell, M. Am. Soc. C. E. With similar columns of carbon steel and nickel steel in which $\frac{l}{r}$ was 27, the average strength of the latter was 75% greater than that of the former; with others, in which $\frac{l}{r}$ was 81, the nickel steel columns averaged only 47% stronger. This indicates clearly the convergence to equality that theory proves must exist in slender columns of high and low steel.

On the Continent of Europe the Euler formula seems to be the standard for the design of columns. This is a grave error which American engineers do not commit. The Euler formula has no application whatever to columns of ordinary lengths, as used in bridges and buildings, for the values increase as short lengths are approached, and it would require steel of almost unlimited strength to satisfy the formula and hold up under the compression.

A short time ago, a gas-holder post, in a structure in Germany, failed, with disastrous results. The column was designed by the Euler formula, which was one of the errors made by the designers,

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 250.

for it was not (as considered by them) a slender column. The gravest error made in the design was the use of batten-plates instead of lattice. Another woful lack in the theoretical treatment of columns is that of emphasis on the extreme importance of some means of carrying shear in both rectangular directions in the column. Batten-plates will not do this in any adequate degree. This column was made up of two 5-in. channels held together by a few pairs of small tie-plates. As the writer has pointed out,* these tie-plates, or batten-plates, cannot prevent the channels from bowing and acting practically as separate slender columns. Fig. 5 shows this column and how and why it could fail as a slender column. It is surprising that a high European authority, instead of condemning this flimsy construction, on the basis of common sense and theory, delivered the following: Mr. Godfrey.

"The use of tie-plated columns, when the section is assumed to be integral, may lead to constructions which do not afford adequate security under loading of unusual character."

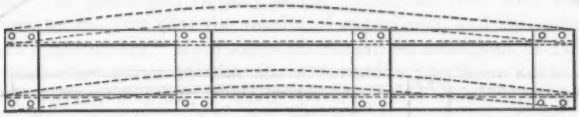

FIG. 5.

Much is said of the impracticability of securing true hinged or pin ends on columns in testing them, and the idea is prevalent that most compression members are in fact practically fixed-ended in structures. This is more of the misinformation of engineering literature. It is much easier to get a practically pin-ended member in a structure than in a testing machine. In the latter, the rigid heads and friction on the pins hold the member under test almost rigid at the ends. In a bridge, the compression members are only insecurely held by other members as weak as, or weaker than, themselves.

A case which came under the writer's notice is that of the strut of a jib crane shown in Fig. 6. The designer considered this as fixed-ended, and proportioned it by the Gordon-Rankine formula. It is no wonder that failure occurred. The writer considered the strut as of the slenderness of one of the channels, and pin-ended. This is the only reasonable way to treat it. It could fail by the bowing of the two channels, as indicated. The single pair of batten-plates could offer but little resistance. The gusset-plates, to which the ends are attached, are more nearly like ideal pin-ended connections than pins would be, for there is practically no resistance against rotation.

* *Engineering News*, July 27th, and September 28th, 1911.

Mr. Godfrey.

These are some of the things that could be written into the subject of columns to replace a vast amount of meaningless mathematics.

The subject of reinforced concrete columns has sprung up with a rank growth of mathematical nonsense which every great reinforced concrete disaster disproves. Tests are interpreted as applying to construction, while they do not embody the essential features necessary to safe construction. Columns utterly lacking in toughness are tested with infinite care (in testing) in order to preserve their evanescent strength; then such columns are built into a structure where toughness is an essential characteristic. Is it any wonder that the Engineering Profession is degraded by periodic wrecks, when its leaders show such lack of common sense?

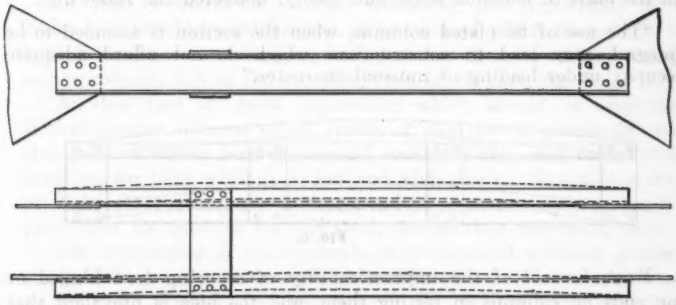

FIG. 6.

Mr. Eckersley.

J. O. ECKERSLEY, M. AM. SOC. C. E. (by letter).—This brief discussion of Mr. Lilly's suggestive paper was prompted by the question: Would it not repay the endeavor to derive a more rigorous treatment for the strength of columns? Science is truly a function of the epoch in its ideals and achievements, and technical knowledge, as we understand it to-day, is becoming pre-eminently mathematical, and justly so, for mathematics unchallenged governs the appreciation and mastery of the physical sciences in theory and practice.

Even though one has the feeling that the solution, in an absolute sense, founded on abstract mathematical reasoning, will be found impossible; at the same time, one recognizes the importance of the endeavor to attain precisely this result.

Although the demands made on mathematical science, to follow Mr. Lilly's paper, are not great, yet, if the rough and ready reasoning of the engineer gave way to the more rigorous analysis, a considerable knowledge in the realm of higher mathematics would be required.

In general, engineers, almost unanimously, regard analyses involving higher mathematics as dispensable. Judging from past experience, however, there appears to be every inducement for the mathematical

engineer to continue his studies with unflagging zeal and confident optimism, for there is little reason to doubt, and many reasons to expect, greater achievements through just such persistent pursuit of scientific investigation. Mr. Eckersley.

This attitude of engineers toward analyses is clearly shown in their endeavor to simplify everything, an endeavor economically and entirely commendable, which, however, introduces simplifying assumptions such that it is questionable whether we may with propriety consider them valid, at least from a mathematical viewpoint.

The syncopation, we might say, of the column formula is no exception. For instance, Rankine's, written in the form, $y = a\ (1 + bx^2)^{-1}$, is a cubic equation; this was simplified to a quadratic by substituting a parabola in the form of $y = c - dx^2$; and, in due time, it was further reduced to the linear form, $y = e - fx$, where the letters, a to f, inclusive, represent empirical constants determined in every case as if the simplifying assumptions of the theory of flexure, initial straightness, homogeneity, central loading, etc., were rigorously obtained. The questioned validity of the deductions from such formulas is shown by the fact that the results of experiment and the deductions are not confirmatory. More exact mathematical treatment of the question than that given by the above formulas has been advanced by several writers, English, French, German, and American; also, the effects of eccentricity and local bending between points of attachment of lattice bars are not new. Mr. Lilly's treatment of the subject, in common with others, has introduced approximations at divers places in the analysis, which permit of criticism from the mathematical standpoint.

To compare some of the salient points of difference between what we may term the rigorous, as compared with the usual, approximate treatment, let us consider the following parallel columns for reference:

	Rigorous.		Usual Approximation.
1st.	When a column is subjected to strain, its dimensions in every direction are altered, the lateral changes following a law similar to that of Hooke.	1st.	Changes of dimensions are construed as negligible.
2d.	Strains do occur in all the three mutually perpendicular planes of reference.	2d.	The strains are assumed to be entirely co-planar, *i. e.*, in one plane.
3d.	A torque would, in general, exist.	3d.	Irrotational stress is assumed.
4th.	The elastic curve, when the column weight is considered, is not a symmetrical curve.	4th.	The weight of the column is neglected, which leads to a symmetrical elastic curve.

Mr. Eckersley.

	RIGOROUS.	USUAL APPROXIMATION.
5th.	With suitable lateral forces, the so-called neutral plane may be broken or even discontinuous.	So far as the geometry of the neutral line is concerned, it is regarded as a continuous curved line having a tangent and osculating plane.
6th.	The curvature would, in general, be tortuous.	In the curvature formula, it is assumed that $dl = dx$, which reduces the exact expression, $\frac{dxd^2y}{dl^3}$, to $\frac{d^2y}{dx^2}$. (Where the curve is such that a great difference in x occurs for a small difference in y, the exact form should be retained.)
7th.	The section after strain is actually curved.	The section is assumed to remain plane.
8th.	Vertical shear-deformation exists.	Vertical shear-deformation is neglected.
9th.	The conjugate effect of transverse strain really transforms the surface of a rectangular sectioned column into an anticlastic surface.	Conjugate effect of transverse strain is neglected.

To examine the column by the more exact treatment, recourse must be had to the general equations of the equilibrium of an elastic solid, and would lead to expressions involving determinants, elliptic functions, Bessel equations, and what not, and is beyond the scope of this discussion. The column would be introduced by definition, endowed with certain ideal properties, and subjected to certain conditions not confined to empiric verification, just as a set of necessary and sufficient axioms is adopted for the various geometries, and the translation, into the language of the applied mathematical treatment, would be accomplished by substituting as many of the properties of the materials as could be experimentally determined or inferred, in lieu of the ideal.

The essential difference between such an analysis and the usual method is that evanescent quantities of a higher order would be retained and their final elimination made when the derivative governing the desired degree of accuracy was determined; while the usual method neglects certain factors in the initial assumptions and later approximations, believing that their effect on the final result is negligible,

Mr. Eckersley.

which, of course, is admissible when the degree of approximation permits, that is, when the displacements are expressed as functions of some selected system of spatial co-ordinates and are developed into series—the approximation ends with the first derivative, and we have the usual Hooke's assumption, of a plane remaining plane under strain. This order of accuracy, however, is only an approximation; yet, under certain conditions, it is sufficiently close.

What the writer wishes to bring out clearly is this: A vast literature has developed on the subject, both at home and abroad, and nowhere has he found what could be called a rigorous solution from the purely "mathematical theory of elasticity" point of view. The question in mind while writing this is: Would it not be profitable to attack the problem from such a point of view, and then use this as a means toward the interpretation and co-ordination of the phenomena? What if the analysis does involve the theory of probabilities, determinants, and higher functions? It is the pursuit along these lines which offers any reasonable excuse to engineers for the existence of anything other than a straight-line formula; for the problem from an engineer's point of view is simply this: Primarily, for very short prisms (so short that no lateral forces act), the crushing strength represents the value of the function. Secondarily, for very long prisms, in general (even though lateral forces act), the bending value is the controlling factor, and represents the function. Hence, all that the engineer desires is a rational formula giving a continuous relation between these two limiting values, even though it contains approximations.

It is obvious how complex the relations between the crushing, shearing, and bending values of the material would be for intermediate lengths, aside from the influence of local bending due to lattice bars, etc. The true form of the expression involving these would be of little interest save to the mathematical engineer, for it must be conceded that, from a practical point of view, a straight-line formula can be used successfully in the design of columns.

Finally, Mr. Lilly is to be congratulated and encouraged to continue his investigations, which will, it is believed, approach more nearly the more rigorous treatment as he considers the neglected factors.

Mr. Prichard.

HENRY S. PRICHARD, M. AM. SOC. C. E. (by letter).—The author considers the Rankine-Gordon formula to be the best of the various formulas which have been put forward to determine the strength of columns, and in support of his opinion he quotes the statement that: "The theoretic basis of Rankine's formula seems far more satisfactory than that of any other which has been proposed"; but he qualifies his opinion in respect to "theoretic basis," by stating that an assumption is made in the derivation of the formula which "errs on the side of safety."

Mr. Prichard.

In dealing with the practical side of his subject, the author gives, in Fig. 4, a curve, *A*, showing the results of some tests which he made on mild-steel solid columns, ½ in. in diameter, and another curve showing the results obtained by using Rankine's formula with constants, which he, the author, has deduced for mild steel; and he states that he "has shown that the experimental curves can be closely approximated by assuming the deflection curve of the column to vary in some proportion less than the square of the length"; that "the resulting formulas then become more complex and are of little use for the practical design of columns," and that "for this reason" he "adheres to the Rankine-Gordon as a practical working formula."

In this comparison of the Rankine-Gordon formula with the results of experiments, the constant used as "the strength to compression" is 80 000 lb. per sq. in. The writer does not share the author's opinions as to the theoretical and practical excellence of the Rankine formula, and he does not approve of the use of such a high unit stress for "the strength to compression."

Rankine, before giving his analysis of beams and columns, states that "the elasticity of every solid is sensibly perfect when the strain does not exceed a certain limit," that "Hooke's Law—*'ut tensio sic vis'*—is sensibly true for all relations between strains and stresses," and that "this condition is fulfilled in nearly all cases in which the stresses are within the limit of proof strength"; and he bases his analyses on these fundamental statements; in other words, he predicates ideal conditions.

In his analysis of beams, he derives equations for deflections based on the fact—quite true for beams—that the entire stress in the extreme fiber is due to bending. Subsequently, he makes the mistake of applying one of these equations to the deflection of columns, entirely overlooking or neglecting the fact that, in all cases of ordinary columns, part, at least, of the stress in the extreme fiber is due to direct compression. This mistake leads to an erroneous formula for columns, which, on the strength of Rankine's endorsement, has deceived and has continued to deceive engineers, and interfere with a correct understanding of the subject, for more than fifty years.

The error is reflected in the author's Equation 6 for deflection of columns, which he makes a factor of the total stress intensity in the extreme fiber, f, instead of a factor of $f - p$, as it should be (p being the load per unit area). The author prefaces this substitution with an unwarranted assumption, which, as he states, "errs," and gives what he terms "the first approximation." When f has a value of 80 000 lb. per sq. in. and the length is 60.8 times the radius of gyration, the effect of this substitution is to change the result of his Equation 7 from 80 000 to 40 000 lb. per sq. in.

Mr. Prichard.

It is astonishing that Rankine should have made, or acquiesced in, this error in regard to the deflection of columns, as a centrally loaded column, made of perfectly elastic material and having an initially straight axis, is truly a spring, and he has proved the following:*

"THEOREM. *That a spring of a given length and section, to the ends of whose neutral surface a pair of forces are applied, will not be bent if those forces are less than a certain finite magnitude.*"

He develops the equation, $P = \frac{\pi^2 E I}{l^2}$ (which is Euler's), and adds, "and this *finite quantity* is the *smallest force which will bend the given spring* in the manner proposed." For instance, a centrally loaded, perfectly elastic, initially straight spring, with a modulus of elasticity of 30 000 000 and a ratio of length to radius of gyration of 60.8, will not be bent if the load is less than 80 000 lb. per sq. in.

There is another limit to the value of P; it cannot, of course, be greater than fA (limiting stress intensity times cross-sectional area), and this latter limit governs for short columns, as the force required to strain such columns to the limiting stress intensity is less than that which it would take to bend them, if they were not thus limited. For instance, if a steel spring be conceived as having a ratio of length to radius of gyration of less than 60.8, and if the limiting stress intensity is 80 000 lb. per sq. in., the stress will reach this limit under a load of 80 000 lb. per sq. in. without any preliminary bending.

In view of the prevalent uncertainty as to the theory of perfectly elastic, initially straight, centrally loaded columns, the writer suggests that the author state whether he accepts this theorem of Rankine's; and if he does not accept it, that he indicate wherein he considers Rankine's "proof" to be in error.

For the limiting stress intensity given by the author (80 000 lb. per sq. in.), the limiting line, on Fig. 4 (beyond which initially straight, perfectly elastic, mild-steel columns will either crush or become plastic and flow, if short, or begin to bend and almost immediately fail,† if long), will follow the 80 000-lb. per sq. in. line from $\frac{l}{\rho} = 0$ to its intersection with Euler's curve at $\frac{l}{\rho} = 60.8$, and from

*"Applied Mechanics," Eleventh edition, pp. 351-352.

† In a paper on the "Theory of the Ideal Column," in *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), pp. 100-102, William Cain, M. Am. Soc. C. E., has shown: "first, that Euler's formula gives the load at which bending just begins, and, second, that a very small increase to this load insures failure." As a numerical illustration, a column pivoted at the ends, 325 in. long, was assumed as built up of two 5-in. channels. The inch being the unit, $A = 3.9$, $I = 14.8$, and $E = 29\,000\,000$ lb. per sq. in. Euler's formula gives the load that causes incipient bending as 40 105 lb. It was computed by an exact formula that an increase of the load of only 5 lb. caused a deflection of 3.44 in. at the center, with a resultant stress on the most compressed fiber greater than the elastic limit. Finally, an increase of 2 or 3 lb. more would entail rupture, or a breaking in two of the column.

Mr. Prichard.

this point it will follow Euler's curve for all longer columns. The difference between this theoretically correct line and the line, Curve 2, of the author's adaptation of Rankine's formula, shows the latter to be in error as a theoretical formula, for such ideal steel under such ideal conditions, from 0 to 50 per cent.

Of course, steel which crushes at 80 000 lb. per sq. in. is not perfectly elastic to this limit, and, of course, the other ideal assumptions of theory are not fully realized. Actually, columns are never quite initially straight and centrally loaded. There is always some initial deviation between the axis and the line of thrust (though it is not always appreciable), and this causes some deflection under any load, though in many cases it is very slight and in some it is not appreciable until the load is nearly equal to either Euler's limit, if the column is long, or to the yield point, if it is of moderate length.* Actually, the limiting stress at which failure occurs, in wrought-iron and steel columns which are too short to have Euler's formula apply, is not constant (even for material of the same quality), as indicated by theory, but varies from a stress somewhat below the yield point, for the longest columns of this class, to the yield point, for short columns, and to the crushing stress for very short ones. This is due to the great reduction in stiffness which takes place at the yield point and to the partial reduction in stiffness from imperfections in elasticity, which develops shortly before the yield point is reached.

The loss in stiffness necessary to cause failure by bending grows less as length increases; hence, the load required to cause the failure of columns of this class grows less as length increases, even when great care is taken to reduce to a minimum the initial deviation between the axis and the line of thrust.

The fact that the strength of wrought-iron and soft or medium steel columns of moderate length is limited to about the yield point, is well illustrated in Tables 2 and 3, and many other series of column tests could be cited if necessary. In fact, the writer does not know of any such columns of moderate length which sustained loads greater than the yield point of the material. In experiments, short columns, solid or of thick material, do, temporarily, at least, sustain loads in excess of the yield point, and their ability to do so has a value as a

* In illustration, the following tests are cited:
A 4-in., wrought-iron, I-beam column, 6 ft. 6¼ in. long with rounded ends and a ratio of length to radius of gyration of 161; tested by Mr. Christie, at Pencoyd, had no appreciable deflection until the load almost reached 10 300 lb. per sq. in., at which point it deflected 0.03 in. It failed at 12 113 lb. per sq. in. Euler's formula for this ratio of length to radius of gyration and for a modulus of elasticity of 27 000 000 gives 10 300 lb. per sq. in. (*Transactions*, Am. Soc. C. E., Vol. XIII (1884), p. 111.)
The Watertown Arsenal Report for 1910, p. 172, describes a steel column, 13 ft. 8¾ in. long, composed of one web 10 by ⅝ in., and four angles, 4 by 3 by ⅝ in., tested with flat ends, which had no deflection up to and including 32 000 lb. per sq. in. At 34 000 lb. per sq. in., the deflection was 0.17 in. and at 34 710 lb. per sq. in., it failed by deflection. The ratio of length to radius of gyration was 100. The yield point, as shown by tests of three similar columns with a ratio of 12, was 36 000 for this grade of steel.

Mr. Prichard.

TABLE 2.—YIELD POINT IN TENSION AND COMPRESSION, AND FAILURE IN COMPRESSION.

All bars from the same blow of Bessemer steel.

All specimens of each size from the same bar, and all of full size, "as from the rolls," except the tension tests of 3-in. flats.

All compression specimens tested with flat ends.

The specimens used for determining the yield points in compression were two diameters long.

All results are given in pounds per square inch.

Compiled from tests made by the late Charles A. Marshall, M. Am. Soc. C. E., and given in *Transactions*, Am. Soc. C. E., Vol. XVII (1887), p. 68, Tables 1 and 2.

Note the great importance of the yield point in limiting ultimate capacity.

temporary safeguard against disaster under excessive loads, even though the columns would be irreparably injured. This justifies a somewhat higher working load for such columns than would otherwise be the case.

Short wrought-iron and steel columns of such solid or thick material, however, are not much used. Most short columns are made of such thin material, have their cross-sections so distended, or have some detail so weak, that if tested to destruction, failure would occur from local bending (or, as the author aptly terms it, secondary flexure), or from the giving way of some detail, under a load not much, if any, greater than the yield point.

The yield points of wrought iron and steel are, beyond question, the critical stresses for wrought-iron and steel columns, and should be

substituted for the crushing resistances given in Table 1 as "the strength to compression." Mr. Prichard.

In this connection, it is useful to know that the yield point of steel (and probably of wrought iron) is practically the same, for metal of the same quality, in compression and tension. This is illustrated in Tables 2 and 4 (after allowing for the fact that the yield points in compression, in Table 2, were determined from very short specimens, which tends, whether the stress be compression or tension, to raise somewhat the yield point), and many other cases could be cited if necessary.

TABLE 4.—COMPARATIVE TESTS IN TENSION AND COMPRESSION OF SPECIMENS, 1¼ IN. IN DIAMETER, FROM OPEN-HEARTH, STEEL BARS OF TEN GRADES.

Specimens turned to 1.0092 in. in diameter. Compression specimens 12 in. long, with ratio of length to radius of gyration of 48.
Compiled from Watertown Arsenal Reports for 1886 and 1887.
All loads in pounds per square inch.

Note that the yield point in tension and compression is about the same for each grade, and that failure of compression specimens of the five lowest grades occurred near the yield point.

Digressing, somewhat, from the direct theme of this discussion: Some engineers, in discussing the question of local slenderness or weakness, have advocated the doctrine that columns should be designed so that they cannot fail from local slenderness or weakness, but will, if tested, develop the full strength of the column considered as a whole. This is entirely a matter of economy and convenience, and of having ample stiffness and sufficient strength to carry the load required with an ample margin of safety. If the column design is good in these respects, there is no reason whatever for changing to a less economical or convenient form of cross-section. The cross-section usually has to be designed with reference to connections, method of loading, and other practical considerations, and, when thus designed, is likely to have section and dimensions which, though amply strong and stiff, will not

Mr. Prichard.

develop the strength of the column, as gauged by its length, radius of gyration, and cross-sectional area, unless sectional area not needed for any other purpose is added. The important consideration is that the strength of a column shall be gauged by its weakest feature.

Reverting to a direct discussion of the paper: The Rankine formula is not a satisfactory one for practical use. It cannot be made to agree well with the results of tests of wrought-iron and steel columns of moderate length, and, when the constants are adjusted to make the formula agree as well as may be with the results of tests of such columns, it gives results much too high for long columns. On the other hand, if, by suitable constants, the formula is made to give proper values for long columns, it gives results unnecessarily low for those of moderate length, and, with the same constants, may give results altogether too high for short columns, as is the case with the author's adaptation of the formula, as gauged by his own experiments. These facts are shown in Table 5, in which it is also shown that, when an allowance is made for slight unintentional eccentricity, to the extent recommended by A. Marston,* M. Am. Soc. C. E., the author's recent experiments confirm with remarkable closeness the theory of eccentrically loaded columns. The comparison is all the more striking and convincing from the fact that the experiments were made by an advocate, on theoretical grounds, of the Rankine formula, who is, presumably, free from any prejudice in favor of the theory which, with some variation in detail, is supported by the analyses of Messrs. Marston, Cain, Moncrieff, Johnson, Jonson, and others who have discussed the subject of columns before this Society.

Marston's equation for nominally centrally loaded columns, and the close approximations to Marston's equation which others have derived, are tedious to apply, but they can be closely approximated as to results by easily applied empirical formulas. The following empirical formulas agree well with the results of the author's experiments on solid mild-steel columns, ½ in. in diameter, except in the case of very short ones, which failed at loads above the yield point. (These loads were, doubtless, much higher than those which the columns could permanently sustain without undue deformation).

For ratios of length, l, to radius of gyration, ρ, of 100 or less,

$$p = 58\,000 - 3\left(\frac{l}{\rho}\right)^2 \qquad (a)$$

For ratios of length to radius of gyration of 100 or more,

$$p = \frac{300\,000\,000}{\left(\frac{l}{\rho}\right)^2 + 7\,\frac{l}{\rho}} \qquad (b)$$

p being the load per square inch of cross-sectional area.

* *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), pp. 108–118.

TABLE 5.—COMPARISON OF LOADS CAUSING FAILURE OF SOLID MILD-STEEL ROUND-ENDED COLUMNS, ½ IN. IN DIAMETER, TESTED BY W. E. LILLY; AS SCALED FROM FIG. 4, WITH RESISTANCE INDICATED BY THEORY, RANKINE'S FORMULA, AND EMPIRICAL FORMULAS, *a* AND *b* (Equations *a* and *b*).
All results are given in pounds per square inch.

*First published by A. Marston, M. Am. Soc. C. E., in *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), pp. 108-113, and since endorsed by many authorities. Marston used a value of 0.06 for $\frac{e\,y}{\rho^2}$ in comparing his formula with Tetmajer's tests of mild steel. This value applied to ½-in. round bars gives $e = 0.00375$ in., as above.

Note that Rankine's formula cannot be made to agree with the "Experiments," while "Theory" agrees very closely when slight eccentricity is assumed.

Mr. Prichard.

These equations are arranged for the sole purpose of formulating the author's experiments on solid mild-steel columns, ½ in. in diameter, and, as arranged, are presented without recommendation for any other purpose. When made entirely general for any grade of steel or wrought iron, they become

$$p = \text{yield point} - \text{constant} \left(\frac{l}{\rho}\right)^2 \quad \ldots\ldots\ldots\ldots (c)$$

$$p = \frac{\pi^2 \times \text{modulus of elasticity}}{\left(\frac{l}{\rho}\right)^2 + x\left(\frac{l}{\rho}\right)} \quad \ldots\ldots\ldots\ldots (d)$$

The range of application of Equation *c*, and the value of its constant, have to be chosen to suit the series of columns for which the formulas are arranged. The value of x has then to be found by first determining the value of p for the length of column at which the application of Equation *c* ends and Equation *d* begins.

Equation *c* is a parabola; a form which the late J. B. Johnson, M. Am. Soc. C. E., advocated for short columns and those of moderate length. He, however, made his parabolas always tangent to Euler's curve, and advocated Euler's formula for long columns. On this basis, the constant for columns with pivoted ends is always

$$\frac{(\text{yield point})^2}{4\,\pi^2 \times \text{modulus of elasticity}}.$$

The writer prefers to increase the constant and modify Euler's formula for long columns, as per Equation *d*, in order to make a greater reduction for length. For bridges and buildings, long columns are usually tabooed, but for some kinds of construction they are not objectionable.

Professor Johnson compared his column formula with the very careful tests made by M. Considère. The tests with which the formulas were compared were of columns consisting of rectangular steel bars with pivoted ends, adjusted so that there was no appreciable eccentricity. The bars were of six degrees of hardness, and the results when plotted agreed with the corresponding six parabolic curves of the formula to an extent that was truly remarkable.

To show that the strength of a column, unless it is very short, is no function of the ultimate strength of the material, either in tension or compression, M. Considère cold-rolled the medium-hard steel, No. 5, which had a yield point of 47 000 lb. per sq. in., until it had elongated 10% of its original length. This raised its yield point to 71 000 lb. per sq. in., while its ultimate tensile strength was raised only from 83 000 to 88 500 lb. per sq. in. The columns of this steel, No. 6, with the yield point of 71 000 lb. and an ultimate of 88 500 lb. per sq. in., were stronger (in the maximum case more than 10% stronger) than the columns of steel, No. 8, with a yield point of 64 000 lb. and an ultimate strength of 98 000 lb. per sq. in.

Mr. Prichard.

Professor Johnson also showed that his parabolic formula agrees well with other tests, notably Tetmajer's.* His (Johnson's) diagrams, comparing his parabolic formula with Tetmajer's tests, were reproduced by Mr. Marston,† with the locus of his (Marston's) formula for eccentrically-loaded columns added, in his discussion of Professor Cain's paper on the "Theory of the Ideal Column." They were again published, as given by Marston, in Professor Cain's discussion‡ of the paper on "Safe Stresses in Steel Columns," by J. R. Worcester, M. Am. Soc. C. E.

These diagrams are very interesting and instructive. They show a close resemblance between tests and theory when provision is made in theory for the inevitable initial deviation between the axis and the line of thrust; that a parabolic, empirical formula for short columns and those of moderate length is about as good and much simpler than the theoretical one; and that the averages of the tests agree well with the parabolic formula advocated by Professor Johnson; but they also show that a curve which gives more reduction for length accords better with the minimum results.

This was one of a number of facts which influenced the writer, in discussing Mr. Worcester's paper,§ to advocate a formula which gives a greater reduction. The formula, the reasons for advocating it, the method of using it in cases of intentional eccentricity, the additional limitations suggested for short columns, and other practical and theoretical considerations were outlined in this discussion and need not be repeated here, but it is best to add a caution with regard to the yield point.

The yield point varies greatly, even in steel from the same melt, as shown in Table 3, and will cause great differences in the strength of columns of ordinary lengths. This is especially important in dealing with columns made of thick plates and large, thick angles, which are likely to have much lower yield points than thinner and smaller sizes of nominally the same grade of steel. It will not do, in such cases, to pin one's faith unreservedly to any formula, no matter how well it is supported by tests of solid bars, ½ in. in diameter, or other small shapes.

Such tests, however, are very useful in determining experimentally the laws of columns by systematically varying one condition while others remain constant. The author's tests are to be commended, in this regard. To plat columns differing greatly in yield point, eccentricity, end restraint, and local stiffness on the same diagram in a kind of hodge-podge, only leads to confusion and tends to discredit the

* The information regarding Professor Johnson's parabolic formula and M. Considère's tests is taken from Professor Johnson's "Materials of Construction," pp. 361-363, and "Modern Framed Structures," pp. 148-152.

Mr. Prichard. valuable information which has been acquired by analytical and experimental investigation. The value of rational investigation, in which sound theory explains and supplements experiments and experiments put to the test and verify sound theory, should receive general recognition.

An important step in this direction will have been taken when it becomes generally recognized that Rankine's formula is based on a blunder caused by a plausible but fallacious assumption of analogy in deflection of beams and columns, that it has only the semblance of a "theoretic basis," and that it is not even a good empirical formula for wrought iron and steel.

Mr. Branne. J. S. BRANNE, M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest, and has been especially attracted by the attempt to find the size of lace-bars to connect the component parts of the columns, in order that said parts may act truly as one piece in the distribution of loading, which produces, generally, both direct compressive stresses and bending stresses, as it may be; and that even wide columns, meaning those of a low ratio of $\frac{l}{r}$ have some side deflection due to compressive loading, speaking now of such deflection in an "ideal column."

That there is a natural irregularity and deviation from a straight line, due to lack of uniformity in the component parts, is well known to all engineers, this very thing making the theoretical determination of strength so hard to reconcile with the data as actually revealed by tests.

It seems to the writer that there are two kinds of compression members: the wide ones and the slender ones; the first failing by flow of metal, directly compressed, the second by flow and flexure stresses, which latter are induced by the sidewise deflection of the compression member. By failing is here meant "a perceptible set, showing unfitness for further loading, not actual destruction."

Experiments have shown that wide columns, when properly fabricated, fail when the nominal unit stress approaches or ranges around the elastic limit. The experiments made by Mr. James E. Howard* show test results on wide columns. Just where to draw the line between "wide" and "slender" columns is not so easy. The Progress Report of the Special Committee on Steel Columns and Struts† gives a series of diagrams of tests, which are condensed into one diagram, Fig. 23, showing the results of many tests. The curves are quite flat up to $\frac{l}{r} = 70$, after which they drop more sharply.

* *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 429.

† *Transactions*, Am. Soc. C. E., Vol. LXVI, p. 401.

Mr. Branne.

The cross-sections of the columns in Mr. Howard's tests were about 90 sq. in., and the ratio, $\frac{l}{r}$, was 26 for Column No. 1, and 47 for Columns Nos. 2 to 5. Columns Nos. 1 and 2 did not fail; but Nos. 3, 4, and 5 did fail, Nos. 3 and 4 in the pin-plates, and No. 5 in the body of the column. The manner of failure in No. 5 was that the webs buckled, resulting in a "sharp bend, or set"; Mr. Howard's Fig. 1, Plate XLII, shows a photograph of Column No. 5 after failure.

In none of these columns was the failure induced to any perceptible degree by flexure stresses, as such combined action of direct compression and bending would have caused failure somewhere below the elastic limit.

It must be remembered here that the test pieces of the component parts showed quite a variation in tensile strength, which makes it impossible to refer to a certain magnitude as the elastic limit of the column, as a whole. Columns Nos. 3 and 4 failed at points where the punching of many holes (with much subsequent riveting) induced numerous and complex local stresses; No. 5 failed by the buckling of the web at a point 12 ft. 8 in. from the end, probably due to local weakness, for the test load gave a nominal average unit stress of 30 490 lb. per sq. in. In these columns the lace-bars could not have had much to do before the elastic limit of the column was reached, when locally weak spots put them into activity. It does not seem possible to calculate the lace-bars in wide columns which fail at unit stresses approaching or ranging around the elastic limit. If lacing is used in such columns, it should be quite heavy, in order to take care of local weaknesses; or, still better, lacing should be avoided, and one should use cover-plates or continuous diaphragms, forming part of the section of the column, so as not to waste material.

If heavy lacing is used, the tie-plates at the ends of the columns should be long and thin, rather than short and thick, to steady up the member as much as possible; and where the component parts are fairly wide, say 15 in. or more, diaphragms should be used at the ends, in addition to the plates, thus helping to equalize the stresses carried into the compression member. Similar precautions should be taken at intermediate points where loads are applied.

As to columns of the second kind, namely, the slender ones, all tests show that failure occurs much below the elastic limit, clearly indicating the presence of bending stresses in addition to the direct compressive stress. The bending will induce shear in the columns, producing compressive or tensile stresses in the lace-bars.

If the deflection be assumed to result from a uniform transverse loading, which assumption is not quite correct, it will be evident that the stresses in the lace-bars are greatest at the ends of a free-end column. If the column is not free to move at the ends, but stands

Mr. Branne.

between this type and the one with restrained ends, the shear is also greatest at the ends, necessarily, but it is evident that greater care should be taken in this latter type to tie the component parts together more securely at the ends than for free-end columns. If comparison be made, then, with uniformly-loaded beams, it will be noticed that in one with free ends the longitudinal stress caused by the maximum center bending moment, $+\frac{wl}{8}$, has to be transmitted from the compression side to the tension side in a length, $\frac{l}{2}$; in the one with restrained ends, the same amount has to be taken up (from $+\frac{wl}{24}$ at the center to $-\frac{wl}{12}$ at the ends), but this presupposes that the column is held rigidly at the ends, a bending moment, $-\frac{wl}{12}$, is already supposed to exist, and this should be taken care of by extra long tie-plates or diaphragms between the channels.

To proportion the lace-bars under the assumption of uniform transverse loading, a working formula has to be used, for example, American Bridge Company, medium steel, $17\,000 \div \frac{1}{11\,000}\left(\frac{l}{r}\right)^2$, or American Railway Maintenance of Way Association, $16\,000 = 70\,\frac{l}{r}$, and the reduction of fiber stress is assumed as the unit extreme fiber stress due to bending, whence the uniform load can be found.

On this basis of approximating the real conditions, which certainly are unknown, it will be found:

(1) When the column is slender, yet the section not great, the average specification covers the size of lattice-bars very well.

(2) When the column section becomes quite heavy, and, at the same time, due to space requirement of some kind, the component parts, generally channel-shaped, are placed closely together, making failure evident in the lace-bars, it will be found that the generally used lace-bars, as given in the specifications, are not strong enough, but must be increased, finally resulting, economically, in doing away with lacing and substituting cover-plates, or a continuous diaphragm, as noted before.

Finally, as regards the wide column, while the lace-bars can have nothing to do from a theoretical sidewise deflection, at the same time, one component part may be stressed more than the other, due to a

faulty foundation or a small error in fabrication, causing an uneven unit stress, which produces stresses in the lacing. As long as the component parts are small, such unevenness can be cared for by the lacing taking up the longitudinal shear; but, when the component parts are very heavy, the lacing cannot make them act as one, for, being proportionally so much lighter than the component parts, they become overstrained and yield. Cover-plates or continuous diaphragms cannot, of course, overcome the faults of foundation or errors in fabrication, but have the strength to transmit unevenness of stress without becoming overstrained, thus making the column act as one homogeneous piece, reducing the unevenness of stress in the component parts. Mr. Branne.

The tests conducted by Arthur N. Talbot, M. Am. Soc. C. E., at the University of Illinois Engineering Experiment Station,* showed an irregular action of the lace-bars, some of the bars showing more stress near the center than at the ends. Further data bearing on these tests may be found in the many interesting notes in the same bulletin.

W. E. LILLY, ESQ. (by letter).—Mr. Godfrey's discussion contains a great deal of controversial matter regarding the strength of columns, and the writer will endeavor to reply to some of the points that have been raised. It is to be regretted, however, that Mr. Godfrey was not more definite in stating his objections. Vague statements, unless based on reasoning of some kind or experimental evidence, can hardly be considered as discussion on the subject. Mr. Godfrey states that he has repeatedly assailed both the Rankine-Gordon and Euler formulas for columns, and has observed and demonstrated, in his practice and reading, that confidence in these formulas has resulted in failure. The writer totally differs with him, after an examination of the majority of the tests made on columns. From the results of his own experiments, he has come to the conclusion that the Rankine-Gordon formula, when secondary flexure is allowed for, may be relied on for the design of columns; and, as he has shown in previous papers, it gives results which agree more closely with the experimental tests than can be obtained by the use of any other formula; further, the formula is logically derived, a merit not possessed by any other column formula. He has fully discussed the derivation of both the Rankine-Gordon and Euler formulas in the papers referred to in the Appendix. Mr. Lilly.

Mr. Godfrey's examples of the uses of Rankine-Gordon's and Euler's formulas are unfortunate, and show how dangerous it is to use the constant in the Rankine-Gordon formula without knowing how it has been derived. Euler's formula always gives a greater value than that obtained from the Rankine-Gordon formula under similar conditions of column loading. The writer would refer Mr. Godfrey

* *Bulletin No. 44*, June 6th, 1910.

Mr. Lilly. to the constants given in the paper and to the manner of their derivation.

Mr. Godfrey states that the Rankine-Gordon formula fails to meet the needs of the practical design of columns, and that the straight-line formula is far superior. It gives results closer to those obtained from experiments, and there are several reasons why it should. In the paper the writer has referred to the merits of the Rankine-Gordon formula as a practical one for the design of columns, and does not propose to discuss it further. He has also referred to the straight-line formula. His own experiments show that it does not give results which agree closely with the experiments, and there are no reasons, based either on theory or experimental evidence, why it should.

Mr. Godfrey mentions two instances of columns, in which the component parts were joined by batten-plates and of the disastrous results which followed the use of these columns. The writer agrees with Mr. Godfrey that lattice bracing should be used, as columns of this kind cannot transmit the shear stresses set up by the bending of the columns.

Mr. Eckersley's remarks are generally in accordance with the writer's views; the mathematical treatment of the column problem, however, in the present state of knowledge, appears to be so full of difficulties as to be almost incapable of rigorous solution, notwithstanding the efforts made in this direction by various investigators. It is for this reason that so many semi-empirical formulas have been put forward at different times, and of these, as stated in the paper, the writer considers the Rankine-Gordon formula, together with his own modification of it, to be the best.

He thinks that any attempt to solve the column problem should be approached somewhat as follows: Let a solid column, as shown by Fig. 1, be given, in which the load is applied at a given eccentricity, e. When loading is gradually applied to the column, it commences to bend or deflect, and the magnitude of the deflection depends on the elasticity of the material, other quantities being assumed as constant. As the loading is increased, the deflection increases, and when it reaches a limiting value, depending on the strength of the material, failure of the column takes place. The problem thus considered shows that, among other quantities, three are involved, namely, the coefficient of elasticity, E, the strength of the material, f, and the deflection, d, when failure of the column takes place.

It follows that any column formula must of necessity, among other quantities, include these three, if it is to be generally applicable. The mathematical treatment of the problem leads to difficulties in determining the deflection, d, and as far as the writer is aware, it can only be approximated to. It remains for future investigators to determine the rigorous form of the function governing the deflection.

The formation of a satisfactory column formula will then be an easy matter. Mr. Lilly.

Mr. Prichard's remarks require a more detailed reply, and the writer will endeavor to discuss the more salient points raised. Mr. Prichard states that he "does not share the author's opinions as to the theoretical and practical excellence of the Rankine formula, and he does not approve of the use of such a high unit stress for the 'strength to compression'"; and, further, after referring to Rankine, he states:

"Subsequently, he [Rankine] makes the mistake of applying one of these equations to the deflection of columns, entirely overlooking or neglecting the fact that, in all cases of ordinary columns, part, at least, of the stress in the extreme fiber is due to direct compression. This mistake leads to an erroneous formula for columns, which, on the strength of Rankine's endorsement, has deceived and has continued to deceive engineers, and interfere with a correct understanding of the subject, for more than fifty years.

"The error is reflected in the author's Equation 6 for deflection of columns, which he makes a factor of the total stress intensity in the extreme fiber, f, instead of a factor of $f - p$, as it should be (p being the load per unit area). The author prefaces this substitution with an unwarranted assumption, which, as he states, 'errs', and gives what he terms 'the first approximation'."

With regard to the foregoing remarks, either Mr. Prichard is in error, or he has not studied the underlying assumptions made in the derivation of the Rankine-Gordon formula; for the real point of the formula is that it does allow for the stress in the extreme fiber due to direct compression. Mr. Prichard is also in error in stating that $f - p$ should be used for p in the derivation of the formula, and the writer would refer him to the articles in *Engineering*, quoted in the appendix to the paper, in which he will find the Rankine-Gordon and Euler's formulas fully discussed. There is no doubt that, after perusing the same, he will qualify his opinion regarding the substitution referred to being an unwarranted one. Mr. Prichard then quotes from Rankine the theorem underlying the Eulerian analysis of a spring or slender column, and states:

"In view of the prevalent uncertainty as to the theory of perfectly elastic, initially straight, centrally loaded columns, the writer suggests that the author state whether he accepts this theorem of Rankine's; and if he does not accept it, that he indicate wherein he considers Rankine's 'proof' to be in error."

In the articles in *Engineering* previously referred to, the writer has already stated his objections to the Eulerian analysis, and pointed out wherein it errs; the assumption of I, the moment of inertia, remaining constant when applied to columns is false; also the value of E does not remain constant outside the range of the elastic limits. An article

Mr. Lilly. in *Engineering** on the strength of columns will give Mr. Prichard further information on this point.

Mr. Prichard does not agree with the writer's high unit stresses adopted for the strength to compression, and states:

"The yield points of wrought iron and steel are, beyond question, the critical stresses for wrought-iron and steel columns, and should be substituted for the crushing resistances given in Table 1 as 'the strength to compression'."

The writer does not agree with this statement; from his own experiments he is of the opinion that the yield point can only be determined with any degree of accuracy on annealed bars. On bars which had been subjected to cold rolling or to permanent strain he doubts whether any real yield point could be said to exist. He thinks that too much importance has been attached to this quantity as a standard measurement. Tables 2 and 3, given by Mr. Prichard, show a variation of the values from 29 000 to 49 000 lb. per sq. in., and, in view of such wide variations, the writer prefers to retain the values for the strength to compression given in the paper. He would refer Mr. Prichard to a paper on the elastic limit and strength of materials,† in which the above points are more fully discussed.

Mr. Prichard refers to the formula for columns given by Marston, and states, in Table 5, that this formula was first given by Marston in the *Transactions*, Am. Soc. C. E., Vol. XXXIX, and since endorsed by many authorities. Mr. Prichard is in error; the formula was given, as long ago as 1878, by Smith,‡ and modifications of it have been given by Perry and Neville. Mr. Prichard puts forward this formula as a rigorously theoretical one; this, however, is not the case, as the writer showed in the articles in *Engineering* already referred to. Considered from the point of view of a practical column formula, it is open to many objections. The values given in Table 5 show this. In the particular case when the eccentricity, $e = 0$, the loads on the column, for values of $\frac{l}{\rho}$ between 0 and 70, are all equal, and, for values greater than 70, the loads follow the Eulerian curve; this is equivalent to assuming that, for values of $\frac{l}{\rho}$ between 0 and 70, the column has no deflection when failure takes place, and then for values of $\frac{l}{\rho}$ greater than 70 for the deflection to vary approximately as the square of the length of the column. This is contrary to experience, as shown by tests on columns, and is evidently incorrect. To assume some value

* August 23d, 1912.

† Read before the Institution of Civil Engineers of Ireland, December 6th, 1911.

‡ *Proceedings*, Edinburgh and Leith Engineering Society.

for the yield point of the material from experiment, and then to assert that no column within the range of $\frac{l}{\rho}$ between 0 and 70, when loaded with the load per unit of area, will bend, is inconceivable; and yet this is the standpoint from which Mr. Prichard bases his faith in the Smith-Marston formula. Experiments show that columns always bend before failure takes place, and the writer is of the opinion that some function of the length must be assumed for the deflection in the derivation of any useful column formula. It is in this respect that the Eulerian analysis has had such a retarding influence on investigations on columns, in the enunciation of a critical load as obtained from Euler's formula, together with a zero deflection of the column, in contradistinction to the idea that the essential point to be considered is the deflection of the column when failure takes place. The Smith-Marston formula has never found favor with engineers, owing to its being troublesome to use in practice; if it were theoretically correct, this would be no argument against it, but, as it is not, there is nothing to be gained in using it. In conclusion, Mr. Prichard states: Mr. Lilly.

"An important step in this direction will have been taken when it becomes generally recognized that Rankine's formula is based on a blunder caused by a plausible but fallacious assumption of analogy in deflection of beams and columns, that it has only the semblance of a 'theoretic basis,' and that it is not even a good empirical formula for wrought iron and steel."

The statement of the derivation of the Rankine-Gordon formula is incorrect; if anything, it applies more nearly to the formula advocated by Mr. Prichard, as the writer has shown in the articles already referred to.

Mr. Branne's remarks are of interest to the writer. As far as he is aware, the Rankine-Gordon formula is the only one which permits the determination of the sizes of the bracing in a logical way, and the examples given in the paper show that the results obtained by its use are closely correct. From a comparison of the tests carried out on columns, it is difficult to generalize, owing principally to the limited range of the length of the columns tested, and it is to be hoped that, in the future, in arranging for further experiments, this point will be borne in mind.

In conclusion, the writer thanks those gentlemen who have discussed the paper. Some difference of opinion was to be expected, the subject being one of much complexity. If the paper leads to a co-ordination of the results of the tests on columns, the writer will feel that he has been amply repaid for the labor of preparing it.

Paper No. 1249

THE FLOOD OF MARCH 22D, 1912, AT PITTSBURGH, PA.*

By Kenneth C. Grant, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, William R. Copeland, Jean de Pulligny, J. Waldo Smith, Morris Knowles, and Kenneth C. Grant.

On March 22d, 1912, the Allegheny and Monongahela Rivers, which join at Pittsburgh to form the Ohio, reached a gauge height of 28.1 ft., the highest stage since February 16th, 1908, when there was a 30.7-ft. flood.† Except for a second flood, on March 20th, 1908, which reached a stage of 27.3 ft., no other flood of importance had occurred at Pittsburgh for four years, although the danger line, 22 ft., had been reached several times, the highest stage occurring on January 31st, 1911, when the rivers rose to a gauge height of 25.2 ft. The record stage of 35.5 ft. occurred on March 15th, 1907, when about $6 000 000 of flood damage resulted.

In view of the exhaustive studies looking toward methods of flood relief that have been made by the Flood Commission of Pittsburgh, which has recently published its report, it is thought that a brief description of the recent flood will prove of interest. To this description has been added a graphical study of the peak reduction that could have been obtained if the system of storage reservoirs proposed by the Flood Commission had been in operation.

* Presented at the meeting of November 6th, 1912.

† The portion of this paper describing the flood was in large part written directly after its occurrence, and published in *Engineering News* of April 4th, 1912. Since this first writing, additional data have become available, and the description has been modified and enlarged accordingly.

At 8 A. M., on March 21st, 1912, the gauge at Pittsburgh registered 17.9 ft. For 5 days prior to this date the rivers had been flowing fairly full, the gauge readings at Pittsburgh varying between 13 and 18 ft. The weather had been mild, and the high temperatures that prevailed for part of the time had gradually brought the ice out of the tributaries and head-waters of the Allegheny. The ice on the Monongahela and its tributaries had gone out some time before. Had cold weather continued until the 20th, when the flood rainfall began, the ice on the Allegheny would have been held back until then, the flood would have been considerably higher, and might have been dangerously increased by ice gorges. The ice moved out of the Upper Allegheny and its tributaries on the 17th. On the Clarion River a heavy gorge formed below Clarion, raising the stage at that place to 13.0 ft. on the 16th, which rapidly reduced to 4.6 ft. on the 17th, when the ice moved out early in the morning. Ice was running on the Allegheny at Parker on the 16th and 17th, and began passing Freeport on the morning of the 17th.

During the 21st the rivers at Pittsburgh rose rapidly and crossed the danger line, or the 22-ft. stage, about 2 P. M., rising steadily until 5 A. M. on the 22d, when the maximum of 28.1 ft. was reached. The crest remained at this level for 2 hours and then dropped at about the same rate as it had risen, falling below the danger line at about 2 A. M. on the 23d, and registering 19.6 ft. at 8 A. M. The rise was probably checked to some extent by a sudden drop in temperature on the 21st. The water was above the danger line for about 36 hours, during which time the total discharge above the 22-ft. stage was about 6 221 000 000 cu. ft. The discharge at the crest of 28.1 ft. was about 300 000 sec-ft.

All the rain causing this flood fell practically in the 12 to 14 hours preceding 8 A. M on the 21st, although in some sections it continued for a few hours after this time. After the middle of March, with the exception of an inch or two in the extreme northern part of the Allegheny Basin, there was no snow on the ground to contribute to the flood run-off.

The precipitation was lightest over the Northern Allegheny Basin, where it was mostly in the form of snow. The Upper Allegheny, therefore, contributed little to the rise, especially as practically all the 6 in. of snow which fell was still on the ground on March 23d. French Creek was at a fairly high stage, being above 10 ft. throughout the

20th and 21st. The Clarion, however, rose to only 6.6 ft., 9.4 ft. below record stage, and Red Bank, Mahoning, and Crooked Creeks were not large contributors, so that the Allegheny at Kittanning rose to only 17.2 ft., 12 ft. below record stage, at 4 P. M. on the 21st. At Freeport, the river registered 23.2 ft. at 6 P. M. on the 21st, when the water was rising at the rate of 0.1 ft. per hour. The main contributor from the Allegheny Basin was the Kiskiminetas River, which reached a stage of 28.0 ft. at Avonmore at 8 P. M. on the 21st, 9 hours before the crest was reached at Pittsburgh.

On the Monongahela Basin, the Cheat, Tygart Valley, and West Fork Rivers were not important factors in the rise. The Youghiogheny, however, was an important contributor, and, with the Kiskiminetas, was the main cause of the high stage attained at Pittsburgh. It reached a stage of 22.7 ft. at West Newton at 8 P. M. on the 21st. Except during the flood of March, 1907, when the maximum at West Newton was 28.2 ft., this river had never been higher than 22.0 ft. at this station. The time necessary for floods of these heights to move from West Newton and from Avonmore to Pittsburgh is from 9 to 12 hours, and both the Youghiogheny and Kiskiminetas, therefore, must have delivered their greatest discharge at Pittsburgh at about flood-peak time, between 5 and 7 A. M. on the 22d.

The high stages in the Kiskiminetas and Youghiogheny Rivers were to be expected, as the rainfall was heaviest over their basins. The maximum rainfall recorded during this storm was at Lycippus, Pa., on the Kiskiminetas Basin, where 3.05 in. fell in the 12 to 14 hours following the evening of March 20th. The next greatest rainfall was at Johnstown, Pa., on the same basin, where 2.91 in. fell during the same period. The region of greatest rainfall centered around these stations. Toward the north the recorded rainfall decreases rapidly in amount, and it is evident that, with the exception of the Kiskiminetas Basin, little of the Allegheny Basin received more than 1 in. of rainfall, while a considerable portion received only ½ in., or less. Toward the south the amount of rainfall recorded decreases more gradually to about 1 in. near Grafton and Parsons, W. Va., and farther south, near the head-waters of the West Fork, to less than ½ in. A considerable portion of the Monongahela Basin, therefore, mostly included within the Youghiogheny water-shed, received 2 in. or more of rainfall, while the larger part received more than 1 in.

The rainfall causing this flood is given in Table 1, and the map of the basins, Fig. 1, shows its distribution. Table 2 gives the daily gauge heights at stations on the main rivers and their tributaries before and after the time of the Pittsburgh peak, including time and height of maximum stage in so far as records exist.

Damage by Flood.—The damage caused by this flood in Pittsburgh and in other communities bordering the rivers above and below that city was considerable. A careful census of flood damage, made by the Pittsburgh Flood Commission after the 27.3-ft. flood of March 20th, 1908, showed a direct loss at Pittsburgh alone, for a flood about 1 ft. lower than the recent stage, of more than $400 000. It would seem reasonable, therefore, to place the direct loss in the recent flood at about $500 000, although, when complete information is at hand, this figure may be modified, especially as certain streets in the flooded district were raised during 1911. About 250 acres of the low-lying

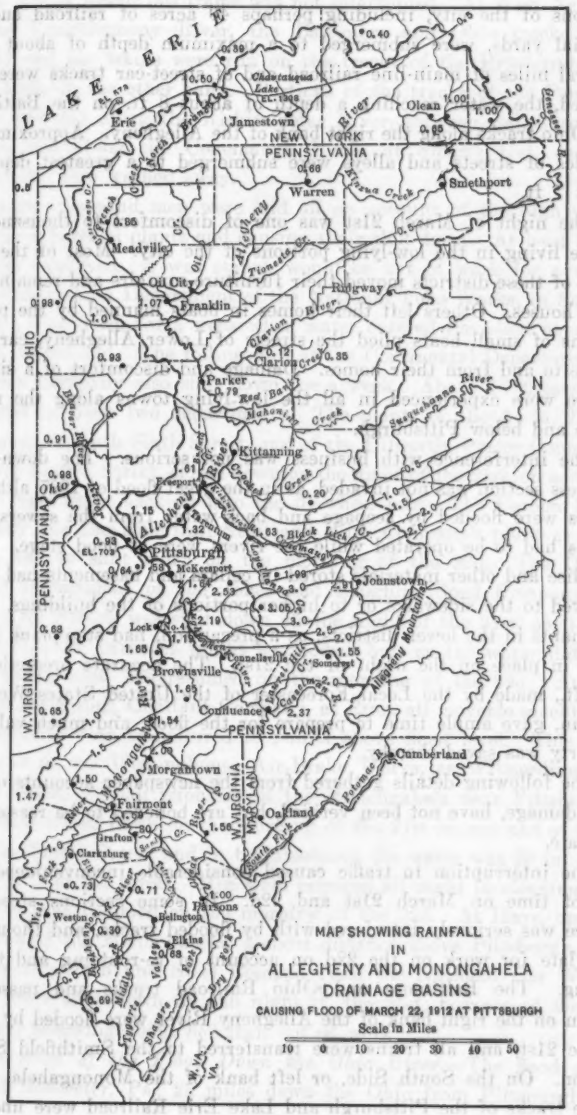

FIG. 1.

TABLE 2.—DAILY GAUGE HEIGHTS AT RIVER STATIONS, FLOOD OF MARCH 22D, 1912, AT PITTSBURGH.

portions of the city, including perhaps 40 acres of railroad and industrial yards, were submerged to a maximum depth of about 9 ft. Several miles of main-line railroad and of street-car tracks were submerged, the water reaching a depth of about 8 ft. on the Baltimore and Ohio tracks along the right bank of the Allegheny. Approximately 6 miles of streets and alleys were submerged to a greatest depth of about 7 ft.

The night of March 21st was one of discomfort to thousands of people living in the low-lying portions of the city. Most of the residents of these districts moved their furniture upstairs and remained in their houses. Others left their homes in boats manned by the police. Dozens of small boats plied the streets of Lower Allegheny, carrying people to and from their homes. Damage and discomfort of a similar nature were experienced in all the low-lying towns along the rivers above and below Pittsburgh.

The interference with business was not serious. The down-town business section was not invaded, as in the great flood of 1907, although cellars were flooded by seepage and back-water from the sewers, and pumps had to be operated while the rivers were at flood stage. Merchandise and other materials stored in cellars and basements had to be removed to the sidewalks or to higher portions of the buildings. The merchants in the lower districts, as a precaution, had stop-plank floodgates in place on the night of the 21st. The accurate prediction of 28.0 ft., made by the Local Forecaster of the United States Weather Bureau, gave ample time to prepare for the flood, and much valuable property was saved thereby.

The following details gathered from the newspaper accounts of the flood damage, have not been verified, but are believed to be reasonably accurate.

The interruption to traffic caused considerable inconvenience and loss of time on March 21st and 22d. In some sections street-car service was seriously interfered with by flooded tracks, and thousands were late for work on the 22d on account of re-routeing and transferring. The Baltimore and Ohio Railroad tracks and passenger station on the right bank of the Allegheny River were flooded by noon on the 21st, and all trains were transferred to the Smithfield Street Station. On the South Side, or left bank of the Monongahela, some of the tracks of the Pittsburgh and Lake Erie Railroad were under a

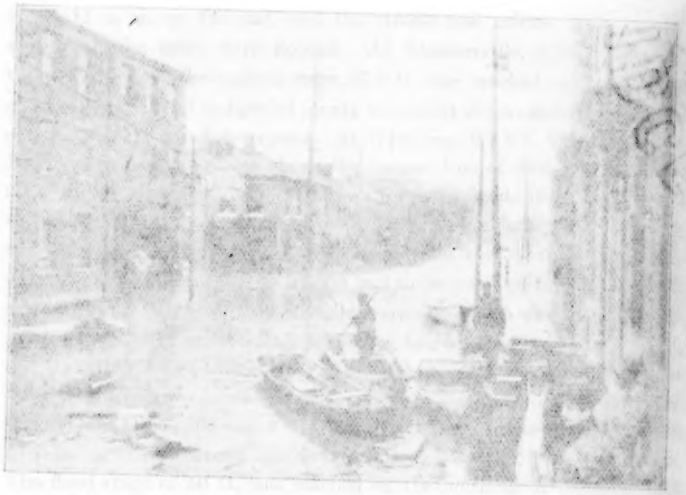
few inches of water, but traffic was not interrupted. At West Newton, on the Youghiogheny River, the Baltimore and Ohio tracks were flooded and the trains were run on the tracks of the Pittsburgh and Lake Erie, on the other bank. Portions of the tracks of the Pennsylvania Railroad along the Kiskiminetas River, between Saltsburg and Salina, and along the Conemaugh River, at Sloan's Cut, east of Blairsville, were washed away.

Several thousand men were laid off on account of the high water entering industrial plants and causing their shut-down. At least 2 000 of these employees, it was stated, would be out of work for a week. The Pennsylvania Department of the National Tube Works, in Second Avenue, shut down for a week when water entered the plant at about 2 A. M. on the 22d. The rolling mill at the Continental Department of the same Company also shut down for a week. About 1 700 men are employed in these two departments. The plants of the A. M. Byers Company, at South Sixth Street, and of the Dilworth, Porter Company, at South Fourth Street, closed down on the night of the 21st, on account of the high water backing into the fly-wheel pits. The Carbon Steel Company and the American Steel and Wire Company's plant at 15th Street had to shut down on the morning of the 22d. The Open-Hearth Department of the Jones and Laughlin Steel Company, at South 27th Street, was shut down on the night of the 21st, as it was feared that the furnaces might be flooded, but, as the water did not reach them, work was resumed on the morning of the 22d. At the mills of the Spang, Chalfant Company, at Etna, all movable machinery and material were transferred to points above flood level. This was also done at the Westinghouse Air-Brake Works, at Wilmerding, on Turtle Creek, a small tributary of the Monongahela near Pittsburgh. This plant closed down on the morning of the 21st on account of high water in Turtle Creek, and in the afternoon the water was 20 in. deep on the floor of the works. Men were engaged all night in cleaning up, and work was resumed on the morning of the 22d. At Hays, on the left bank of the Monongahela, a short distance above Pittsburgh, the Monongahela Iron and Steel Company and the National Car Wheel Works were shut down on the night of the 21st, because of flooded furnaces, throwing about 650 men out of work.

Movement of the Flood Down the Ohio River.—The flood crest reached Rochester, Pa., 25 miles down the Ohio from Pittsburgh, at

about 11 A. M. on the 22d, and the streets and cellars in the lower section of the town were flooded. At Steubenville, Ohio, 68 miles below Pittsburgh, the highest stage, 37.0 ft., was reached on the evening of the 22d. Several industrial plants were shut down, and railroad and street-car traffic was interrupted. At Wheeling, W. Va., 90 miles below Pittsburgh, the water rose above the danger line of 36.0 ft. at 1 P. M. on the 22d, and reached the maximum for this flood, 38.6 ft., at about midnight on the 22d. Street-car traffic was interfered with and, on certain lines, was suspended. Basements and cellars in the low districts were flooded, and merchandise had to be removed to the sidewalks and to upper stories. Several mills were obliged to close. The crest reached Parkersburg, W. Va., 183 miles below Pittsburgh, at 4 P. M., on the 24th, when a stage of 37.0 ft., or about 1 ft. above the danger line, was recorded. Little damage is done at this stage at Parkersburg. Cincinnati, Ohio, 468 miles below Pittsburgh, had its highest water, 53.4 ft., or 3.4 ft. above the danger line, at 3 P. M. on March 27th. The flood stage of 50 ft. was reached on the morning of the 25th, and residents in the low-lying districts began to move out of their houses. The water began to overflow some of the railroad tracks on the 26th, when the gauge read 52.2 ft. at 8 A. M., but the service was not interrupted. At Cincinnati a stage of 54 ft. or more prevents trains from entering the Union Central Depot. The river at Cairo, Ill., at the mouth of the Ohio, 967 miles below Pittsburgh, reached its maximum of 54.0 ft. (9 ft. above the danger line) on April 6th. The previous recorded maximum was 52.2 ft., in February, 1883. The river at this point was above the danger line of 45 ft. for 32 days, from March 22d to April 22d, inclusive.

The flood on the Mississippi during April, 1912, was one of the worst ever experienced on that river, and in some sections exceeded all previous records. Many lives were lost, and enormous damage resulted from overflow. The Ohio River was the principal contributor to this rise, although part of the flood-water came from the Lower Missouri and Upper Mississippi. The Arkansas and Red Rivers were not important contributors. Professor H. C. Frankenfield has published* an excellent article recording the history of the conditions preceding this great flood, and the stages of its progress down the river. The data presented in that article bring out the fact that, unquestionably,



* *Engineering News*, April 18th, 1912.

FIG. 2.—WEST RELIANCE STREET, ALLEGHENY, ON THE MORNING OF MARCH 22D, 1912.

FIG. 3.—RIVER AVENUE, ON THE RIGHT BANK OF THE ALLEGHENY RIVER, ON THE MORNING OF MARCH 22D, 1912.

flood stages in the Mississippi are raised by the levees, and that the end has not yet been reached, as far as extreme high stages are concerned, especially in the event of the possible combination of great floods in both the eastern and western tributaries.

Estimated Reduction of the Pittsburgh Crest by Storage Reservoirs.—Before proceeding to a discussion of the reduction of the flood of March 22d, 1912, which could probably have been obtained at Pittsburgh if a system of flood-control reservoirs had been in operation, the following outline of the studies made along these lines by the Flood Commission of Pittsburgh will perhaps be of interest.

The Report of the Flood Commission was issued in April, 1912. It gives a detailed account of the extensive surveys and studies made by the Commission for the purpose of determining the feasibility of preventing floods at Pittsburgh by storage reservoirs on the Allegheny and Monongahela Basins. The forty-three most favorable sites were selected from a large number considered, and detailed estimates were made of the capacities and costs of the respective reservoirs.

These surveys and studies showed that, at certain sites, the maximum storage feasible was greater than needed for flood control. For example, if all forty-three reservoirs were constructed to maximum capacity, the storage in excess of that required for flood-control purposes would amount to 4 357 000 000 cu. ft. on the Allegheny Basin, and 17 937 500 000 cu. ft. on the Monongahela Basin, the total maximum capacity found available being nearly 103 000 000 000 cu. ft.

The capacities of these reservoirs were cut down, therefore, in each case to the amount necessary to control floods from the drainage areas above the respective dams. The total capacity of the twenty-one projects on the Allegheny Basin then amounted to 49 725 800 000 cu. ft., and of the twenty-two on the Monongahela Basin to 30 772 000 000 cu. ft., or a total of 80 497 800 000 cu. ft. These reservoirs would control 8 454 sq. miles, or 73% of the Allegheny drainage area, and 3 379 sq. miles, or 46% of the Monongahela drainage area; or a total of 11 833 sq. miles, or 62% of the total drainage area above Pittsburgh. The total cost of the forty-three projects would be $34 170 800.

An analysis of the effect of these forty-three reservoir projects in reducing floods at Pittsburgh was then made for the eleven principal floods from 1898 to 1908. Prior to 1898, sufficient data for such studies were not available.

This study of the Pittsburgh peak reduction was made graphically by a series of mass-diagrams, in which the estimated flood volumes contributed by the various controlled tributaries were assembled in their calculated positions under the main volume curve representing the Pittsburgh peak, or flood crest, and the reduced peak was obtained by deducting these tributary volumes from the volume of the main peak, which is what would actually take place if the proposed reservoirs on these tributaries were constructed. A diagram of this kind was constructed for each of the eleven floods considered.

By these diagrams it was ascertained that, of the eleven floods studied, all except the highest, that of March, 1907 (35.5. ft.), would have been reduced well below the danger line. The March, 1907, flood would have been reduced to 25.3 ft., and would have been above 22 ft. for 22 hours, as compared with the actual 61 hours. These eleven floods remained above the 22-ft. stage from 34 to 86 hours. The longest flood, that of March, 1905, which reached the gauge height of 29 ft., remained above the 22-ft. stage for 86 hours. This flood would have been reduced to a gauge height of 18.3 ft. It was also found that, with 62% of the total drainage area controlled, a reduction of from 39 to 84% of the peak discharge would have been obtained, or an average of 53 per cent.

Relative Effectiveness of Reservoirs.—It is evident that the amount of flood reduction effected by a given reservoir project is not merely a matter of the magnitude of the flood in the tributary it controls; it is just as much a question of how the contribution of that tributary arrives, with reference to the time of the crest, in the main river.

Inspection of these mass-diagrams, by which the reductions of the Pittsburgh peaks were estimated, showed that certain tributaries are notable and repeated offenders in Pittsburgh floods, that is, their flood-volume curves arrive there at about the same time as the Pittsburgh peak. It is obvious that the most effective storage would be that controlling their flood-waters. Therefore, a study of the relative effectiveness of the various projects was made on this basis, and it was found that, except in the case of the 1907 flood, a comparatively small number of reservoir projects is needed to reduce floods at Pittsburgh to below the danger line; and that certain projects would have but little effect, and, therefore, should be dismissed from further consideration for flood-prevention purposes.

FIG. 4.—MAHONING CREEK, PENNSYLVANIA. VIEW UP STREAM AT DAM SITE.

CONSERVATION
NATIONAL PARKS

Thus, it was found that if fifteen of these least effective projects were rejected, reducing the cost by about $6 000 000, all the eleven floods considered would still be reduced to below the danger line except that of 1907, which would be reduced to 26.1 ft., or only 0.8 ft. above the point to which it would be reduced by the construction of all forty-three projects.

A further analysis, taking into account the relative cost as well as the relative effectiveness of the respective projects, reduced the number to seventeen. These seventeen selected projects control a drainage area of 8 023 sq. miles, or 69% of the Allegheny Basin, and 2 159 sq. miles, or 29.5% of the Monongahela Basin; or a total of 10 182 sq. miles, or 54% of the total drainage area above Pittsburgh. Thirteen of the projects, with a total capacity of 42 178 500 000 cu. ft., are on the Allegheny Basin, and four, with a total capacity of 17 302 900 000 cu. ft., are on the Monongahela Basin, the total capacity on the two basins being 59 481 400 000 cu. ft. The total cost of the seventeen reservoirs would be $21 672 100, or an average cost of $364 per 1 000 000 cu. ft. of storage capacity.

The locations of these seventeen selected projects, together with the drainage area controlled by each, are shown on Fig. 5.

It was found that, if these seventeen projects had been constructed, the average reduced peak for the eleven floods would have been 18.9 ft.; and that in only the two highest floods, March 15th, 1907 (35.5 ft.), and March 1st, 1902 (32.4 ft.), would the reduction have been less than to the danger line of 22 ft. In the 1902 flood the reduced peak would have been only 0.3 ft. above the danger line, and would have been above that line for such a short time as to be negligible. The reduced peak of the 1907 flood, however, would still have been 6.8 ft. above the danger line, and a certain amount of overflow and damage might still result from occasional great floods, if the flood relief work should be confined to the construction of the seventeen selected reservoirs.

Combination of Reservoirs and Low Wall.—The reduction of the maximum flood to this height, or even to 30.0 ft., however, would greatly reduce the amount of wall necessary to prevent overflow. Investigation showed that the cost of the low wall which could be used in combination with the seventeen selected reservoirs would be so small that it would be far cheaper to construct it than to build the large amount of additional reservoir storage which would be necessary to reduce the occasional great floods below the danger line.

These seventeen selected reservoirs would reduce the flood heights so much that no wall would be required on the Monongahela or Ohio Rivers. It would be necessary to construct a wall only along a few low-lying portions of the Allegheny. This low wall, in combination with the reduction in flood heights which would be obtained by reservoir storage, would prevent overflow by a 40-ft. flood at Pittsburgh. It would cost about $670 000. The total cost, therefore, of the wall and reservoirs would be $22 342 100.

If certain revisions in the river channels were made, the total value of the land reclaimed along the river front would amount to about $2 307 000. The total net cost of the low wall and the seventeen selected reservoirs combined, therefore, would be $20 035 100.

Reduction of the Flood of March 22d, 1912.—The flood of March 22d, 1912, is the first of any importance that has occurred since gauging stations have been in operation on all the tributaries controlled by the seventeen selected reservoirs referred to. The accompanying graphical estimate (Fig. 6) of the probable reduction in the Pittsburgh peak which could have been obtained had the system of reservoirs recommended by the Flood Commission been in operation is, therefore, of peculiar interest, as confirming the claims made by the Commission and showing the conservative character of the assumptions made necessary by incomplete data in certain portions of the above described flood-reduction studies.

The peak reduction diagram, Fig. 6, is similar to the diagrams used in the studies made by the Flood Commission. The discharges at Pittsburgh were obtained by gauge heights furnished by the U. S. Weather Bureau, and an approximate discharge curve for the Ohio River at Pittsburgh was based on measurements by the U. S. Engineers. The flood-volume curves of the tributaries controlled by the seventeen selected projects are, with two exceptions, based on actual stream-flow measurements. The curve representing the flood discharge of the Allegheny River at the site of the lower of the three Allegheny projects, a short distance above Oil City, is based on discharge measurements at Red House, N. Y.; the Loyalhanna Creek curve is based on the records of Black Lick Creek and a study of rainfall data, the Loyalhanna gauge having unfortunately been out of commission during this flood.

These tributary flood-volume curves, representing the flood-water which would have been held back by the proposed reservoirs, are plotted under the Pittsburgh peak in the positions in which it is estimated

they actually arrived at Pittsburgh, based on the calculated time of travel of floods from the respective dam sites to the latter place. On account of their smaller size, they are plotted to a vertical scale twice as great as that used for the Pittsburgh peak. By subtracting the sum of their ordinates at a series of points, that is, one-half the graphical sum, on account of the difference in scales, from the corresponding ordinates of the Pittsburgh peak, a reduced peak has been obtained, the highest point of which represents a discharge of only 168 000 sec-ft., corresponding to a gauge height of 16.9 ft. This represents a reduction in discharge of 132 800 sec-ft., or 43%; and in gauge height, of 11.2 ft., or to 5.1 ft. below the danger line.

Table 3 contains various data with regard to the seventeen reservoirs. It also includes the results of an analysis of the peak reduction diagram, and brings out the relative effectiveness of the respective projects in reducing this particular flood.

The term, "effective capacity," has been used to designate that part of each tributary flood-volume curve falling within the effective zone, or the time when the Pittsburgh crest was above the danger line, or 22-ft. stage. In other words, it represents the portion of the capacity used in storing damaging flood-water. The reduction in gauge height to be credited to a given project has been obtained by multiplying the total reduction, 11.2 ft., by the percentage of total effective capacity credited to each project.

It will be noted that, with the exception of the Youghiogheny project, all the reservoirs are of ample capacity to have controlled the damaging flood-water delivered from their respective catchment areas. The Youghiogheny reservoir would have filled up a few hours before it ceased to deliver damaging flood-water. The position of this filling up has been indicated on the peak reduction diagram, Fig. 6; and, beyond this point, the ordinates of the Youghiogheny flood volume curve have not been used in reducing the Pittsburgh peak.

About 293 000 000 cu. ft. of additional storage capacity would have been needed to store all the damaging flood-water delivered by the Youghiogheny above the reservoir. The surveys showed that, by increasing the height of the dam to 96 ft., about 984 000 000 cu. ft. of additional storage could be obtained at this site, and the capacity of this reservoir should be increased by part of this amount, at least, in order to insure complete control of all floods from its catchment area.

NOTE.—Total drainage area of Allegheny River is 11 580 sq. miles; of Monongahela River is 7 340 sq. miles.

* Excluding area controlled by No. Br. French project. † Excluding area controlled by Tionesta project.

It should be noted, however, that before the discharge of about 17 000 sec-ft., which the Youghiogheny was delivering at the time the reservoir would have filled up, could have been reached in the stream below the dam, enough water would have been stored in the reservoir to give a head of about 2.5 ft. on the spillway. With a surface area of 940 acres, this would have given an additional storage of about 102 000 000 cu. ft.

The costs per 1 000 000 cu. ft. of total and of effective capacity are also shown in Table 3. In the last three columns, the projects are ranked according to these costs, the lowest being No. 1; and, according to effectiveness, the project with the greatest reduction in gauge height to its credit is ranked as No. 1.

Evidently, it does not follow that, because a reservoir has a low cost per 1 000 000 cu. ft. of storage, it is the cheapest to build for flood-control purposes. The water which it controls may be that of a tributary which rarely, if ever, delivers that flood-water at Pittsburgh during the critical period of damaging flood height. Whereas, another reservoir, of high cost per unit of storage, may control a stream which is invariably an offender whenever its drainage area receives flood rainfall. A number of favorable reservoir sites having been selected and surveyed, and estimates of the capacities and costs of the respective projects having been determined, if only a certain number of them are to be built, the ultimate criterion for their selection for flood-control purposes is not the lowest cost, nor even the greatest effectiveness; it is both. In other words, the final selection should be based on the lowest cost per unit of effectiveness.

Thus, in Table 3, it will be noted that, in this particular flood, the Clarion No. 3 project ranked 13 in effectiveness and 11 in cost per unit of effectiveness, although it ranked 1 in cost per unit of total capacity. The Youghiogheny project, on the other hand, although it ranked 16 in cost per unit of total capacity, being exceeded only by the French Creek project, ranked 3 in effectiveness and 2 in cost per unit of effectiveness.

It is obvious, of course, that such a selection of reservoirs cannot be made from a study of one flood, for no two floods are alike in their origin. The rainfall varies widely in amount, in distribution, and in relative time of arrival. Moreover, even with the same rainfall, the run-off from a given part of a drainage area, being affected by

many conditions, may vary widely. It is necessary, therefore, that the volume and distribution of storage shall be adequate to control all possible conditions and combinations of run-off.

It was in the foregoing manner, after making a similar analysis of the action of the forty-three reservoirs in the eleven principal floods from 1898 to 1908, that the seventeen reservoir projects recommended by the Flood Commission of Pittsburgh were selected. As previously stated, it is estimated by the Commission's engineers that, with these seventeen reservoirs, all floods at Pittsburgh, including a possible future 40-ft. flood, would be reduced to a point where overflow and flood damage could be prevented by a low wall along a few low-lying portions of the Allegheny River; and that the total net cost of these reservoirs and the wall, taking into account the value of the land reclaimed, would be only about $20 000 000, or less than twice the direct losses from flood damage sustained during the past ten years at Pittsburgh alone. Moreover, the flood relief would not be confined to Pittsburgh, but would be extended along the rivers and their principal tributaries above that city, and down the Ohio River for many miles below it. For example, at Wheeling, W. Va., 90 miles below Pittsburgh, the greatest recorded flood, that of 1884, 53.1 ft., could have been reduced by 13 ft.; and the next greatest, that of March, 1907, 50.1 ft., by 14.5 ft.

Proceeding farther down the Ohio, it is evident that, as other important tributaries enter, this storage would become a decreasing factor in reducing the Ohio floods. In so far as such floods originate above Pittsburgh, the storage would be effective, but complete control of floods at these lower points would necessitate the construction of additional storage on the tributaries entering the Ohio between Pittsburgh and the point where flood relief is desired. A similar solution of the problem on the other tributaries of the Ohio would extend the flood relief throughout its entire valley.

Above Pittsburgh, the Allegheny River, from its mouth to Oil City —a distance of about 134 miles—would be relieved from frequent disastrous floods. Flood levels on the Kiskiminetas River, for a distance of 41 miles above its mouth, would also be considerably lowered. On the Monongahela River, floods would be greatly reduced from Fairmont, W. Va., to Pittsburgh, a distance of 127 miles. On the West Fork River, they would be controlled for a distance of 38 miles above the mouth, and, on the Youghiogheny River, they would be lowered considerably for a distance of 83 miles above its mouth.

The system of storage reservoirs could be operated primarily for flood prevention during the flood season, and for increasing the low-water flow during the low-water season. A study of the flood records shows that 80% of the floods has occurred in the months from November to March, inclusive; and that the 20%, occurring in the period from April to October, inclusive, has been of relatively less severity, and could have been prevented from doing damage by the low wall which has been proposed in combination with the reservoirs.

With the amount of flood-water which, by this method, could be safely retained in these reservoirs until needed in dry weather, combined with the surplus spring and early summer flow that could be gathered, a notable improvement in the low-water flow of the main rivers and their tributaries could be effected. The low-water flow of the Allegheny at Pittsburgh could be increased to about 3.5 times its minimum throughout the entire dry-weather season; that of the Monongahela to about 6 times its minimum; that of the Kiskiminetas River to about 6 times its minimum; and that of the Youghiogheny River to about 10 times its minimum. These increases of low-water flow are those which would obtain with only the seventeen selected projects constructed, and would, of course, extend down the Ohio. At Wheeling, the low-water discharge could be maintained at 3 times the present minimum, corresponding to an increase in stage of 2.3 ft.

The extent of these improvements in low-water flow will be appreciated when it is realized that 267 miles of main rivers and 386 miles of tributaries, or a total of 653 miles of stream channels above Pittsburgh, would have their low-water discharge considerably increased and made uniform during dry weather. If all the forty-three projects referred to were constructed, there would be, of course, a considerably greater increase of low-water flow, which would extend over 393 miles of main rivers and 570 miles of tributaries, or a total of 963 miles of stream channels above Pittsburgh.

The benefits to navigation, sanitation, water supply, and water-power, which would result from such an improvement in stream regimen would naturally be very considerable. They form a strong additional argument in favor of the construction of storage reservoirs for purposes of river regulation and flood control, and broaden the problem to one demanding State and National consideration.

DISCUSSION

Mr. Le Conte.

L. J. LE CONTE, M. AM. SOC. C. E. (by letter.)—The writer is deeply interested in this paper, because the general scheme for flood control therein considered was, in his younger days, a pleasing day-dream which haunted him for years. Long experience in this line of thought, however, has brought a realization of many practical difficulties which cannot be easily adjusted. The author says:

"The system of storage reservoirs could be operated primarily for flood prevention during the flood season, and for increasing the low-water flow during the low-water season."

This is perfectly feasible, and true in every respect, provided every private or quasi-private interest is prevented from interfering with free and untrammelled operation in the interest of flood control purely.

The author also states:

"The benefits to navigation, sanitation, water supply, and water power, which would result from such an improvement in stream regimen would naturally be very considerable."

This is exactly where the fundamental difficulties of the whole scheme come in. Experience everywhere shows that it is almost impossible to reconcile private interests and flood-control interests in one and the same scheme. The conflict is irrepressible, and, in a majority of cases, the combined scheme is utterly impracticable. A single instance is sufficient to show the true nature of the irrepressible conflict. The same reasoning will apply to any one of the seventeen reservoirs proposed.

Complete flood control requires that all the storage reservoirs shall be practically empty just before the expected peak flood arrives, say, in February and March of each year. This will furnish the desired storage room for the great rush of flood-waters, and everything will work satisfactorily. On the contrary, how does this requirement affect private interests? Water-supply and water-power interests both demand that the reservoir shall be filled as early in the wet season as possible so as to be absolutely sure of a full reservoir before that season is over. This means that the expected great "peak flood," which comes in February and March, will rush down the river and into a full reservoir, pass over the crest of the dam unrestrained, and continue down stream just exactly as it did before the dam was built. As a result, the flood height in the lower river would be the same as before the reservoir system was built, if not greater, inasmuch as the proposed improvements are supposed to raise the low-water plane of the river to some extent.

From this it is clear that, as a rule, flood-control schemes cannot be combined with such schemes as water supply, water power, irriga-

Mr. Le Conte.

tion, etc., on account of conflicting interests which are almost insurmountable. This is the principal reason why this truly fascinating problem has remained dormant for sixty years or more, and has never received a practical solution.

The writer ventures to submit a few mild suggestions, which, of course, pass for what they are worth. Where the flood-danger period does not extend over 2 or 3 months each year, the storage reservoir waters could be used for power or water-supply purposes during the remaining 9 or 10 months. During the 2 or 3 months when the storage reservoirs must be kept practically empty—in anticipation of the great peak flood—all the power plants and water-supply plants must necessarily be kept going with auxiliary steam plants erected for the special purpose. The long transmission lines in California generally have auxiliary steam plants in the cities where they sell their power and light. These auxiliary plants are started up whenever there is a breakdown on the main transmission lines; therefore, a stoppage of 2 or 3 months at the main power-house is not vital. Likewise, in the case of a water-supply company: if the natural flow of the stream above the reservoir site, in February and March, is sufficient for water-supply purposes, all well and good, and no steps need be taken for an auxiliary supply; but, if it be short of requirements, a small auxiliary steam pumping plant could be located just below the dam site, the pump wells being fed by underground seepage from the reservoir above. The capacity of this plant need be only sufficient to cover the deficiency.

Mr. Copeland.

WILLIAM R. COPELAND, ASSOC. AM. SOC. C. E. (by letter).—Mr. Grant evidently prepared his paper with the idea of proving that the construction of storage reservoirs on the water-shed of the Allegheny River will protect the residents of Pittsburgh and vicinity from damage by flood. He seems to have overlooked an important matter in this connection, and that is the question of the effect which may be produced on the Allegheny by the storage of acid waters from coal mines in such reservoirs.

Consider, for example, the proposed reservoir on the Loyalhanna. This river, rising on the western slope of the Allegheny Mountains, flows northwestward for about 30 miles until it joins the Conemaugh at Saltsburgh, forming the Kiskiminetas. From its source to Latrobe, it lies in a rather broad, open valley. Between Latrobe and Saltsburgh, however, it winds through a valley, so narrow and deep in many places that it becomes a gorge.

This valley is crossed at four or five places by dikes of stone which form natural dams, and they have been raised in height artificially for the purpose of storing water for mill powers. The pools thus formed—each a mile or more in length—serve as catch-basins for the mine drainage entering the stream from each side.

Mr. Copeland.

This mine water has several marked characteristics, one of which is that its specific gravity is greater than that of ordinary surface water. Therefore, the drainage drops to the bottom of the river, collecting, of course, in the pools above the dikes. Another bad feature of mine drainage is the free acid and acid salts which it contains.

Chemical analyses have shown that water flowing from coal mines in this region carries from 100 to 500 parts per million of free acid. Dilution and reaction with the alkaline carbonates carried by the surface waters tend to reduce the acidity, but, nevertheless, a sample of water taken from the bottom of a pool in the Loyalhanna in September, 1899, contained 200 parts per million of free acid—and the sample was taken just after a considerable flood had passed down the stream.

July, August, and the first half of September had been very dry, but about September 15th a thunder-storm having the characteristics of a cloudburst broke upon the upper water-shed. So great was the rainfall that the run-off raised the river more than 2 ft., creating a current in the Loyalhanna which swept the immense volumes of acid mine drainage stored in the pools into the Kiskiminetas, and eventually into the Allegheny.

Millers and farmers have complained for years that the mine waters of the Loyalhanna eat up their iron water-wheels, and poison stock which drink from the stream. One man told the writer that he had lost a 1-in. iron crow-bar through the ice on the river during the preceding winter, and that by spring the bar had been eaten in two.

The head-waters of the Loyalhanna contain fish, frogs, lilies, and all the natural aquatic life of the region; but below the entrance of the first coal-mine drains, at the outskirts of Latrobe, not a fish nor a weed can be found in the water.

When the mine water—swept into the Kiskiminetas by that September flood—reached its month, the acid burned the legs of Italian laborers working on a bridge pier, and drove them out of the river. Passing into the Allegheny the sulphur water killed tons of fish in its run of 40 miles to Pittsburgh, and the rotting bodies created such foul conditions that the Superintendent of the Pittsburgh water supply at once started an investigation regarding the cause of the death of the fish.

Smaller floods of this character are of common occurrence in the Allegheny, and are becoming more common annually. The volume of mine water is increasing, too, as new coal mines are being opened yearly, the workings in others are being extended, and last, but by no means least, the drainage from all former openings continues to pour unceasingly into the watercourses.

Mr. Copeland.

At present the dikes and dams are so low that the Loyalhanna is flushed out several times a year, but what will happen if a great reservoir is formed by throwing a dam across the stream near its mouth, as indicated on the plan, Fig. 5. Such a structure will surely store the acid mine drainage, and, if any exceptional flood, from a cloudburst or other severe storm, sweeps the water out of the reservoir, far greater volumes of stronger acid water will be poured into the Allegheny than has ever entered it at one time before.

When this happens, the water consumers in all the towns on the river, and the men in charge of the water purification works at Pittsburgh and elsewhere, may well take heed lest the mine drainage destroy their boilers and water mains, and even close the water-works plants temporarily.

The location of the dam on the Loyalhanna has doubtless been chosen in order to get a maximum amount of storage and to decrease the danger of flood from this region to a minimum; but, in view of the presence of mine water on the lower water-shed, is it advisable to locate the dam at the proposed site? Would it not be better to build the dam above Latrobe, for instance, at Ligonier? Part of the town, a railroad, and some highways would doubtless be wiped out, and the volume of water stored would be reduced. Some persons might argue, further, that the process of holding back the alkaline surface water at Ligonier would cause a more concentrated sulphur water to flow into the Allegheny. This effect could be easily remedied by opening gates at the dam, and really improve present conditions by keeping a larger and more uniform flow through the lower valley at all seasons.

If the dam is ever built at the site proposed in Fig. 5, channels should be cut through all the present dikes to drain the heavy acid water from the lower parts of the pools; and blow-off gates should be placed in the bottom of the dam through which a constant discharge of water will be maintained for the purpose of preventing the acid mine drainage from destroying the gates or even injuring the structure itself, as well as the city mains and plants on the lower rivers.

Mr. Knowles calls attention to the fact that the Flood Commission considered the question of the action of acid mine waters in storage reservoirs, and decided that there was no danger from this source. The speaker desires to add a word of caution, because there are two factors which, from the nature of the acid mine water and well-known hydraulic laws, contradict the reasons suggested by Mr. Knowles.

Mine water is heavier than surface water, and can be made to mix with it only by prolonged agitation. The theory that because mine water is brought into the presence of great volumes of surface water the acidity will be neutralized by dilution is disproved by the evidence

Mr. Copeland.

presented by such rivers as the Loyalhanna and Youghiogheny. The acid mine drainage entering the latter from the coal mines of the Connellsville region gathers in pools at the bottom of the river as far away as McKeesport. This fact can be verified by the manager of the water-softening plant at that city.

Moreover, all persons who have to deal with solutions—especially with those of metallic salts—find that constant agitation for hours is required to make the heavy liquors mix with the dilution waters, and that this agitation must be kept up constantly in order to prevent the two kinds of waters from separating into layers.

Four or five years ago the writer traced the acid mine water flowing out of the Kiskiminetas down the left bank of the Allegheny River as far as Tarentum—a distance of about 10 miles. The condition was all the more noticeable because an island, which lies in the river about ½ mile above Tarentum, divided the stream into a streak of clear strongly acid water on its left shore and muddy and strongly alkaline waters on its right shore. This fact was not confined to the writer's observation, but was confirmed by the ferryman who lived on the left bank of the river, at the foot of the island, and by the officials of the Pennsylvania Salt Company's works at Natrona. These gentlemen, whose plant was under suspicion at the time as the source of the acid water in the river, had made tests on many samples of the river water, and found that it was acid for a large part of the year along the left bank and alkaline on the right.

Moreover, the surface water carried into the Loyalhanna by spring rains will probably be several degrees warmer than the water which has been lying at the bottom of the reservoir all winter. This difference in temperature will tend to make the surface water run over the top of the mine drainage lying in the deep pools on the floor of the basin.

Finally, it is a matter of common observation that a sudden inrush of flood-waters tends to push the water in the reservoirs out bodily, instead of mingling with it. Therefore, the promoters of these storage reservoirs in coal-mine districts are warned that Nature is not likely to destroy the acidity by dilution, and that the builders of dams must provide artificial means for making surface water mix with the mine waste, otherwise the building of dams will be dangerous to the inhabitants of the lower water-sheds.

The writer desires to suggest a second time that the pools in the bottoms of these reservoirs be filled with sand and gravel or drained, and that gates, left open in the bottoms of the dams, shall maintain a constant discharge of the heavy liquors collecting along the beds of the reservoirs.

Mr. de Pulligny.

JEAN DE PULLIGNY, M. AM. SOC. C. E.—The speaker knows very little about the Ohio River, as he only saw it once, but can say a few words about the very severe floods which have to be controlled in Paris, where they caused great damage three years ago. At the present time the speaker understands that the waters are rising again very rapidly, and the people are anxious to know whether they will have to undergo the same severe experience.

One of the solutions proposed has been the building of dams up stream. The Seine has several affluents, and the rising of the flood at Paris depends largely on the way in which the various rivers above send down their flow. If the floods arrive at Paris simultaneously, the rise there is very high; if they pass one after the other, the rise is much less, so that keeping one flood waiting a few hours and allowing it to escape afterward might be sufficient to prevent any great rise at Paris.

Besides the construction of reservoirs up stream, other measures have been proposed, and, generally speaking, all those which allow the water to flow freely between the city embankments and below the city may help, to a certain extent, to lower the crest of the flood.

It has been proposed to build, around the city, a deviation canal which would receive the flow of the Marne (an affluent of the Seine) above Paris, and carry it below the city. For helping the flow of waters below Paris, it has been proposed to construct an underground canal from Bougival to Poissy, which would cut straight across the several loops formed by the river below the city. All these works and many others would surely be useful, but, unfortunately, their cost would be very large.

Mr. Smith.

J. WALDO SMITH, M. AM. SOC. C. E.—The speaker is not familiar with the Ohio River, or with the circumstances or conditions which control the flow of the Allegheny in the Pittsburgh District, but if these streams are like those with which he is familiar in New York State, New England, and New Jersey, he is convinced that there has been no great flood, but that at some time there will be a greater one, and that there has occurred no great drought, but that at some time there will be a drier one.

To control these floods, and to utilize their waters by storage, is an extremely difficult problem. Floods in the rivers with which the speaker is familiar do not occur by rule; they are likely to occur in any month of the year. He has known of floods in July, in August, in September, in October, in January, March, April, May, and June, and, no doubt, a careful comparison of the records would show that floods had occurred in the other months of the year as well, and severe floods too. In order, then, to utilize the run-off waters for the development of an average power or for augmenting the low-season flow

Mr. Smith. and, at the same time, furnish adequate protection against floods, is a difficult problem.

This discussion is a general one, for, as already stated, the speaker is not familiar with the problems of the Allegheny River, and it may be that floods in that region usually occur in certain seasons only.

Mr. Knowles. MORRIS KNOWLES, M. AM. SOC. C. E.—To the speaker and to others who have studied the conditions in Pittsburgh, this paper is exceedingly interesting. It will be recalled that some criticisms of the Flood Commission's Report have been based on the fact that it was founded on incomplete data regarding rainfall, run-off, and river gaugings; yet this paper is a study, using actual rainfall measurements and stream gaugings on every one of the streams on which the Flood Commission recommended reservoirs. The close correspondence of the results to those calculated on necessarily incomplete data for the Report proves the reasonableness of the Flood Commission's assumptions and justifies its belief that the seventeen recommended projects would prove effective in controlling floods.

Another interesting feature is the light thrown on the one flood which would not have been lower than the damage height, even with the seventeen reservoirs in operation, namely, the flood of 1907. The main causes at the time of that flood were the Kiskiminetas and the Youghiogheny, just as in the flood of 1912, although not exactly to the same degree. This study confirms the view that even these two offending streams could have been controlled (when we consider their time and intensity effect acting with all others) so that conditions would have been materially better.

A word as to the recurrence of floods, and as to the reasonableness of considering any project, not only for this purpose, but for other and correlated purposes: During the past 38 years, about 75% of the floods at Pittsburgh have occurred between December 1st and April 1st; the remaining 25% have been scattered through the other months, and, with one or two exceptions, have been small and of short duration. Of this 25% not one would have topped the flood wall which the Flood Commission recommended to supplement the seventeen reservoirs. The reservoirs, therefore, would have been necessary for flood protection only during 4 months of the year, and could have been operated for other purposes during the remaining 8 months. It was this which led the Pennsylvania Water Supply Commission to incorporate such restrictions as the following in two power company charters that have been granted since the Flood Commission made its report:

"That the requirements of the Corps of Engineers, United States Army, in charge of the Allegheny River, as to the minimum stream discharge must be embodied in any plan for using the water stored, as well as the rights of lower riparian owners to have available at all

times at least the minimum stream flow, as determined by the Water Supply Commission of Pennsylvania, must be protected. Mr. Knowles.

"That the operation of reservoirs, in so far as the control of floods and the maintenance of low-water flow is concerned, shall be subject to the direction and jurisdiction of the Water Supply Commission of Pennsylvania."

There has been some discussion with regard to the effect on acid conditions. The speaker had hoped that the report of the Flood Commission had made it evident that in this matter, also, there was great benefit to be obtained by this plan. All but four of the proposed reservoirs are located on portions of streams which are not now acid. It is true that some others may become acid, but the location of the reservoirs, near the head-waters, and above most of the mine developments, will restrict this to a minimum. Moreover, the effect at the low-pool dams is no criterion whatever of what will happen in a very large basin with a comparatively high dam. There a sudden rise will not flush out the acid which has accumulated in the bottom, but will dilute it to a greater and greater degree until it overflows the spillway. The same great dilution will take place when a full reservoir is drawn down to prepare for another flood.

The speaker has not the exact figures in mind, but the increased stage at low water on the Allegheny River and the consequent dilution, made possible by the proper operation of the seventeen reservoirs, would result in a reduction of both the hardness and the acidity of that river of something like one-half or one-third at extreme stages, with a marked reduction at other times.

The idea of the beneficial use of such reservoirs for many purposes other than the prevention of floods has resulted, as Mr. Grant has remarked, in the organization of a group of interested people in Pennsylvania; some of these are capitalists seeking investment and some are public-spirited citizens and representatives of civic bodies, who have come together on the common ground of desiring a sane development of the water resources of the State. They believe that the doing of one thing does not necessarily antagonize the doing of another, and that many great benefits can be obtained through private development with State regulation and co-operation. They are, therefore, interesting themselves in developing the water laws of the State.

KENNETH C. GRANT, ASSOC. M. AM. SOC. C. E. (by letter).—The seventeen reservoirs described in the paper have a combined capacity of about 60 000 000 000 cu. ft. The greatest flood that has ever visited Pittsburgh had a volume of only 26 000 000 000 cu. ft. above the flood stage. The recent flood of January 9th, 1913,* the fourth greatest in 48 years, had a volume of only 13 000 000 000 cu. ft. above the flood stage. Mr. Grant.

* Described in *Engineering News*, January 30th, 1913.

Mr. Grant.

It is not unreasonable to expect, therefore, even without the graphical proof described, that the reservoir system proposed by the Flood Commission will control floods at Pittsburgh effectively; and the discussions have not expressed any doubts of their effectiveness in this respect. It has been stated, however, that the reservoirs could not be used for flood control and for improving the low-water flow of the rivers as well. It is claimed that such a scheme is utterly impracticable, and has never reached a practical solution.

Reservoirs combining the purpose of flood control with those of water supply, water-power, and navigation are not an experiment. They have been built and are being operated successfully in other countries. The writer has had the opportunity of examining these works on two occasions during the last few years. Some of them he has described briefly* in his discussion of the paper by John H. Lewis, Assoc. M. Am. Soc. C. E.; others are to be found in Germany and Bohemia. A large reservoir constructed on a tributary of the Oder River, in Southeastern Germany, for flood control and water-power development, has given such good results during the 8 years since its completion, that another and larger project has been constructed, and is just about to be put in operation. Another large project is being constructed by the German Government on a tributary of the Weser, combining the purposes of flood control, improvement of navigation, and water-power development.

One of the discussions calls attention to the conditions that would obtain where the reservoirs were constructed on streams carrying a large quantity of acid from the mines. It is claimed that the greater specific gravity of the acid would lead to its concentration at the bottom of the reservoirs, and that, in the event of a great flood filling the reservoir, this acid would be swept out and become a menace to water supplies below. As a matter of fact, this very property of the acid, which would keep it at the bottom of the reservoir even when overflow took place over the spillway, simplifies the problem of avoiding the conditions of concentrated acidity that are described. By placing gates at the extreme bottom level of the reservoir, and others higher up, this acid could be released gradually from the bottom gates during flood times, to mingle with, and be diluted by, the large flood discharge. If found necessary, a simple arrangement of baffles would make this mixture complete.

The reservoir particularly referred to is near the mouth of Loyalhanna Creek. It is suggested that the dam be built farther up the creek, above Latrobe, in order to avoid storing the mine water, most of which originates on the lower portion of the drainage basin. There are several reasons why this should not be done, chief among which

* *Proceedings*, Am. Soc. C. E., for December, 1912, p. 1753.

Mr. Grant.

are the great reduction in the drainage area controlled, and the fact that the very conditions pointed out as so objectionable—the flushing out of the acid in the existing pools—would be done away with by locating the dam near the mouth and taking care of the acid as before suggested.

It must be borne in mind, moreover, that only two of the thirteen reservoirs proposed on the Allegheny Basin, those on Loyalhanna and Black Lick Creeks, are to be on streams that carry any appreciable quantity of mine drainage; and that the discharge from the other eleven reservoirs will dilute, to a large extent, any acid water that may come from these streams. Such dilution, of course, would not occur if the rainfall were local around the Loyalhanna or Black Creek basins; but that is just where the beneficial effect of the reservoir near the mouth of each creek would make itself felt, by holding back the acid at the bottom until a favorable time for its discharge.

TRANSACTIONS

Paper No. 1250

THE ECONOMIC ASPECT OF SEEPAGE AND OTHER LOSSES IN IRRIGATION SYSTEMS.*

By E. G. Hopson, M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, W. C. Hammatt, Luther Wagoner, and E. G. Hopson.

In a report to the Comptroller of New York City, made by John R. Freeman, M. Am. Soc. C. E., in 1900, on the New York water supply, attention was drawn in a very clear and forceful manner to the enormous proportion of waste incident to the operation of a great city water-works system. The subject had been dealt with before by other engineers, and has been handled in a very comprehensive way by others since, but the writer did not recall at the time ever having seen the subject dealt with so comprehensively as in Mr. Freeman's report.

On page 38 of that report there is an interesting diagram showing the consumption of Croton water hour by hour during a typical week. By an ingenious interpretation of related, but more or less disjointed, bits of evidence, it was shown that of a daily delivery of 115 gal. to each inhabitant of the city, only about 40 gal. were really used and about 75 were wasted, that is, the proportion of use to waste was about 1:2.

It was further deduced that of the 75 gal. wasted, 65 was in all probability needless waste, and could be stopped by the adoption of proper measures. Naturally, the question arose as to whether it was worth while for a city to continue to lavish vast sums in the construction of new works, the greater part of the product of which

* This paper was presented at the Annual Convention at Seattle, Wash., and also at the meeting of December 4th, 1912.

would flow into the sea without benefit to any one, or whether it would not be better policy to devote some of this money to internal improvements in works already built, whereby savings equivalent in their effect to extensions of the supply system could be effected. Since the Freeman report was made much additional information has been gained on waste and its prevention in city water-works systems, and it has been shown that the amount of what was termed by Mr. Freeman needless waste is not quite so great as had been supposed. The question as to whether enforced economy in use is better policy than increasing the capacity of the system is still, to a large extent, a debatable one.

The reasons in favor of moderate consumption and avoidance of waste apply with even greater force to an irrigation system than to a city water-works system, in spite of the fact that the cost of the latter is relatively much higher than that of irrigation works. In a great city the cost of water-works is a comparatively light burden to the community, the expense to the individual of an unrestricted supply of pure water being one of the smallest items in his annual expense account. On the other hand, anything in the nature of restriction in use directly affects the personal convenience of each inhabitant, and is resented; he often prefers paying an extra trifle in order to enjoy not only a sufficiency but an excess.

With an irrigation system conditions are different. Usually, the supply is limited in quantity, and a waste in one direction is immediately reflected by straitened conditions in another. A system of irrigation work is designed to supply a definite quantity of water to each acre of land. The engineer makes certain allowances for waste and losses by seepage and evaporation. If his calculations are correct, the land receives a supply considered by him as sufficient, but not excessive. If, however, through some unexpected cause, the waste or losses are greater than were anticipated, less land can be brought under cultivation than had been contemplated, or farmers are compelled to get along with less water than had been considered necessary; hence the results are felt immediately and directly.

In the case of irrigation, as with a water-works system, losses can be classed as curable and incurable, and it is the writer's purpose to consider briefly those classes, as illustrated by works constructed by the Government in the Northwest during the last five or six years.

Roughly speaking, incurable losses in irrigation systems result directly through water lost by absorption in the beds of reservoirs and evaporated into the air. Curable loss lies almost wholly in that absorbed in the beds of canals and other conduits.

In the great storage reservoirs required for irrigation works it is obviously an economic impossibility to accomplish anything in the way of preventing absorption or seepage losses in their beds. Whatever losses result through this cause must be accepted as unavoidable. The engineer, however, must be prepared to accept responsibility for results, as his advice or decision on the all-important question of selecting or approving a reservoir site is the only safeguard against what may be disastrous loss if his judgment is ill-advised. For this reason the writer is illustrating the fundamental differences in conditions and results in four typical irrigation reservoirs built in the Northwest by the United States Government.

The East Park Reservoir is strictly a storage reservoir, built on a branch of Stony Creek, one of the Coast Range feeders of the Sacramento River. The dam site is a good one, being a notch in a great conglomerate dike or ridge that runs through the country in a north and south direction, and the dam is a solid masonry structure of the gravity type on an arched plan. The bed of the reservoir is practically wholly in the typical California shale. The dam was completed in 1910, and water was first stored in the winter and spring of 1910 and 1911. Weekly measurements are taken of the influent and effluent, the storage, and the rates of evaporation.

The maximum capacity of the reservoir is 45 000 acre-ft., and the maximum area of water surface is 1 690 acres. Table 1 shows the results in the season of 1910-11, the season being from November 1st to November 1st, in this and all the following cases.

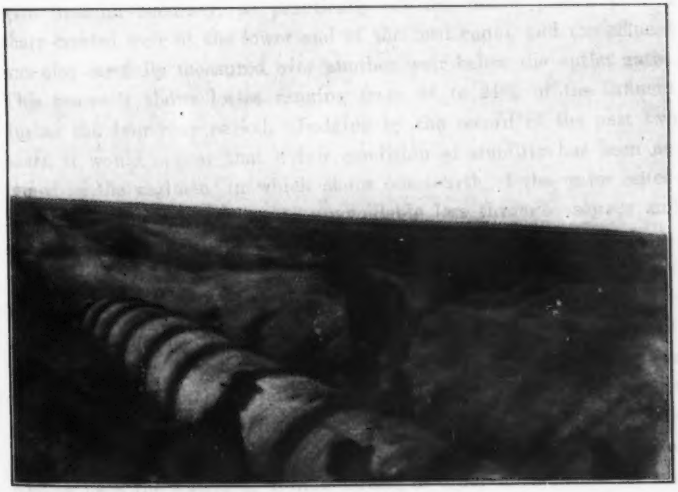
FIG. 1.—COLD SPRINGS RESERVOIR, OREGON.



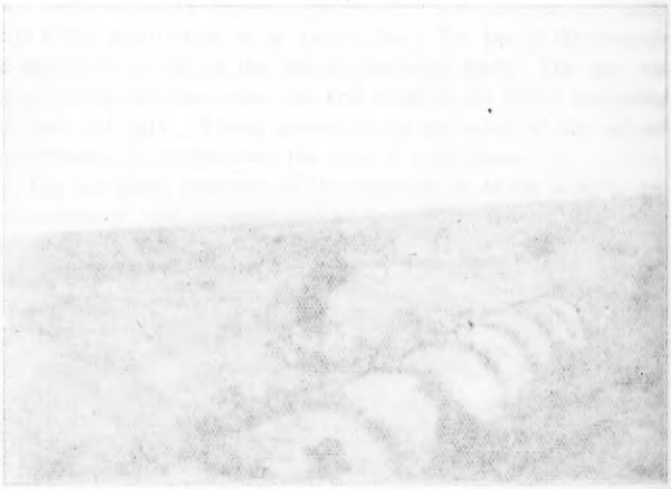


FIG. 2.—JOINTING 46-INCH CONCRETE PIPE, UMATILLA PROJECT.

This reservoir represents the highest condition of efficiency of any of the four described. The records fail to show any seepage loss, the only appreciable loss being that by evaporation; thus nearly 90% of the water entering this reservoir is available for use.

The Cold Springs Reservoir of the Umatilla Project, in Oregon, is a good average reservoir, from a Western standpoint. In the East it would probably not be regarded as a site of special promise. The dam is an earthen one, nearly 4 000 ft. long, of a maximum height of nearly 100 ft. The general structure of the country is volcanic, with vast overlying beds of stratified sands, gravels, and hardpan. The valley constituting the reservoir site is the outlet of some 200 sq. miles of drainage area with little or no ordinary run-off. The reservoir is supplied by a feed canal, some 25 miles long, diverting from the Umatilla River at times when the latter has available water. The capacity of the reservoir is 50 000 acre-ft., and its maximum area is 1 550 acres.

This reservoir was first placed in commission in the spring of 1908, and has been operated ever since. There are, therefore, four yearly records of results. In this case measurements were obtained with unusual accuracy, as practically all the inflow passed over a sharp-crested weir at the lower end of the feed canal, and the effluent was also carefully measured over another weir below the outlet gates. This reservoir shows losses ranging from 34 to 24% of the influent during the four-year period. Judging by the record of the past two years, it would appear that a fair condition of stability has been attained in the regimen, in which about one-fourth of the water entering this reservoir is subject to unavoidable loss through seepage and evaporation. Table 2 gives a summarized tabulation of the results.

The Clear Lake Reservoir, in California, situated just south of the California-Oregon line, is a feature of the Klamath Project. It occupies a great natural depression or sink, some 25 000 acres in extent, at the reservoir flow line. About one-half of the bed consists of a natural sink of alkaline water known as Clear Lake which for ages has received and evaporated the surplus waters of Willow Creek. This reservoir was built by the Government principally for the purpose of holding back the waters of Willow Creek, in order to facilitate the unwatering of lands marginal to Tule Lake, a body of water into which Willow Creek ultimately discharges. The reservoir was intended to

combine the purposes of a great evaporating pan and a regulator of the diversion channel that diverts the discharge of Lost River from Tule Lake into Klamath River. More recent plans, however, have considered its possibilities as a source of irrigation supply. The capacity of the reservoir is enormous, as compared with the available water supply, being 450 000 acre-ft., with an area of 25 000 acres. The dam on Willow Creek is a rock fill structure, some 30 ft. high, which was completed in 1909. There are two years' records of the action of this reservoir, as given in Table 3.

TABLE 3.—CLEAR LAKE RESERVOIR.

Use, waste, and surplus	13 000	9	113 000	50

The rate of evaporation in this vicinity has been estimated at a little more than 4 ft. in an average year. It will be noted that evaporation is the principal loss in the Clear Lake Reservoir, as had been anticipated. The seepage losses during the first year were heavy, but, apparently, the marginal lands have filled up, so that the losses in 1911 were comparatively moderate. It is important to note that in a year of copious run-off, like 1910-11, as much as 50% of the

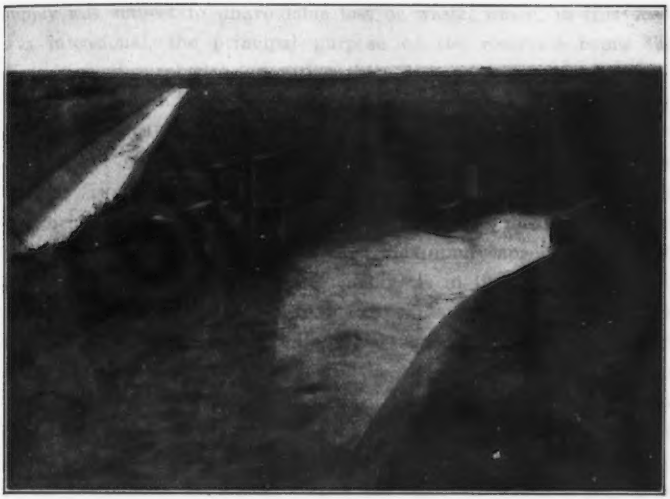

FIG. 5.—MORTAR-LINED LATERALS AND CONCRETE STRUCTURES, UMATILLA PROJECT.

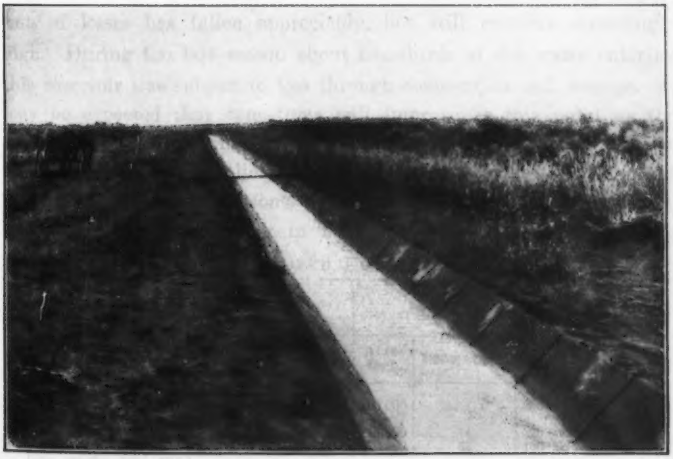

FIG. 6.—MORTAR-LINED LATERAL, UMATILLA PROJECT.

supply was subject to unavoidable loss or waste, which, in this case, was intentional, the principal purpose of the reservoir being the disposition of surplus water, rather than its conservation for use.

The Deer Flat Reservoir, a feature of the Boise Project, in Idaho, presents different natural conditions from the three preceding types. It does not occupy a natural drainage valley or sink, but, on the contrary, is situated on a flat saddle between the hills, the lower ends of which are closed by two earthen dams. It has a maximum area at high-water line of 9 250 acres, with a maximum capacity of 186 000 acre-ft. The reservoir derives its supply, as in the case of the Cold Springs Reservoir, through a feeder canal, known as the New York Canal, diverting from the Boise River some 10 miles southeast of Boise. The reservoir was first placed in commission in 1909, and has been in operation ever since. The bed consists in large part of silts, sands, and gravels, with a covering of from 3 to 5 ft. of soil. Seepage losses in this case have been pronounced from the outset, and constitute the bulk of all losses. When the reservoir was first placed in commission almost 90% of the water entering it was lost by absorption in the reservoir bed. In that year, however, the reservoir was only filled to one-tenth of its capacity. During the next two seasons larger and larger quantities of water were introduced, and the proportion of losses has fallen appreciably, but still remains exceedingly high. During the last season about two-thirds of the water entering this reservoir was subject to loss through evaporation and seepage. It may be expected that conditions will improve at this point as the adjacent and underlying strata of the reservoir gradually become filled by the constant application of water, but the extent and period of these ameliorating conditions are quite uncertain. A summarized tabulation of results is given in Table 4.

TABLE 4.—DEER FLAT RESERVOIR.

	1909.		1909-10.		1910-11.	
	Acre-feet.	Percentage.	Acre-feet.	Percentage.	Acre-feet.	Percentage.
Influent	64 000	.....	130 000	.....	230 000	.....
Effluent:						
Evaporation	4 000	6	18 000	14	20 000	9
Seepage	55 000	86	80 000	62	140 000	61
Use, waste, and surplus	5 000	8	32 000	24	70 000	30

The foregoing records, while incomplete and faulty in many respects, are among the best obtainable in a new country, and in any event are instructive. The general problem of reservoir losses is often given less attention by engineers than its importance warrants. In many cases the dam site is apt to monopolize attention, and an engineer accustomed to deal with reservoir sites in Eastern river valleys, where the adjacent water-tables are high and the losses are generally confined to evaporation, may be led to the commission of grave mistakes. A great deal has been said and written about return flow. One of the writer's earliest recollections in connection with reservoir studies was the discussions in the *Transactions* of the Society between Messrs. FitzGerald, Stearns, Fteley, and others, on ground-water storage of certain reservoirs in the East. Mr. FitzGerald's conclusions as to the general inadvisability of giving credit to the invisible storage of a reservoir are wise. Save under exceptional conditions, the writer doubts whether much, if any, additional draft can be made from Western reservoirs in excess of the visible storage. During the past four years the Cold Springs Reservoir has absorbed some 30 000 acre-ft. of water in its bed; it has apparently yielded back only about 1 500 acre-ft. The Deer Flat Reservoir has absorbed apparently 270 000 acre-ft., with little or no return.

It is important to note that, in a reasonably good, representative, irrigation reservoir, such as Cold Springs, one-quarter of the water turned into it is lost; and that, apparently, under the most favorable circumstances, as at East Park, 10% will be lost.

The main lesson to be derived from these few illustrations is that the geologic structure of the site should be given the most careful consideration, as it is vital to determine in advance, as nearly as may be, the amount of reservoir losses, and whether they are likely to be of a permanent character.

On the Umatilla Project, the cost of the irrigation works per acre of irrigable land is from $60 to $70; on the Truckee-Carson Project, about $40; on the Orland Project, about $50; on the Tieton, about $90; on the Sunnyside, about $50; and on the Klamath, from $30 to $40; say, an average of about $55. This is a fair indication of the general run of costs in large irrigation work in that part of the country, and is probably lower than the average costs on newer projects, either Government or private.

FIG. 7.

The various losses in the water-supply system, as expressed in percentages of water diverted, are as shown in Table 5.

TABLE 5.—PERCENTAGES OF LOSSES.

	Reservoir.	Canal losses.	Totals.
Umatilla	20	32	52
Truckee-Carson	0	41	41
Orland	8	23	31
Klamath	0	48	48
Tieton	0	24	24
Sunnyside	0	27	27

These losses, running from one-fourth to upwards of one-half of the whole supply, are, unfortunately, not all. They include only the losses from the diversions down to the end of the regular lateral systems operated by the Government; but below these are the ramifications of the small ditches built by the farmers to distribute water to their farms. These farm ditches are usually small earthen trenches, in which heavy seepage occurs before the water actually reaches the crop. In some cases farmers use water-tight flumes and pipes for their local distribution, but the proportion of these cases is as yet comparatively small, although on the increase. It has been estimated that seepage losses in the farmers' ditches on many projects is not less than 50% of the losses in the main canal and lateral systems. Allowing for the losses in the farmers' ditches not included in Table 5, the latter might be revised as shown in Table 6, it being understood that the losses in the farmers' ditches are merely the expression of individual opinion, not of actual measurement.

TABLE 6.—PERCENTAGES OF LOSSES.

	Reservoir.	Canal Losses.		Totals.
		Canals and laterals.	Farmers' ditches.	
Umatilla	20	32	15	67
Truckee-Carson	0	41	15	56
Orland	8	23	10	41
Klamath	0	48	15	63
Tieton	0	24	8	32
Sunnyside	0	27	7	34

Seepage losses on the Umatilla Project early assumed serious proportions owing to the sandy character of the soil and the gravelly substrata. With the unlined earthen ditches, as originally constructed, only about one-third of the water diverted reached its proper

destination. The works were costly, and the quantity of the supply was limited. Unless means could be found to lessen these losses, it was evident that the entire area could not be irrigated, and the building costs would not be wholly repaid.

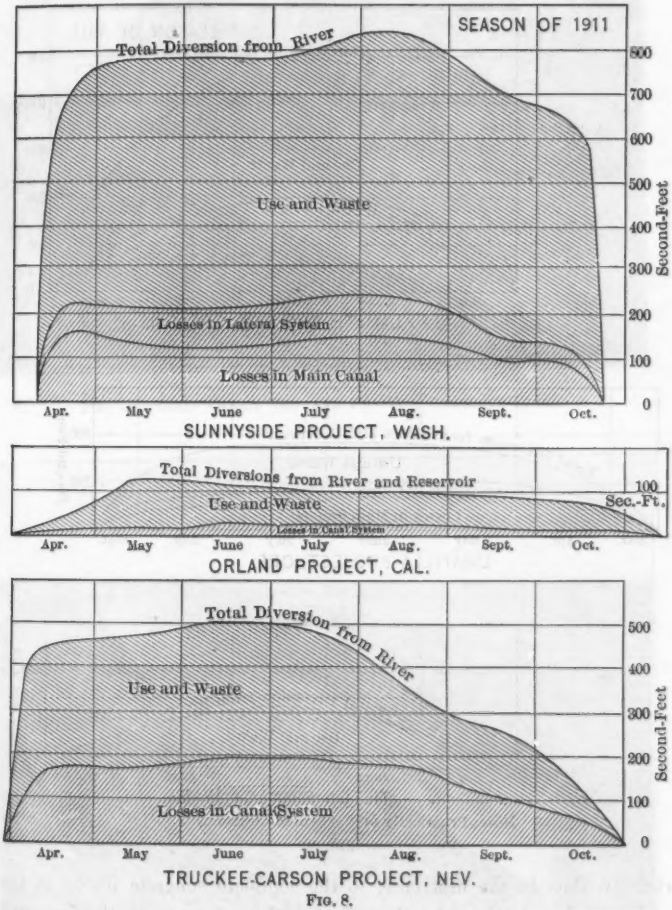

FIG. 8.

About equally severe proportional losses were found on the Truckee-Carson Project, in Nevada, and on the Klamath Project, in Oregon, but in both these projects there is more elasticity, due to their greater

available supplies, and, in the case of the Klamath Project, to the small aggregate quantity used.

Losses on the Tieton and Sunnyside Projects are probably much more satisfactory than in the average well-constructed project in that

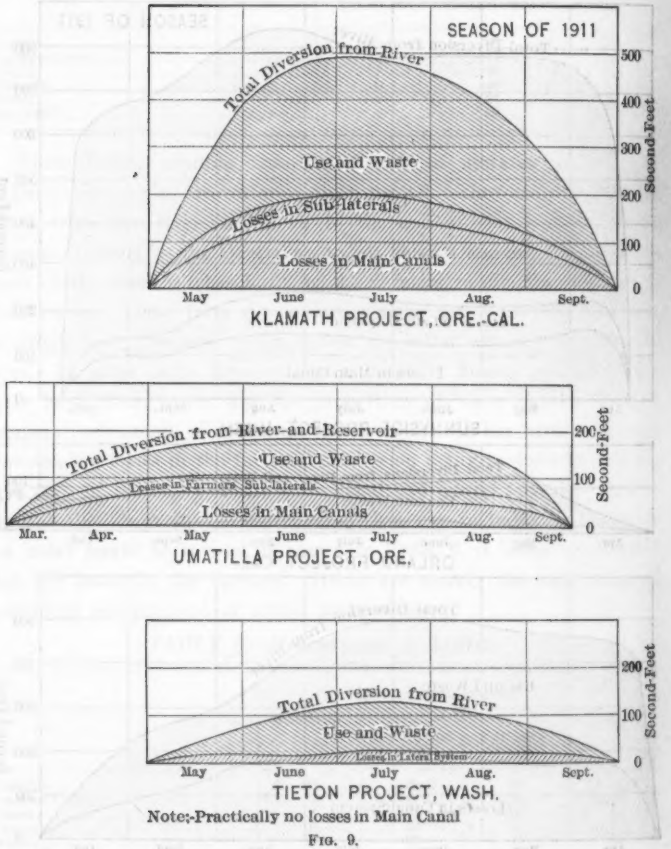

FIG. 9.

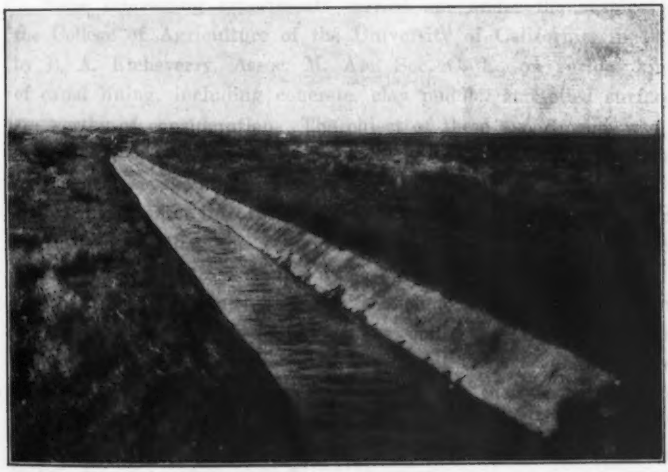
vicinity, due, in the first case, to the complete concrete lining of the main canal and the tight character of the substrata of the irrigated lands. In the Sunnyside Project, the relatively small canal losses are due mainly to the fine texture of the soils.

FIG. 10.—MAIN CANAL, TRUCKEE PROJECT, CONCRETE LINED.



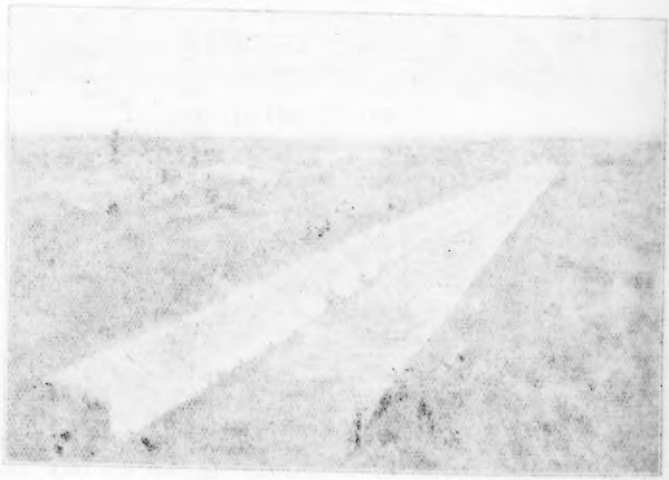


FIG. 11.—MORTAR-LINED LATERAL, UMATILLA PROJECT.

It is probably a fact that in the average project from 40 to 50% of the supply is lost by seepage in the beds of channels before it reaches the actual point of application. As the farmer is paying from $30 to $90 per acre for this water, the loss is very appreciable.

In Southern California valuable orchard lands have been under irrigation for a generation. Crop values have been very high, and, in many cases, the water supply has been so limited that effective measures toward conservation have been enforced. On many projects in that region the distributing channels are lined with concrete, or pipe is used liberally. The high values of lands and the scanty water supply have rendered these measures not only desirable but necessary. Strict economy in use has also been enforced, for the same reason, but, in the newer projects in the Northwest, where crops of lower values obtain, it has not hitherto been seriously regarded as feasible to resort to such expensive treatment. Conditions, however, have changed materially with regard to crop values, and many of the water supplies which appeared to be inexhaustible a few years ago are being rapidly fully appropriated, so that reasons for economy and waste prevention are becoming more and more cogent.

Some interesting experiments carried out under the auspices of the College of Agriculture of the University of California, in 1906, by B. A. Etcheverry, Assoc. M. Am. Soc. C. E., on various kinds of canal lining, including concrete, clay puddle, and oiled surfaces, are worthy of consideration. The object of these experiments was to determine relative costs and efficiencies of different classes of lining in reducing seepage and preventing the growth of vegetation. Without attempting to enter into the details of these experiments,* the general results showed that the concrete lining alone, although the most expensive, gave assured results. The oiling, as would be expected, is very much cheaper than any other treatment, costing only about one-quarter as much per square foot as concrete. During the first year it appears to be of some value in reducing seepage losses, measurements showing that the losses, as compared with those in an untreated earthen canal, are only about 40% of the latter. The oil seemed to be principally valuable in preventing a growth of vegetation. The clay puddle lining gave somewhat better results in preventing seepage

* "Lining of Ditches and Reservoirs to Prevent Seepage Losses," *Bulletin No. 188*, Agricultural Experiment Station, University of California.

than the oiled surface. The mortar and concrete linings, however, prevented from two-thirds to nine-tenths of the total losses, and, of course, entirely stopped the growth of vegetation.

Apparently, the effect of the oil treatment is only temporary, and a year or two afterward, a re-examination of the canals in which the experiments were made showed that the growth of vegetation in the oil-treated canals was equal to that in those untreated, and in all probability the seepage losses were also as great.

In 1910 and 1911, a lateral on the Umatilla Project was lined with mortar, 1 in. thick, and careful measurements were made to determine the losses. The lateral had been selected for lining on account of the very porous character of its bed and in order to reduce seepage loss. With the lateral closed at the ends by dams, measurements showed that the water surface lowered about 0.1 ft. each day in the lined ditch, and by applying this rate of loss to the canal system as a whole, making due allowance for velocity of flow, it was computed that the aggregate seepage loss in the project, if all the canals were lined, would be about 5% of the supply. With the unlined system the loss is close to 50 per cent. Subsequent measurements have confirmed the above, and, from these and other data, the conclusion has been reached, that seepage losses can be kept down to less than 10% of the amount diverted, if good linings are placed.

During the past two years much canal and ditch lining has been placed on Government projects in the Northwest. These linings are from 1 to 4 in. thick, depending on the size of the canal and the conditions. The heavy linings are of regular sand and gravel concrete having about 1 part of cement to 8 parts of sand and gravel. They are generally placed without forms, the sides of the channel being trued up and a rather dry mix being used. The cost has usually been about $6 per yd. The great bulk of the ditch lining, however, has not been of regular gravel concrete but of mortar, which is usually composed of 1 part of cement to 4 parts of sand. Before placing the mortar the ditches are carefully trued up by running a movable form or templet along their courses, and wetting and tamping the earth around the form. Immediately after the form is removed, the mortar is placed and kept damp until it has set well. It is jointed usually at about 4-ft. intervals in order to take care of temperature shrinkage. This

lining is done with much rapidity by experienced gangs. The materials are mixed in small portable gasoline-driven mixers, and the completed canals are kept full of water. The costs of work of this kind, carried out on a fairly large scale, for lining 1½ in. thick, reinforced at the top by an extra heavy curbing, run from 55 to 60 cents per sq. yd., inclusive of all administrative and engineering charges and of the earthwork. In general, the cost of the earthwork is about one-third of the entire cost.

Take, for example, a small lateral of the Umatilla Project lined in this way during 1911: The length was 12 400 ft.; the ditch dimensions were 4 ft. wide at the bottom, and 4 ft. deep, with side slopes of 1½ to 1; the entire cost of the work averaged $1.05 per ft. Comparing a small ditch thus lined with an unlined one, the former will cost from three to four times more than the unlined ditch, but one of the economic advantages which the lined ditch possesses is the greater velocity of flow possible and the consequently smaller cross-sectional area of the channel. Another important advantage in lined ditches is the avoidance of drop structures. It is surprising what a large proportion of the total cost of ditch building goes into drop structures which are necessary in order to keep velocities below the eroding point in an earthen channel. With lined channels high velocities are not only possible, but desirable, in order to keep the channel clean.

As an illustration of what proportion the cost of structures in a distribution system bears to the entire expense of the latter, figures taken from the Orland Project in California are given. This territory is notably free from topographic irregularities, and the earth is firm and good for building purposes. The proportion of cost of structures, therefore, would be expected to be small.

The lateral system covers 14 000 acres, and includes 54 miles of ditches ranging in capacity from 12 to 75 sec-ft. Very little ditch lining has been placed, but the structures are all of concrete, the cheapest building material. The cost totals are as follows:

Excavation work	$64 376
Structures	57 632
Total	$122 008

The structures included in these cost totals comprise the following types:

Checks and drops	$20 885
Turn-outs	12 901
Bridges	9 972
Railroad crossings	6 924
Special structures	5 805
Spillways	1 143

Checks, drops, and turn-outs total $33 780, or 28% of the entire cost of the lateral system. All this cost could not be obviated by lining the system, but certainly a very large proportion could.

With a smaller cross-sectional area, the saving in drop structures, and the more direct and economical location possible in the lined ditches, the actual difference in cost per acre of land served by lined or unlined canals is comparatively small. It will generally be found to be less than $10 per acre, in many cases less than $5. If one takes into consideration the operating economics, the lined laterals have a distinct advantage by their freedom from breaks, seeped banks, and growth of vegetation in the channels, all of which should admit of a material reduction in operating costs. If these latter savings could be calculated from an investment standpoint and capitalized, any advantage in first cost of the unlined ditches would probably disappear, and a substantial margin be shown on the other side.

While considering canal lining, it would be well to give a little attention to the merits of pipe work in a distributing system. Large quantities of pipe have been used in the distributing systems of the Umatilla, Tieton, and Sunnyside Projects. The great bulk of this pipe is of concrete, both reinforced and plain, in sizes running from 54 in. down to 12 in. in diameter. The sizes below 24 in. have been usually made by the dry process, the reinforcement consisting of outside wire winding under tension. The larger diameters have usually been wet mixed, the pipe being manufactured in yards and hauled and laid like cast-iron pipe. Some of these lines of pipe are of great length, and work under heads running up to 110 ft. They have always given satisfaction, from every standpoint. A distribution system consisting wholly of concrete pipe would be undoubtedly the most satisfactory from an operating standpoint, and although the

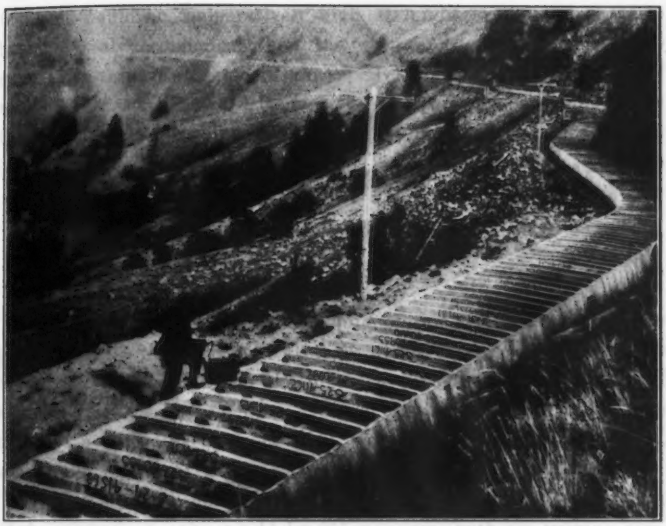

FIG. 12.—TIETON MAIN CANAL, CONCRETE LINED.

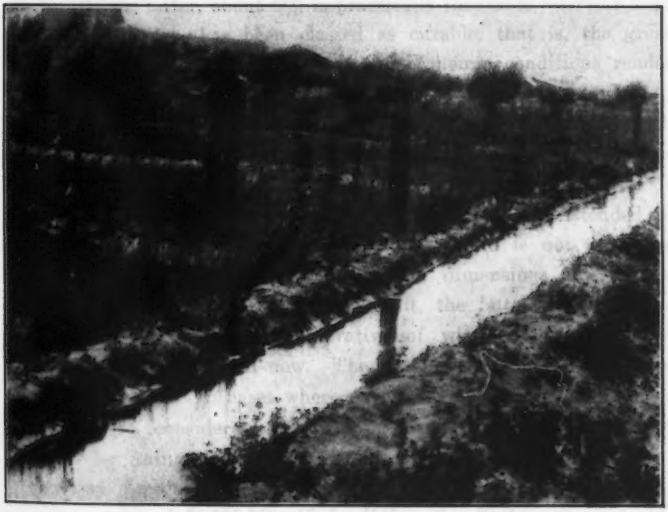

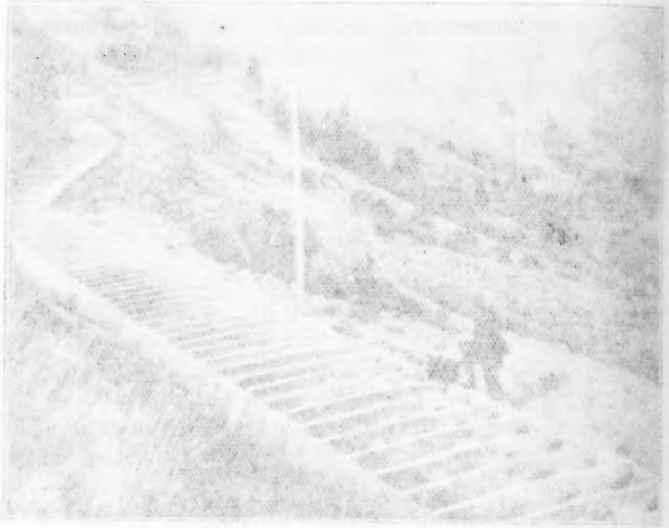

FIG. 13.—TYPICAL FARMERS' LATERAL, UMATILLA PROJECT.

first cost would be comparatively high, it might in the end prove to be more truly economical than the open-ditch system. With concrete pipe seepage losses are practically negligible. A number of tests of different lines of 4-ft. pipe, under operating conditions, show the following, all this pipe having a shell 3 in. thick:

	Length.	Head.	Average seepage per mile.
1	4 700 ft.	39 ft.	0.07 sec-ft.
2	5 400 "	28 "	0.05 " "
3	3 600 "	19 "	0.04 " "
4	9 800 "	85 "	0.20 " "

Apparently, the loss per mile in pipe of this size is nearly directly proportional to the head, and averages about 0.02 sec-ft. per mile for each 10-ft. head carried on the pipe. A pipe-distributing system of concrete throughout, under an average pressure head of 50 ft., with delivery to each 40-acre subdivision, would thus only lose about 1%, which is unimportant.

Taking the average of the six projects quoted, the average cost of the irrigation works would be $55 per acre, with an average combined loss in reservoirs and canals of about 50% of the entire water supply. Of the latter, about 6% is practically incurable reservoir loss; the remaining 44% has been classed as curable, that is, the great bulk of it can be cured or prevented if economic conditions render such action wise.

Should the ditch systems of these projects be wholly lined with concrete or pipe, the losses might be reduced from 44% to 10%, or less, a net saving of 34%, or, say, one-third of the whole supply. It is evident, therefore, that either the systems could be extended to cover about one-third more area, or if such land is not available, the works might be constructed of smaller dimensions and at less cost. In the case of works already built, the latter alternative is inapplicable, and is merely illustrative of what might have been done, but cannot be helped now. The lesson, however, should be applied to new work. In cases where new lands can be taken in under existing works, consideration should be given to the possibilities of extension by lining the present systems.

Suppose, for example, a project of 20 000 acres costing $55 per acre, or a total of $1 100 000; if, by lining the ditches, the irrigable

area can be increased to 27 000 acres, there will be first an additional cost for the new laterals with lining, which has been found to be about $18 per acre in a fairly difficult country, or, for the 7 000 acres, an additional construction cost of $126 000 will be necessary. Secondly, there will be the cost of lining the present ditch system, covering 20 000 acres, which, taken at $12 per acre, would mean an added charge of $224 000. The gross cost of the extended project, therefore, would be $1 450 000, or an average cost of $54 per acre. This, apparently, does not result in a material reduction in the acreage cost, but the great advantage lies in rendering available for profitable use the larger areas of land, the conservation of the water supply, and the avoidance of drainage evils referred to later. As a matter of fact, the process of extending a project already constructed with unlined earth canals, by the subsequent lining of ditches, is always much more expensive than if constructed *de novo* with the entire system lined.

In the case of a proposed large extension of the Umatilla Project, it is planned to line the entire canal system from the head-works down to the minor ramifications of the distribution system delivering to each 40-acre subdivision. At no point in the system will the water be exposed to avoidable seepage loss, and when the head-gates at the reservoir are opened, the Government will have the assurance that more than 90% of the supply will actually reach the cultivated fields.

Closely connected with the question of canal losses is the drainage problem. On nearly every irrigation project large and frequently increasing areas will be found subject to the rise of ground-water. The principal contributing influence in most cases is the seepage loss from the lateral systems, although a proportion, of course, is due to over-irrigation of the fields. On the Sunnyside Project, in Washington, some 4 000 or 5 000 acres of the best land were seriously affected a few years ago, large areas having been practically forced out of cultivation. In this case the Government was compelled to build a deep channel at a cost of some $340 000, mainly for the purpose of affording an outlet to the surplus water. On the Minidoka Project, in Idaho, the drainage feature is one of the most serious problems. At Umatilla the seepage water accumulating below the project in the Umatilla River has increased the summer flow some 100 sec-ft., and has rendered necessary the excavation of extensive drainage

ditches through the lower lands. At Klamath some $40 000 has been expended during the past three years on this account, and, on the Truckee-Carson Project, it is planned to expend not less than $400 000 in addition to the large sums already disbursed. There is no question that much relief from this increasing danger will be experienced by eliminating from the ground-water accumulations the bulk of the canal seepage. It is the writer's belief that, as time goes on, it may even be found necessary for legislatures to require canal systems to be lined or otherwise protected from seepage loss, not only in the interests of the investor and water user, but as a reasonable measure of conservation when water supplies are limited. As an engineering and business policy, it is well in the front rank, and should be considered by all who are building new works or operating and extending those already constructed.

DISCUSSION

Mr. Le Conte.

L. J. LE CONTE, M. AM. SOC. C. E. (by letter).—The curable and incurable losses of water in an irrigation system are certainly worthy of the most careful study and judicious consideration. The loss due to leakage from the reservoir bed is usually regarded as incurable, nevertheless, the site ought to be most carefully examined, geologically, before it is finally accepted.

Experience everywhere shows that when a large storage reservoir is built, the knowing ones always buy the water rights on the adjoining stream on the lower side. They know from experience that the leakage from the reservoir will swell the run-off of the adjoining stream. Where the stratification dips naturally from the reservoir site toward the stream in the adjoining water-shed, the leakage may be very serious. A notable case is that of the River Glyde, in Ireland, where the rainfall and run-off were being carefully observed by able engineers. Observations for 3 months in the rainy season showed a rainfall of 5.89 in. and a run-off of 9.35 in. This result gave rise to a great deal of merriment, at the time, but subsequent observations proved that the flood-waters from the higher adjoining water-shed found underground passages and escaped into the Glyde water-shed, thus swelling the observed run-off to abnormal dimensions. This was discovered by putting coloring matter in the upper stream and noting its appearance in the waters of the Glyde at a lower level, where the gaugings were being made. This simple experiment explained the whole mystery.

This only goes to show how fallacious it is to assume that the run-off records account for all the water that naturally comes from the direct water-shed. In point of fact, a large percentage of it may come from an indirect water-shed. A notable case is that of the Danube River; observations at the Iron Gate show that a large percentage of the summer flow goes through subterranean channels, and swells the summer flow of another stream in an adjoining water-shed.

It is quite common in every-day practice to pick out a dam site where a dike cuts across the valley, the presumption being that all danger of underground flowage is thereby avoided. This is true, but, at the same time, it makes a fine face for leakage to run along over and into the adjoining water-shed.

Mr. Hopson's estimate of a loss of 55% seems to be extravagant. In designing new works, it is generally customary to allow for a loss of one-third of the total, two-thirds of the water being delivered at its final destination. Of course, when the canals are first opened to service, the loss is very great (fully 55 to 60%); but it gradually grows less and less as the channels silt up. Shortly after the works

Mr. Le Conte.

are opened, the maintenance force begins the work of puddling the canal beds. This, of course, is usually done at times when the water is least needed for irrigation, and duties are not pressing. This puddling is kept up each year, until it is completed, when the total loss from seepage and evaporation is generally reduced from 60 to 33⅓%, but as low as 25% in some cases. In a majority of cases, the quantity of water saved by the canals being lined or unlined, but puddled, as usual, is not to exceed 25% at best, and may be much less; hence, lining is certainly questionable. Of course, in all cases where water is highly valuable, the scheme of lining the canals is entirely feasible and desirable; but, in pioneer countries which are being developed, the first cost is practically prohibitive, and, as a rule, that work is left to future generations.

The important point made by the author, however, that the cost of an unlined canal system and a lined canal system will be practically the same, certainly calls for full investigation. At present the writer is unable to see it in the light presented. The author also calls attention to the great saving in drainage troubles, brought about by a general and complete system of lined canals, laterals, and distributing ditches. There seems to be little doubt that the drainage troubles would be greatly mitigated; at present, they constitute the most distressing feature of irrigation works, the unsanitary conditions created and developed by the best types being notorious.

In most cases surface and sub-drainage take care of themselves. The natural drainage channels should be used for that purpose exclusively. They should be cleaned out and some little money should be spent in deepening, straightening, and correcting any natural defects.

The lamentable effect of excessive irrigation, on the one hand, and defective drainage, on the other, are beyond ordinary comprehension. When all the facts of any case are properly grasped, the drainage problem naturally develops into a veritable sink-hole for the waste of public money; hence the necessity for the exercise of the highest grade of good judgment.

In India the British Government was compelled to pass the most drastic laws to control irrigation.* On sanitary grounds, no water is allowed to be issued for autumn crops nearer than:

5	miles	from	a	military	post.
1	mile	"	"	native town of more than	10 000 inhabitants.
½	"	"	"	" " " "	5 000 "
¼	"	"	"	" " " "	1 000 "

200 yd. from small villages.

*See discussion by Surgeon-General H. W. Bellew on paper "The Evils of Canal Irrigation in India, and Their Prevention," by T. H. Thornton, *Journal*, Society of Arts, Vol. XXXVI, p. 521 (Mar. 23d, 1888); and "The Injurious Effects of Canal Irrigation on the Health of the Population of the Punjab, and Their Remedy," by Surgeon-General H. W Bellew, *Journal*, Society of Arts, Vol. XXXVI, p. 640 (May 11th, 1888).

Mr. Hammatt.

W. C. HAMMATT, M. AM. SOC. C. E. (by letter).—The question brought out in this excellent paper is of great interest to irrigation engineers. It is really, however, a business proposition, as to how much expense is justifiable for the purpose of preventing, or diminishing, the losses and damage due to seepage from canals and ditches. Into this determination enter so many factors, that no rule or formula, however complex, can be made to cover the subject.

The quantity of seepage from canals has been the subject of many investigations, and is dependent on many conditions, which conditions will affect its cure. The writer knows of cases where, at certain seasons of the year, the seepage into a reservoir from its water-shed more than offsets the evaporation therefrom, so that the reservoir remains practically stationary under a 120° sun.

In both reservoirs and canals, the seepage loss is dependent on the depth of water in the canal, the breadth of the wetted perimeter, the soil through which the canal is excavated, the kind of subsoil and the distance thereto, the height of the ground-water, the slope of the country, the growth of weeds in the canal, the character of the vegetation outside of the canal, and many other factors. All water which seeps from the canal can be accounted for and traced to its destination. In some cases it has a flow through the soil, in a definite direction and at a determinable speed, toward some open watercourse or underground reservoir. The character of the soil through which the canal is cut may make a variation in the rate of seepage of from 0.3 to 1.6 vertical ft. per day—the limits of measurements made by the writer. Aquatic grasses and weeds require water for their growth, aid seepage by loosening the soil and facilitating the passage of water to the subsoil, and increase evaporation through their leaves. Measurements under the supervision of the writer have shown this to increase the natural seepage as much as 40 per cent. A certain quantity of seepage goes to supply the wants of near-by vegetation, thus creating a flow and a gradient in that direction.

The seriousness of the loss by seepage depends on various causes, among which are the following: The scarcity of water and consequent loss in crop value, due to lack of the quantity lost by seepage; the character of the soil, and the consequent tendency toward the rise of the ground-water; and the character of crops, and the effect on them of a high or low water-table.

In Southern California, where water is scarce and the crops consist mainly of citrus fruits, the value of the water for crop propagation will pay for an immense expense for seepage prevention. On the other hand, in Central California, where water is plentiful and the crops are grain, cereals, and alfalfa, and $5 per acre per year is a prohibitive price for water, very little expense for the prevention of losses is justifiable. It is seldom that the seepage from a canal is suf-

ficient to water-log the soil. At the maximum rate the writer has seen, namely, 1.6 vertical ft. in 24 hours, the seepage from a canal carrying 100 sec-ft. would be about sufficient per mile to raise the ground-water 1 ft. in 900 acres. As the 100 sec-ft. would irrigate about 16 000 acres, and as only about 10% of this would go toward crop propagation, the remainder staying in the soil, the small proportion of ground-water due to canal seepage is apparent. Consider also that the farmer's tendency is to over-irrigate, especially where water is sold at a flat price per acre without regard to the quantity used, and we have the reason for the drowning of so many good farming areas. Mr. Hammatt

B. A. Etcheverry, Assoc. M. Am. Soc. C. E., has made a great study of various linings for canals and ditches.* The data which he has compiled show a maximum cost of lining of about 6 cents per sq. ft., and this is for thin mortar lining which is only adaptable to canals in solid ground capable of resisting the pressure, and with no possibility of settlement. In most of the canal systems of Central California, the cost of the entire system, exclusive of the preparation of the land itself, has fallen to between $10 and $25 per acre of irrigated land. The cost of lining only the main canals and branches would raise the cost of the systems from 25 to 50%, which would only be justified by a continued scarcity of water.

The writer has only discussed the lining of canals for the prevention of seepage losses. Where the point of diversion is so much above the point of use of the water that a steep grade and a swift flow is obtainable, the lining of the canal—by reducing the coefficient of roughness and by increasing the allowable velocity—will reduce the section sufficiently to repay its cost, partly, if not wholly. Another element is the growth of weeds, which would be eliminated by a concrete lining.

To summarize: The question as to the lining of canal systems should be decided by balancing, against the cost of such lining, the value of the water lost, the damage done by that water, the cost of excavation and of structures saved, and the elimination of the cost of canal cleaning.

LUTHER WAGONER, M. AM. SOC. C. E.—Under the speaker's direction, a concrete lining was applied to a ditch near the Mokelumne River, in California, in 1912. To test seepage loss, a portion of the unlined ditch was filled 2 ft. deep with water; it settled at the rate of 1 in. per hour, and one day later there was a depth of water of 4 in. in the ditch. This loss, in comparison with the total quantity of water carried by the ditch, was small. The chief object of the lining was to avoid the numerous breaks caused by gophers. Mr. Wagoner.

* These data may be found in *Bulletin No. 188*, Agricultural Experiment Station, University of California, and in *Bulletin No. 44*, Department of Agriculture, Victoria, B. C.

Mr. Wagoner.

As there was no local supply of concrete material, the best bid obtainable was 9.7 cents per sq. ft. for a 1:10 gravel concrete, 2 in. thick. This was applied to the dressed banks and kept wet by watering with a hose. Later, a 1:2 grouting was washed over the surface. After two days, a section of the lined ditch was filled 2 ft. deep with water for use on the following section. One week later there was 1 ft. of water in the lined ditch, the loss of 1 ft. being seepage and use. It was not especially desired to cut down the seepage loss, but rather to stop perforation by gophers, and, for this reason, as well as to reduce costs, a 1:10 mixture was considered of ample strength to stand up on a 1 to 1 slope, and that it would be gopher-proof.

It was brought out at the Hetch Hetchy public hearing, before Secretary Fisher, at Washington, D. C., on November 25th-30th, 1912, that all unlined ditches sustain a considerable loss. F. H. Newell, M. Am. Soc. C. E., Director of the Reclamation Service, conceded that losses on the Turlock and Modesto, California, ditches and laterals might reach from 35 to 45% of the water turned into them, and that a 2-in. sand-cement lining might cut down the losses to 15 per cent.

The possible saving of from 20 to 30% of the water by lining would only be an economic possibility when water is high priced, or when it can be used for a high-priced crop like citrus fruits. For the ordinary crops, and present conditions in Central California, it does not appear as yet that there is any economic warrant for lining. As the wealth of the community increases, doubtless this will be done, largely for the purpose of extending the use of the water over a greater acreage, as the areas of good lands are greater than can at present be supplied with water.

Mr. Hopson.

E. G. Hopson, M. Am. Soc. C. E. (by letter).—In closing the discussion on this paper, the writer notes that some who have taken part therein have expressed the opinion that in certain localities, with which they are familiar, conditions would not warrant the cost of protecting ditch systems against seepage losses by lining. In the paper the writer has only attempted to indicate that, under certain conditions, such lining is warranted, and that the conditions requiring lining are tending to increase each year, judging the matter entirely from the economic standpoint.

In making this statement it is well understood that, with low-priced crops, reasonably tight soils and subsoils, and an abundant water supply, the extra expense of placing concrete in the canals is unwarranted. A few years ago such action would have been considered unwarranted in almost every case. The writer has endeavored to illustrate the changes in opinion that are being forced by more straitened conditions in water supply, as irrigation development proceeds and the available lands are being more fully utilized, giving as

Mr. Hopson.

an example an important project, the feasibility of which has mainly depended on the economic use of the water supply, only possible by the avoidance of waste by seepage in the beds of the canals.

In placing concrete lining in irrigation laterals, attention is called to the necessity of making careful selection of the ingredients of the concrete. The writer has had experience in ditch lining which has not fulfilled the purpose of minimizing seepage, mainly due to the use of coarse aggregates in the concrete itself. Coarse aggregates give a concrete which, possibly, is entirely satisfactory, from the standpoint of strength and durability, but relatively porous. In selecting the aggregates, it is believed to be very important to obtain well-graded mixtures containing sufficient fine material to furnish a dense water-tight concrete, using the term "water-tight" in the relative sense. A little care in making the selection and grading can generally be expected to give good results.

SPECIFICATIONS FOR METAL RAILROAD BRIDGES MOVABLE IN A VERTICAL PLANE.

By B. R. Leffler, M. Am. Soc. C. E.

With Discussion by Messrs. Augustus Smith, Charles H. Mercer, P. J. Reich, and B. R. Leffler.

The excellent paper and specifications for movable bridges by C. C. Schneider, Past-President, Am. Soc. C. E.,* though quite general, pertained mostly to the common swing bridge, or one which rotates about a vertical axis. The writer has felt the need of specifications covering railroad bridges movable in a vertical plane, which necessity was created by the third and fourth track work in progress on the railroad with which he is connected. The common swing bridge is not well adapted to more than two tracks. The writer knows of only two four-track swing bridges in operation.

There seems to be a real necessity among engineers for specifications covering movable bridges of this class. The engineer who has not given long and special study to this class, which is handled mostly by patentees, cannot give adequate consideration to the various designs presented to him under intense competitive conditions. These specifications are intended as an aid to his judgment.

It is not considered wise, at this time, to enter into a discussion of the relative merits of the various patented bridges, the purpose of the specifications being to aid in producing a first-class structure for any style which may be adopted.

Some unsettled technical questions are considered, such as stresses in wire ropes bent over a sheave, the rating and testing of electric

* *Transactions*, Am. Soc. C. E., Vol. LX, p. 258.

motors, the character of the grooves for the lubrication of trunnions carrying heavy loads, the designing of keys and key-ways, etc.

The writer anticipates that the average mechanical engineer will not agree with the views on stresses in wire ropes. He believes that mechanical engineers use methods which are too loose (under the guise of so-called practical experience) in designing machinery parts. As generally used, wire rope is much over-stressed, principally by being bent over sheaves which are too small. Such practice may do where the rope is readily inspected and easily replaced, but wire rope for supporting counterweights in lift bridges should be designed by formulas which take into account the leading factors affecting the life and strength of the rope. A large factor of safety should then be used.

The rating of electric motors is that adopted by the American Institute of Electrical Engineers, in June, 1907. Some engineers specify a half-hour rating, which usually means a motor of the crane type. Motors for mill work are now being made, and are superior to any other type for strength and ruggedness; these are tested on the one-hour rating, and are suitable for bridgework.

Considerable care should be devoted to the design and workmanship of grooves in large trunnions for lubrication. The grooves should be large and allow of being cleaned. Compression grease cups should be used.

The design and workmanship of keys and key-ways do not usually receive enough attention, as keys come loose and cause damage and delay in the operation of bridges. Erectors sometimes use offset keys, made in the field, for adjusting the relative position of machine parts; but such keys are very objectionable. A key of minimum size, based on the diameter of the shaft and low unit stresses, has been specified.

Cut gear teeth are specified for wheels transmitting considerable power. This is somewhat unusual; but, as most railroad bridges are not hand-operated, the resulting smoothness in the running of the machinery is desirable. Cut gears add a very small percentage to the total cost of a structure. The cutting of cast gears sometimes reveals defects which otherwise would remain hidden.

Two formulas are presented for the strength of shafting, axles, etc. This subject is not treated very clearly in works on machine design. The use of the term "equivalent twisting moment" is confus-

ing. The formulas conform to the practice in structural designing of giving a value for tension or compression, and one for shear, respectively.

The writer believes that bridge engineers often specify too high a wind pressure. As usually specified for stationary structures, this includes an allowance for unknown lateral forces which are caused by a train moving over a bridge. Obviously, a smaller wind pressure should be specified for a bridge in motion. A pressure of 10 lb. per sq. ft. means, according to the formula, $P = 0.0032\ V^2$, a velocity of 56 miles per hour. The machinery should be able to hold the structure for a pressure of 15 lb. The wind pressure on a long bascule bridge is a large item.

Designers are sometimes too careless in their methods of designing machinery, relying mostly on rules-of-thumb or so-called experience. All resistance should be separately (and finally in their totality) considered. Coefficients should be adopted for the various sliding and rolling surfaces. The resistance of the moving span and attached parts should be reduced to a single force acting at the rack or in the operating cable. The motor torque for overcoming this resistance, and the machinery resistance, should be shown for all positions of the moving structure. The best method is to plot curves showing the torques, etc.; the time of opening, in 5- or 10-sec. intervals, should be plotted as abscissas, and the motor torque, resistance at rack, etc., as ordinates.

A moving structure is subject to some impact stresses due to its own motion, the magnitude of which cannot be found. The coefficients given simply express the writer's opinion.

No claim of originality is made for all parts of the specifications. The writer is largely indebted to Mr. Schneider's paper; to J. A. L. Waddell and J. L. Harrington, Members, Am. Soc. C. E., for workmanship and material for wire rope and attachments; and to others. To some extent his labors have been those of a compiler.

There is scarcely any first-class technical literature in the United States on the bending of wire rope.*

The writer has endeavored to make the specifications complete, but, of course, this was impossible. Some points are not covered; for instance, a specification should be framed to cover the design of segmental

*Attention is called to the article by Chapman, in the *Engineering Review*, London, October, 1908.

and track girders in rolling bridges, with special reference to taking care of the heavy concentrated load.

A rough test of the power required to open a double-track trunnion bridge of 159-ft. span, weighing, for parts in motion:

Machinery	156 877 lb.	
(Steel) Counterweight	538 313 "	Counterweight truss-link plate.
Span	797 009 "	Operating struts.
Concrete	2 570 000 "	
	4 062 199 lb. = 2 031 tons.	

TEST OF POWER:

	216	93	Time required to close = 2 min.

SPECIFICATIONS FOR BRIDGES MOVABLE IN A VERTICAL PLANE.

Scope.

1.—These specifications are intended to cover bascule bridges, which are such as rotate about a horizontal axis; and vertical lifts, which are those in which successive positions are parallel.

2.—The specifications of The New York Central Lines for Steel Railroad Bridges, for 1910, shall apply to movable bridges, except as noted herein.

Manner of Bidding.

Parts Classified as Machinery.

3.—Drums, cylinders, eccentrics, trunnions and their cast supports, shafting, pistons, gear wheels, racks, boxings, bearings, couplings, disks, cast sheaves and wheels, worm gearing, valves, pins about the axis of which the connecting members rotate, whistles, ram screws, end bridge-locks, rail-locks, indicators, cranks, axles, hooks, wrenches, and similar parts of machinery which require machine-shop work, shall be classified as machinery and be paid for at a common price per pound. Electric motors are not classified as machinery.

Sheaves.

4.—The large sheaves of vertical lift bridges, the webs and diaphragms of which are built up with plates, angles, and rivets, shall be paid for at a separate price per pound of finished weight, including casings and fastenings to trunnions.

Air Compressor Boilers.

5.—Air compressor tanks and steam boilers shall be paid for at a separate price.

Wire Ropes and Cables.

6.—Wire ropes and cables shall be paid for at a separate price per pound.

Sockets, Pins, Levers, etc.

7.—The sockets, pins, equalizing levers, and cable attachments to the trusses and counterweights shall be paid for at a separate price per pound.

Structural Steel Parts.

8.—Structural steel supporting the machinery proper, counterweight frames, counterweight trusses, towers, and links, shall be classified as structural steel and be paid for at the same price per pound as for the span itself.

9.—Structural steel which can be fabricated by the common shop methods as punching, reaming, drilling, shearing, planing, etc., as is usually done for stationary structures, shall be classified as structural steel and be paid for at the same price per pound as for the span itself.

Segmental Girders.

10.—Segmental girders in rolling bascule bridges and the horizontal girders on which they roll shall be paid for at a separate price per pound. This does not include any bracing, floor system, or other structural members which may be attached.

Electrical Equipment.

11.—Electrical equipment, such as wiring, switch-boards, controllers, lights, blow-outs, cut-offs, solenoids, switches, motors, etc., shall be paid for on a lump-sum basis.

12.—Cast-iron parts used in counterweights shall be paid for at a separate price per pound.

13.—Concrete in counterweights shall be paid for at a price per cubic yard in place.

Extra Parts, etc.

14.—It is to be understood that if any extra parts are needed, or any question arises, all difficulties shall be settled on the pound price basis as quoted and accepted for the parts in question.

General Details of Designing.

Self-Centering Devices.

15.—Self-centering and seating devices shall be used on the free ends of the moving span. Holding and forcing-down devices shall be used for the free ends of each truss.

Rail-Locks.

16.—Designs for bridging the gap between the shore rails and moving rails shall be furnished by the Railroad Company. Loose rails will not be allowed.

Air Buffers.

17.—Air buffers shall be furnished at the free ends of the moving span.

Counterweights.

18.—The counterweights shall be easily adjustable. Usually, this shall be done by adding or taking away cast-iron parts, or small concrete blocks.

Stairways.

19.—Metal stairways, with 1½-in. hand-rail, shall be provided, for access to the machinery, trunnions, and counterweights.

Girders in Rolling Bridges.

20.—The reinforcements of webs in the segmental girders and track girders of rolling bridges shall be symmetrical about the center planes of the webs. The center planes of the segmental webs shall coincide with the corresponding center planes of the webs of the track girders.

Coefficients of Friction for Moving Span and Attached Parts.

21.—In calculating the resistances to be overcome by the machinery, the resisting forces shall be reduced to a single force acting between the pinion and operating rack, or in the operating cable. In determining this force, the following coefficients shall be used in starting the span, and, except for the stiffness in cables, shall be reduced one-half after motion is begun:

For friction on trunnions	$\frac{1}{5}$
For rolling friction of rolling bridges	$\frac{1}{12}$
For stiffness in cables	$\frac{1}{200}$

Losses in Operating Machinery.

22.—In figuring the machinery losses between the operating rack or operating cable and the motor, the following coefficients shall be used: for the efficiency of any pair of gears, 0.94; for journal friction, 0.07. The losses of any worm gear shall be taken at 30% for an angle of thread 20° or more.

Time to Open.

23.—The time to open the bridge after the ends are released shall be as specified on the proposal drawing.

Inertia.

24.—The force necessary to overcome the inertia and produce acceleration and retardation for the time of opening shall be considered. The machinery shall be capable of stopping the bridge in 6 sec.; for this purpose, the coefficient of friction in the friction brake shall be taken at not less than 25 per cent.

Impact in Structural Parts.

25.—In calculating the dead-load stresses in the moving structural parts, for the various positions of the open bridge, such stresses shall be increased 25% as allowance for impact. For stationary structural parts (as towers, and supporting girders in rolling bridges), to which moving parts are attached, or on which such parts roll, 15% of the static load shall be added as impact.

26.—In structural steel parts, where a percentage of the dead load or static load is added for impact, the unit stresses for stationary structures shall be used; the impact percentages are an allowance similar to that provided by an impact formula for stationary railroad bridges.

Impact for Machinery Parts, etc.

27.—The allowance for impact in trunnions, cables, cable attachments, and machinery parts is taken care of by lowered unit stresses.

Wind Pressure.

28.—The least wind pressure to be assumed in proportioning the machinery or moving parts shall be 15 lb. per sq. ft. on the exposed surfaces of the moving parts as projected on any vertical plane. The machinery shall be strong enough to hold the moving parts in any position for this pressure, and be capable of opening the bridge in the specified time at 10 lb. per sq. ft. wind pressure.

28a.—On the ordinary open-floor bridge with ties, the exposed surface to wind shall be taken as equal to 80% of a full quadrilateral the width of which is the distance from center to center of trusses and the length of which is that of the moving span.

Detailed Drawings.

29.—The Contractor shall make complete detailed drawings of the machinery, so that any other shop can take them and duplicate the machinery. No reference to patterns or individual shop practices will be considered in lieu of the complete drawings. These drawings shall show a general outline of the assembled machinery. The drawings shall be made on tracing cloth, each sheet 24 by 36 in. in outside dimensions. These drawings shall become the property of the Railroad Company on the completion of the job.

Outline Drawing of Machinery.

30.—The Contractor shall furnish an outline drawing of the machinery, on which are shown the forces acting on the gear teeth, the twisting moment and bending moment on shafts, and other necessary information for checking the strength of the machine parts. A tabulation of the formulas and methods of calculation shall be shown complete enough to allow them to be checked.

Torque Curves.

31.—The Contractor shall show by a drawing of curves the torque to be exerted by the motor or prime mover, as follows:

1. A torque curve for acceleration and retardation;
2. A torque curve for the frictional resistances;
3. A torque curve for any unbalanced condition of the structure;
4. A torque curve for the wind load;
5. A torque curve showing the greatest combination of resistances acting at any one time.

In figuring the friction at starting (this being twice the running friction), no acceleration of the moving mass shall be considered. This friction shall be considered as reduced to the running friction in the first second after the power is applied.

Center of Gravity.

32.—The Contractor shall check the location of the center of gravity of the moving span, including all parts attached thereto, and also the location of the center of gravity of the counterweight, including counterweight girders and trusses, by computations based on accurate weights calculated from shop plans. He shall submit duplicate sketches and copies of these computations accompanied by weight bills to the Railroad Company for approval.

Hand Operation.

33.—All bridges shall be equipped with hand-operating mechanism. The number of men and the time required to operate shall be estimated on the assumption that the force one man can exert on a lever is 40 lb. with a speed of 160 ft. per min. developing about ⅛ h.p. For calculating the strength of the machinery, the power of one man shall be assumed as 125 lb., but 150 lb. shall be the minimum used and applied to the extreme end of a lever.

Operating Machinery.

34.—The parts shall be simple in design, and easily erected, inspected, adjusted, and taken apart. The fastenings shall hold the parts in place securely after they have been set.

Kind of Material.

35.—Rolled or forged steel shall be used for bolts, nuts, keys, cotters, pins, axles, screws, worms, piston rods, trunnions, and crane hooks, if any.

36.—Trunnions, pins, and shafting more than 3½ in. in diameter shall be of forged structural steel. Shafting 3½ in. or less in diameter may be of cold-rolled steel.

37.—Forged or cast steel shall be used for levers, cranks, and connecting rods.

38.—Cast steel, or forged steel, shall be used for couplings, end shoes, racks, toothed wheels, brake wheels, drums, sheaves, and hangers where the supported weight will cause tensile stresses. Large sheaves may be built of structural steel.

39.—Pinions shall be made of forged steel, and cut from the solid metal.

39a.—Pinions shall have not less than fifteen teeth.

40.—Sockets used for holding the ends of wire ropes shall be forged without welds, from the solid steel.

Cast Iron.

41.—Cast iron may be used in boxes for shafts 2 in. or less in diameter, and which obviously carry light loads. Other boxes shall be of cast steel.

42.—Cast iron may be used in eccentrics, cylinders, pistons, fly-wheels, and parts of motors which are usually made of cast iron. Cast iron shall not be used for any trunnion or axle support.

Metal for Bushings.

43.—Phosphor-bronze, brass, and Babbitt metal shall be used for the bushing or lining of journal bearings and other rotating or sliding surfaces, to prevent seizing.

44.—Phosphor-bronze, only, shall be used for bushing for the trunnions of bascule and lift bridges, or in any large bearing carrying heavy loads.

45.—The bushings for large bearings, such as for trunnions and similar parts, shall be held from rotating in their casings. The force tending to cause rotation shall be taken as one-eighth of the load on the trunnion or bearing, and as acting tangent to the surface between the back of the bushing and casing. It shall be practicable to take out the bushing when the trunnion is slightly lifted.

Castings.

46.—Castings which are to be attached to rough unfinished surfaces shall be provided with chipping strips. The outer unfinished edges of ribs, bases, etc., shall be rounded off, and inside corners filleted.

Bolts and Nuts.

47.—Bolts and nuts, up to 1½ in. in diameter, shall have U. S. Standard V-threads. Nuts and exposed bolt heads shall be hexagonal in shape, and each nut shall be provided with a washer. If the nut will come on an inclined surface, a special seat, the top surface of which is at right angles to the bolt, shall be cast or built up to receive the nut. Bolt heads which are countersunk in castings shall be square.

48.—Nuts which are subject to vibration and frequent changes of load shall have locking arrangements to prevent the gradual unscrewing of the same. If double nuts are used for that purpose, each nut shall be of the standard thickness. Nuts shall be secured by split pins put through the bolt.

Screws

49.—Screws which transmit motion shall have square threads.

Tap-Bolts, Set-Screws, etc.

50.—Tap-bolts and stud-bolts shall not be used, except by special permission.

51.—Set-screws shall not be used for transmitting torsion to shafts or axles. They shall be used for holding keys, or other light parts, in place.

52.—Collars shall be used wherever necessary to hold the shaft from moving horizontally. Each collar shall have at least two set-screws at an angle of 120 degrees. Collars.

53.—Shaft couplings, unless of the flexible kind, shall be of the flange type, or split muff with bolt heads and nuts countersunk. Shaft Couplings

54.—Couplings shall be keyed to shaft.

55.—Gib-head or hooked keys shall be used for keying machinery parts to shafts, except where otherwise shown. The keys shall have the proportions shown in Fig. 1, in which d is the diameter of the shaft Keys.

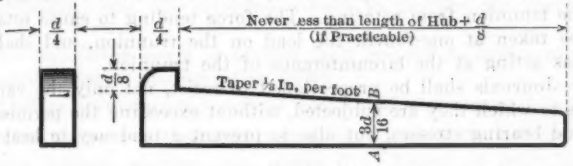

FIG. 1.

$A\ B$ is a mid-section of the tapered length. The sides shall be parallel.

56.—If the foregoing shape of key gives unit stresses in shear or bearing exceeding those in the table of allowable unit stresses, its section must be increased.

57.—The key shall be sunk in grooves in both hub and shaft. The finish of the grooves and key shall be such as to give a full bearing on all four sides, except as taper of key will not allow.

58.—If practicable, the groove in the shaft shall be made long enough to allow the key to be inserted without moving the wheel sidewise. After the key is firmly seated, the groove shall extend beyond the point of the key a distance not less than $\frac{3\ d}{8}$ to allow for future tightening; the clear distance between hub and hook of key shall not be less than $\frac{d}{8}$.

59.—The depth of the groove in the shaft shall be $\frac{3\ d}{40}$, measured at the side of the groove.

60.—In the case of large shafts carrying heavy parts, two or more keys of special design shall be used. In such cases, the matter shall be taken up with the Engineer, for special study.

61.—The foregoing requirements for keys and key-ways are for major machinery parts, the use of which is intended to develop the full torsional strength of the shaft. For minor parts, the keys and key-ways shall be proportioned for that size of shaft in which torsional strength would be developed by the minor parts.

Set Screws for Keys.

62.—Keys shall be held in place by set-screws.

Hub.

63.—If practicable, the length of the hub shall be not less than $2d$. Its thickness shall be not less than $\frac{d}{3}$. The hub shall have a light driving fit.

64.—The groove in the hub shall be made on the center line of an arm.

65.—Hubs shall be bored truly at the center of the wheel.

Keys in Trunnions.

66.—For trunnions and similar parts, which are designed chiefly for bending and bearing, the keys, key-ways, and bolts shall be designed to hold the trunnion from rotating. The force tending to cause rotation shall be taken at one-fourth the load on the trunnion, and shall be taken as acting at the circumference of the trunnion.

Journals.

67.—Journals shall be proportioned to resist, not only the various stresses to which they are subjected, without exceeding the permissible fiber and bearing stresses, but also to prevent a tendency to heat and seize.

Bushings.

68.—Steel bearings carrying steel shafts or journals shall be lined with bronze or brass. If shafts are 3 in. or less in diameter and of a slow motion, Babbitt metal may be used. Bearings of steel on steel for moving surfaces will not be allowed.

68a.—Divided journal and trunnion bearings shall be used, and the cap shall be fastened to the base with turned bolts recessed into the base. The nuts and heads shall bear on finished bosses cast on the bearing.

Boxes.

69.—In cast-iron boxes carrying light shafts, no lining is needed.

70.—The bearings of shafts shall be placed as near to the points of loading as possible.

71.—The foot-steps of vertical shafts shall be of axle or tool steel, and shall run on bronze disks.

Lubrication.

72.—Provision shall be made for the effective lubrication of journals, or any other sliding surfaces. Closed oil or compression grease cups shall be used. Grooves shall be cut in the surface of the trunnion to provide for the proper distribution of grease or oil.

Grease Grooves.

73.—The grooves in large trunnions shall approximate to a U shape; the size shall be such that a wire $\frac{5}{16}$ in. in diameter may lie wholly within the groove. The edge of the U shall be rounded to a radius of $\frac{3}{16}$ in.

74.—The grooves shall be straight, running parallel to the axis of the trunnion. They shall be not less than three in number, and located so that all parts of the bearing surface of the bushing will be swept by the contained lubricant, in an opening, and in a closing of the bridge. The grooves must allow of being cleaned with a wire.

Grease Cups.

75.—In any trunnion bearing, or similar heavy bearings, strong compression grease cups shall be used for the grooves.

76.—Oil and grease ducts shall be located so that the lubricant will flow by gravity toward the bearing surface.

77.—Dust covers shall be provided for principal bearings, in particular for trunnions. Dust Covers.

78.—Line shafts, extending from the center of the bridge to the end, shall not be continuous, but shall be connected with claw couplings. Each length of shafting shall rest in not more than two bearings, with the couplings close to the bearings. Shaft Supports and Couplings.

79.—If shaft supports are connected to the floor-beams, in bridges having long panels, intermediate supports shall be used; these shall be adjustable, and are intended merely to prevent the shaft from sagging.

80.—Equalizing gears or devices shall be used to insure equal action at the pinions and operating racks. Equalizing Gears.

81.—The unsupported length of shafts shall not exceed $L = 80\sqrt[4]{d^2}$ for shafts supporting their own weight only; $L = 50\sqrt[4]{d^2}$ for shafts carrying pulleys, gearing, etc., where L = length of shaft between center of bearings, in inches; and d = diameter of shaft, in inches. Unsupported Length of Shafts.

82.—Line shafts connecting machinery at the center to that at the ends shall run at fairly high speed. The speed reduction shall be made in the machinery near the end.

83.—In designing circular shafting, trunnions, and axles, the greatest unit fiber stress in tension or compression due to bending shall be calculated by the following formula:

$$f = \frac{32}{\pi d^3}\left(\frac{3}{8}M + \frac{5}{8}\sqrt{M^2 + T^2}\right).$$

84.—The maximum unit shear shall be calculated by the following formula: Formulas for Shafts.

$$S = \frac{16}{\pi d^3}\sqrt{M^2 + T^2}.$$

85.—In these formulas, f = unit fiber stress in tension or compression; S = unit shear; d = diameter of shaft; M = the simple bending moment; and T = the simple twisting moment.

86.—If a shaft, trunnion, or axle has one key-way cut, f and S shall be increased by one-sixth; if two key-ways are cut, increase by one-fourth. If the shaft, etc., is enlarged through the hub, this does not apply. Effect of Key-Ways in Shafts.

87.—In calculating the bending moment on shafts, trunnions, and journals, the distance from center to center of bearings shall be taken. Distance Between Shaft Supports.

88.—Gear teeth shall be of the involute type, with an angle of obliquity of 20 degrees. The roots below the clearance line shall be filleted. Style of Gear Teeth.

89.—The width of the teeth may be as great as four times the pitch, but not more, except for wheels running at a very high velocity, as in motors where abrasion is to be considered.

Strength of Beveled Gear Teeth.

90.—In estimating the strength of teeth in bevel wheels, the pitch at the middle section shall be taken.

Pitch Circle.

91.—For the purpose of setting gear teeth accurately in the field erection, the pitch circle shall be scribed on the ends of the teeth.

Worm Gearing.

92.—Worm gearing, for transmitting power, shall have an angle of thread not less than 20 degrees. The worm shall run in oil. A bronze or brass collar shall be used at the end of the worm and at the end of the wheel axle, to take care of the end thrust. The wheel shall be of bronze. If a nut engages the worm, the nut shall be of bronze.

92a.—Worm wheels shall have not less than twenty-eight teeth.

93.—Worms which are to be used for actuating signals, indicators, or other minor parts may have an angle of thread less than 20 degrees.

93a.—Safety guards shall be provided around gears and other moving parts where it is necessary for workmen to be while the machinery is in motion.

Counterbalancing, Operating Ropes, and Attachments.

Wire Ropes and Cables.

94.—Wire rope shall be made by some manufacturer approved by the Engineer.

95.—The counterbalance ropes shall be of plow-steel wire, and shall consist of six strands, of nineteen wires each, laid around a hemp center.

96.—Ropes shall be laid up in the best manner, and shall be thoroughly soaked in an approved lubricant during the process of manufacture.

97.—The counterbalance ropes shall be made from wire which has been tested in the presence of an inspector designated by the Engineer, and which, for sizes from 0.076 to 0.150 in. in diameter (the limiting values used in counterbalance ropes), exhibits the following physical properties:

a.—The tensile strength shall be not less than 225 000 lb. per sq. in. for wire from 0.150 to 0.126 in., nor less than 230 000 lb. for wire from 0.125 to 0.101 in. in diameter; nor less than 235 000 lb. for wire from 0.100 to 0.076 in. in diameter.

b.—The total ultimate elongation, measured on a piece 12 in. long, shall be not less than 2.4 per cent.

c.—The number of times a piece 6 in. long can be twisted around its longitudinal axis without rupture shall be not less than 1.4 divided by the diameter, in inches.

d.—The number of times the wire can be bent 90° alternately to the right and to the left, over a radius equal to twice its diameter, without fracture, shall be not less than six. This test shall be made in a mechanical bender constructed so that the wire actually conforms to the radius of the jaws and is subjected to as little tensile stress as possible.

98.—The rope shall be made in one piece, if possible. Its breaking strength, as determined by the test described in Paragraph 101, shall be not less than

Ultimate Strength of Cables.

4 900	lb.	if	$\frac{1}{4}$	in.	in diameter.
11 800	"	"	$\frac{3}{8}$	"	"
20 600	"	"	$\frac{1}{2}$	"	"
32 400	"	"	$\frac{5}{8}$	"	"

465 000	"	"	$2\frac{1}{2}$	"	"

99.—In case the breaking strength of the rope falls below the values cited above, the entire length from which the test pieces were taken shall be replaced by the manufacturer with a new length, the strength and physical qualities of which come up to the specifications.

100.—Sockets used in connection with this rope shall be forged, without welds, from solid steel. In every case the dimensions shall be such that no part under tension shall be loaded higher than 65 000 lb. per sq. in. when the rope is stressed to its ultimate strength, as named above. The sockets must be attached to the rope by a method which is absolutely reliable and will not permit the rope to slip in its attachment to the socket.

101.—In order to show the strength of the rope and fastenings, a number of test pieces, not more than 10% of the total number of finished lengths which will be ultimately made, nor less than two from each original long length, and not more than 12 ft. long, shall be cut, and shall have sockets, selected at random from those which are to be used in filling the order, attached to each end. These test pieces are to be stressed to destruction in a suitable testing machine. Under this stress the rope must develop the ultimate strength given in Paragraph 98.

102.—The sockets must be fastened to the rope so that there is no slipping of the rope in the basket. If slipping should occur, then the method must be changed until one is found whereby slipping can

be entirely avoided. The sockets themselves shall be stronger than the rope with which they are used; if one should break during the test, then two others shall be selected and attached to another piece of rope and the test repeated; and this process shall be continued until the inspector is satisfied of their reliability, in which case the lot shall be accepted. If, however, 10% or more of all the sockets tested break at a load less than the minimum ultimate strength of the rope given in Paragraph 98, then the entire lot shall be rejected and new ones shall be made of stronger material.

Length of Rope.

103.—The length of each rope, from inside of bearing to inside of bearing of sockets, shall be determined, and a metal tag having the said length stamped thereon shall be securely attached to the rope.

104.—The purchaser reserves the right to test each wire rope connection, after its attachment is made, up to one-half of the ultimate strength of the rope, and, if it shows the least sign of weakness, it shall be rejected and replaced.

Facilities for Testing Rope.

105.—The manufacturer shall provide proper facilities for making the tests, and shall make at his own expense all the tests required. Tests shall be made in the presence of an inspector who represents and is paid by the Engineer.

Shipment of Rope in Coils.

106.—Ropes shall be shipped in coils the minimum diameter of which is at least thirty times that of the ropes, and they shall be uncoiled for use by revolving the coil, not by pulling the rope away from the stationary coil.

Equalizing Levers.

107.—The equalizing levers connecting the ropes to the counterweights and their pins more than $3\frac{1}{2}$ in. in diameter shall be of forged steel; pins $3\frac{1}{2}$ in. in diameter or less shall be of rolled machinery steel. The levers shall be neatly finished, and shall conform to the dimensions shown on the drawings.

Workmanship.

108.—For the parts of the operating machinery of movable bridges which are usually exposed to the weather, the finish shall be confined to the bearing, rotating, and sliding surfaces, and wherever it is required to produce accurate fits and precise dimensions.

109.—Castings shall be cleaned, and seams and other blemishes removed.

110.—Drainage holes, not less than $\frac{3}{4}$ in. in diameter, shall be drilled in places where water is likely to collect.

Play of Unfinished Bolts.

111.—Unfinished bolts may have a play of $\frac{1}{16}$ in. in the bolt holes. Turned bolts must have the diameter of the shank at least $\frac{1}{16}$ in. larger than the diameter of the threaded portion, and must have a driving fit in the bolt hole.

Racks and Contact Surfaces.

112.—The backs of racks and contact surfaces shall be planed.

Tread-Plates.

113.—The top and bottom of the tread-plates and contact surfaces in rolling bridges shall be planed to fit. A full bearing must be made.

114.—The periphery and the ends of teeth which mesh with a shrouded pinion shall be planed, and the pitch line scribed thereon.

115a.—The joints between the caps and bases of journal and trunnion bearings shall be planed. The ends of the bases and surfaces in contact with the supports shall be planed. Bolt holes for holding the cap to the base and for holding the base to its support shall be drilled.

Finishing of Trunnions, etc.

115.—Journals and trunnions shall be turned with a fillet at each end and at points where the section changes. Trunnions and journals 8 in. and more in diameter shall have a hole, 1½ in. in diameter, bored through on the longitudinal axis. Journals, trunnions, and bushings must be polished after being turned. The use of a cutter which trembles or chatters will not be allowed.

Grooves.

116.—The grooves in the surfaces of trunnions or similar large bearings shall be machine cut. Chipping and filing will be allowed only for removing small inequalities. The grooves shall be smooth, especially the rounded corners.

Hubs.

117.—Hubs of wheels, pulleys, couplings, etc., shall be bored to fit close on the shaft axle. If the hub performs the function of a collar, the end next to the bearing shall be faced. Holes in hubs of toothed gear wheels shall be concentric with the pitch circle.

Cut Gears, etc.

118.—The periphery of gear wheels shall be turned. Gear wheels which are part of the train which actuates the moving span, or the bridge-locks, or the rail-locks, shall be cut. Machine-moulded teeth may be used for actuating signals or small parts.

Beveled Gears.

119.—Beveled gears shall be cut. The cutting shall be done by a planer having a rectilinear motion to and from the apex of the cone. Rotating milling cutters shall not be used.

Grooves in Sheaves.

120.—The grooves in the circumference of sheaves carrying wire ropes shall be turned to a radius which will fit the rope. This is to be done after the sheave is completely assembled and permanently riveted up.

121.—At the juncture of the shrouding and teeth in pinions, cleaning, chipping, or other means shall be used to insure the meshing of the pinion teeth and rack teeth.

122.—Threads on worms, and the teeth of worm wheels shall be cut and shall fit accurately. Point contact shall be avoided.

123.—Any two surfaces which slide, roll, or bear on each other shall be planed.

Assembling of Machinery.

124.—Machinery parts shall be assembled on the supporting members in the shop, and shall be aligned and fitted, with holes in the supports drilled, and with the members in correct relative position. The members shall be match-marked, both to the supports and to each

other, and re-erected in the same relative position; or, if not assembled in the shop, connecting holes in the supports shall be drilled in the field.

Holes for Sheaves for Vertical Lift Bridges.

125.—The holes in the girders and columns for the bolts connecting the main sheave bearings to their supporting girders shall be drilled from the solid through cast-iron or steel templets on which the bearings were set and accurately lined when the holes in the bearing were bored. The bolt holes and the bolts shall be turned to the same diameter and the bolts driven to place without injury to them, the bearings, or the girders or columns.

Shop Test on Trunnions.

126.—If trunnions rotate in fixed pedestal bearings, such as the sheave trunnions in vertical lift bridges or similar bearings, the pedestals shall be firmly mounted in the shop, the trunnions placed therein and covers bolted; the whole, when assembled, shall simulate the assemblage in the field as nearly as practicable. The maximum torque in inch-pounds required to rotate the trunnion shall be $\frac{W r}{10}$, where W equals the weight of the trunnion, in pounds, and r equals the radius of the trunnion, in inches. If large structural parts rotate about the axis of the trunnion, the trunnion shall be inserted in its bushing in the structural part and rotated. If the shop position of the structural part is flat, which is the usual case, the axis of the trunnion will be vertical, and there will be no load on the bearing; in this case the maximum torque required to rotate the trunnion shall be $\frac{W r}{50}$. At least four complete rotations of the trunnion must be made. If any grinding or hard turning is found, it must be remedied. These trunnion tests shall be made in the presence of the Railroad Company's inspector, and with such apparatus as will readily determine the torque.

Facing of Couplings.

127.—Faces of flange and split muff couplings shall be planed to fit. The couplings shall be keyed to the shaft.

128.—A special effort to secure good workmanship on keys and key-ways shall be made.

Coating of Surfaces.

129.—Machined surfaces shall have a coating of white lead applied to them.

130.—Machinery which is of the regular standard manufactured type, such as steam, gasoline, electric motors, pumps, air compressors, etc., shall be guaranteed by the manufacturer as to efficiency, and shall be subject to the approval of the Engineer. Motors shall be tested to prove that they fulfill the specified requirements and develop the desired speed, power, and torque.

Brake Test of Motors.

131.—The rating of a motor shall be the horse-power determined by the brake test.

A. I. E. E. Rules.

132.—The electric equipment shall conform to the Standardization Rules of the American Institute of Electrical Engineers, as approved June 21st, 1907. (See "Standard Hand Book for Electrical Engineers," 3d Edition, Sect. 19.)

133.—The unit stresses per square inch, to be used for parts in which main stresses are not increased by impact, shall be as follows:

STRESSES IN ONE DIRECTION, IN POUNDS PER SQUARE INCH.

Material.	Tension.	Compression.	Fixed Bearing.	Shear.
Machinery steel.....	9 400	$9\,400 - 40\frac{l}{r}$	11 000	6 200
Structural steel.....	8 500	$8\,500 - 36\frac{l}{r}$	.....	5 600
Steel castings.....	7 000	$8\,000 - 35\frac{l}{r}$	.....	5 000
Phosphor-bronze.....	6 600	.....	.....	4 600
Cast iron	3 000	8 000	.....	3 000
Shear on keys...	.....	4 900 lb.		
Bearing on keys.	.....	8 800 "		

134.—The maximum unit tension in plow-steel cables shall be one-sixth of the ultimate. The maximum unit tension is equal to the direct unit stress plus the extreme fiber unit stress in the individual wire due to bending over the sheave.

Reversal of Stresses.

135.—For stresses which are reversed at the rate of five or more times per minute, use one-half of the above unit stresses.

136.—If wire rope is bent over a sheave, the bending stress and permissible load on the rope shall be calculated as follows:

Let P = the total pull or permissible load, on the rope, in pounds;
K = extreme unit fiber stress in the greatest individual wire;
E = modulus of elasticity = 28 500 000;
a = cross-sectional area of rope, in square inches;
d = diameter of thickest wire, in inches;
D = diameter of sheave to center of rope, in inches;
S = greatest unit tension allowable;
α = angle of helical wire with axis of strand;
β = angle of helical strand with axis of rope;
c = diameter of rope.

$$\text{Then } K = \frac{Ed \cos.^2 \alpha \cos.^2 \beta}{D} \quad \ldots\ldots\ldots\ldots\ldots (1)$$

$$P = a\left(S - \frac{Ed \cos.^2 \alpha \cos.^2 \beta}{D}\right) \quad \ldots\ldots\ldots\ldots\ldots (2)$$

For rope having six strands of nineteen equal wires each,

$$P = a\left(S - \frac{1\,800\,000\,c}{D}\right) \quad \ldots\ldots\ldots\

143.—The foregoing formula is for involute teeth having an angle of obliquity equal to 20 degrees.

144.—The pressure, in pounds per linear inch, on rollers at rest shall be, for rolled and cast steel, 600 d, where d equals the diameter of the roller, in inches. Pressure on Rollers.

UNIT STRESSES FOR BEARING ON ROTATING AND SLIDING SURFACES.

145.—The maximum bearing values for rotating and sliding surfaces, in pounds per square inch, shall be as follows:

For bearings on which the speed is slow and intermittent:

	Pounds per square inch.
146.—Pivots for swing bridges: Hardened tool steel on special phosphor-bronze	3 000
147.—Trunnion bearings on bascule bridges: Axle steel on phosphor-bronze, average	1 500
and never greater than 1 700 lb. for maximum bearing for any position of the bridge.	
148.—Wedges: Cast steel on cast steel or structural steel	500
149.—Screws which transmit motion on projected area of thread	200
150.—For ordinary cases, parts moving at moderate speeds:	
Hardened steel on hardened steel	2 000
Hardened steel on bronze	1 500
Tool steel (not hardened) on bronze	900
Structural steel on bronze	600
Cast iron on structural steel	400
Cast iron on cast iron	400
On cross-head slides, speed not exceeding 600 ft. per min.	50

151.—In order to prevent heating and seizing at higher speeds, the pressure on pivots or foot-step bearings for vertical shafts and journals shall not exceed:

$$\text{On pivots} \ldots\ldots p = \frac{40\,000}{n\ d} \text{ per square inch.}$$

$$\text{On journals} \ldots\ldots p = \frac{300\,000}{n\ d} \text{ per square inch.}$$

Where n = number of revolutions per minute,
and d = diameter of journal or pivot, in inches.

152.—For crank pins and similar joints with alternating motion, the limiting bearing values given in the above formula may be doubled.

Stresses on Rollers.

153.—The permissible pressures, in pounds per linear inch of roller in motion, shall be as follows:

For cast iron	$p = 200d$
For steel castings	$p = 400d$
For axle steel	$p = 500d$
For tool steel	$p = 800d$
For hardened tool steel	$p = 1\,000d$

Where p = pressure per linear inch of roller,
and d = diameter of roller, in inches.

154.—The foregoing values are for rollers and bearing surfaces of the same material; if rollers and bearing surfaces are of different materials, the lower value shall be used.

Motors.

155.—The kind of motor best adapted to any particular case depends on local conditions, and should be left to the judgment of the Engineer.

Mechanical Power.

156.—If the bridge is operated by mechanical power, the motor shall be of ample capacity to move or turn the bridge at the required speed. All machinery parts shall be designed with sufficient strength to resist the greatest pressure which can be exerted by the motor. No matter what mechanical power is used, all bridges shall also be provided with hand-power operating machinery.

Friction Brakes.

157.—Friction brakes, to be operated by hand or foot, shall be provided where the motor is located in the operator's house. They shall be attached to the secondary shaft of the motors which connect to the moving gear, and shall have sufficient capacity to stop or hold the moving span in any position, under all conditions.

Operator's House.

158.—If mechanical power of any kind is to be used for operating a movable bridge, a suitable house shall be provided for the operator. The house shall be of such dimensions as required for the purpose for which it is to be used. It shall be placed in a position where the operator can observe the signals and see the approaching vessels and trains, and with enough windows of sufficient size, so that this view will not be obstructed. If the operator's house is above or below the floor of the bridge, suitable steel or iron stairs with railings shall be provided to lead from the floor of the bridge to the floor of the operating house. The house shall be of fire-proof construction, consisting of a steel frame, steel floor-joists and a fire-proof floor. If the house contains motors and machinery, the floor shall preferably consist of steel plates, but, if the motors are located elsewhere, the floor between the joists may be of concrete construction. The sides and roof shall be of metal, concrete, or any other non-combustible material. The hand-rail for stairways and other places shall be of 1½-in. gas pipe.

Heating of Operator's House.

159.—Whenever the climatic conditions require it, provision shall be made for heating the operator's house. If steam power is used, the house shall be heated by a steam coil or radiator fed from the boiler. If electric power is used, the heat may be supplied by electricity. If gasoline is used, or any other power which cannot be utilized for heating, a coal, wood, petroleum, or gas stove, as directed by the Engineer, shall be provided.

Steam Engine.

160.—If a steam engine is used, it shall consist of a double-cylinder, reversing engine, the piston speed of which shall not exceed 200 ft. per min.; it shall develop the desired power and speed with a steam pressure of 50 lb. per sq. in. The engine shall be connected to the operating machinery by an approved friction clutch, arranged so that the moving and locking machinery can be operated alternately or stopped without stopping the engine.

Steam Separator.

161.—In the steam supply pipe, and close to the steam chest, shall be placed a steam separator. This separator, under test with quality of steam as low as 66%, shall show an average efficiency of 85% in five tests.

Boilers.

162.—The steam shall be generated by one or two upright, tubular boilers, each of which shall have twice the capacity of the engine. The boilers shall be designed for a steam pressure of 150 lb. per sq. in., and shall be adapted to the kind of fuel specified by the Engineer; they shall be of open-hearth steel in accordance with the specifications for boiler plates, Paragraphs 246 to 251, inclusive. They shall be encased in asbestos and covered with Russia iron.

163.—The boilers shall also be in accordance with the specifications of the Mechanical Department of the Railway Company, and shall conform to the civil laws.

Flues of Boilers.

164.—Vertical boilers shall have submerged flues at the top.

Horse-Power of Boilers.

165.—The total horse-power of the boilers shall be twice that of the engine, and shall be computed by the following rule: Calculate the inside area of the tubes, the area of tube sheet next to the fire, and the sides of the fire-box where this is in contact with the fire. Take the sum of these areas in square feet and divide by fifteen. The intention is to allow 15 sq. ft. of heating surface per horse-power. At least $\frac{1}{3}$ sq. ft. of grate surface shall be provided per horse-power.

Equipment of Engine-Room.

166.—The engine-room shall be provided with a steel water tank of sufficient capacity; a duplex, steam feed-pump; and an injector for each boiler, with necessary pipes and connections for feeding boilers separately or together; steam water-lifters with necessary strainers, flexible hose, and piping to lift the water from the river into the tank; a coal hoist and a steel coal-bin of sufficient capacity. The engine-room shall be provided with a suitable indicator for recording the positions of the moving span in turning and locking. A work-bench with

a full set of machinist's tools shall be provided, such as a vise, wrenches, chisels, hammers, files, oilers, oil-cans, and oil-tank.

Whistle.

167.—A whistle having a bell 5 in. in diameter and 12 in. long, shall be installed complete. If operated by air, the compressor and air tank shall conform to the following specifications: The compressor shall be motor driven, the motor and compressor being on one frame, and geared. All working parts shall be completely enclosed, and self-lubricating. The compressor shall have a piston displacement of from 25 to 30 cu. ft. per min. when working against a tank pressure of 90 lb. per sq. in. The compressor shall be provided with strainer, and automatic governor and switch, in order that the compressor may start and stop automatically at any predetermined tank pressure. The air receiving tank shall be 36 in. in diameter and 8 ft. long, or of equal capacity. The tank shall be galvanized, and good for a working pressure of 100 lb. per sq. in. It shall be provided with pressure gauge and pigtail, pop-valves and drain cock, and have standard flanges bushed for 1½-in. pipe. The Contractor shall furnish all pipe, pipe fittings, and valves, and all shall withstand a working pressure of 100 lb. per sq. in.

Gasoline Motor.

168.—If a gasoline motor or other internal-combustion motor is used, a low-speed engine of the most substantial kind shall be selected, the maximum piston speed of which shall not exceed 350 ft. per min. The engine shall have a reversing gear provided with approved friction clutches, to be operated by a hand-wheel. The countershaft connecting the engine with the operating machinery shall be provided with disengaging couplings, arranged so that the moving and locking machinery can be operated alternately and in either direction without stopping the engine. Motors of 10 h.p. and more shall be started by compressed air. The engine-room shall be provided with a water tank of sufficient capacity. The gasoline tank shall be located outside of the engine-house. The engine-room shall be provided with indicators for recording the positions of the moving span, and lifting and locking apparatus. A work-bench with a full set of machinist's tools, etc., shall be provided, the same as specified for steam engines.

Electric Motors.

169.—Electric motors and generators, if for direct current, shall be of the railway series, interpole type, water-proof, with slotted-drum armature, and form-wound armature coils. They shall be a standard commercial type in common use.

170.—The coils shall be impregnated.

171.—Motors, generators, automatic circuit breakers, solenoids, brakes, and other electric mechanism shall be tested at the factory by the manufacturer in the presence of the Railway Company's inspector.

Testing of Motor.

172.—The rating of a direct-current motor is the horse-power output at the armature shaft which gives a rise of temperature above the surrounding air (referred to a room temperature of 25° cent.) not exceeding

90° cent. at the commutator and 75° cent. at any other part after one hour's continuous run at its rated voltage (and frequency in the case of an alternating-current motor) on a stand with the motor covers removed and with natural ventilation. The rise in temperature is to be determined by thermometer, but the resistance of no electric circuit in the motor shall increase more than 40% during the test.

172a.—Alternating-current motors shall show, in a run for heat test, the following maximum temperature rises above 25° cent. for the surrounding room: For ½-hour run under nominal load, 40° cent.; for 3-min. run under 150% nominal load, 55° cent.

173.—Direct-current motors shall be capable of carrying a load of 200% for 3 min. with the same temperature rise and momentarily of 400% without injury, starting cold in each instance.

Torque of Motor.

174.—The motors under test shall develop the required horse-power and torque at the armature shaft. Characteristic curves showing the results of the test shall be furnished by the manufacturer.

175.—The motor frame shall have two bearings for the countershaft and shall have a forged-steel cut pinion, out of one piece, keyed to the end of the armature shaft and secured by a lock-nut.

175a.—If the motor is enclosed in a case, as mill motors are, small openings of sufficient size shall be provided in the case for the inspection, removal, and replacing of brushes.

176.—One cast-steel cut gear, bored and key-seated for attachment to the countershaft, shall be furnished with the motor. The gear and pinion shall be covered by a sheet-steel or malleable-iron split gear case, supported by the motor frame and completely covering the gear and pinion. An opening, with a hinged cover, shall be provided in the gear case for inspection and oiling. The gear ratio shall be such that the full speed of the countershaft will not be more than 125 rev. per min.

Spare Motor Parts.

177.—For each size of motor furnished, the Contractor shall supply the following spare parts: One armature, one field coil, one pinion, one gear, and one set of brushes. These parts shall be finished and fitted in such a manner as to admit of being installed in their respective places without further fitting or adjustment.

Mounting Motors.

178.—The motors shall be mounted in such a manner as to admit of easy access for inspection and repairs; they shall be supported securely by brackets or suitable foundations.

179.—If the machinery and motors are on the moving span, they shall be capable of being operated satisfactorily in any position of the span.

Controllers.

180.—The controllers for motors shall be located in the operating-house. The controllers shall be of the reversing drum type, with magnetic blow-out, and shall be capable of varying and maintaining

the speed of the motors throughout the entire range desired, without injurious sparking, and without shock due to sudden variation in speed. The controllers shall be capable of doing their work for the usual loads, and excess loads, that may come upon the motors, with a temperature rise not exceeding that specified for the motors.

181.—One controller, with the necessary resistances, shall be furnished for controlling the operation of each main operating motor. They shall be connected so that the motors may be operated together.

Type of Controllers.

182.—The controllers for direct-current motors shall be of the series-parallel type; or of the type in which the field is varied, as may be done for the interpole type of motor.

Controllers, Where Needed.

183.—One controller shall be furnished for the operation of the rail-locks, and one for bridge-locks. These controllers shall be designed so that the operation of any motor can be cut out by pulling a switch on the switch-board, without affecting the operation of any of the other motors.

Automatic Cut-Offs.

184.—An automatic cut-off or short-circuiting device shall be provided which will throw out the circuit breakers, cut off the current from the operating motors and set their brakes when the bridge is 5° from its open position, and its closed position. Spring switches shall be provided which, if closed and held closed, will put the cut-offs out of commission and thus enable the bridge tender fully to close or open the bridge.

185.—The end-lock motor shall be stopped and its brake set automatically at each end of its travel.

Resistances.

186.—Resistances shall be of the cast-grid type, and of such capacity that the motor can be operated continuously at any point of the controller when developing full-load torque, or for 10 min. when developing 50% over-load torque, without sufficient rise in temperature of the resistance to cause deterioration of any part. The resistances shall be mounted so as to admit of free ventilation and be without injurious vibration.

Electric Brakes.

187.—The main operating motors, rail-lock motors, and bridge-lock motors shall be provided with approved post brakes which are held in set position by a spring with such force as to overcome not less than 50% of the maximum torque required. The friction surfaces are to be of materials not affected by moisture. The brakes are to be released by solenoids of ample power and heating capacity whenever the motors are taking current, and are to be automatically set whenever the current fails or is cut off from the motors. Weather-proof motors shall be provided with weather-proof solenoids. Brakes shall be provided with a foot-switch release for coasting purposes. Means shall be provided for mechanically releasing the brakes when the bridge is to be operated by hand or other equipment.

Emergency Brakes.

188.—An additional emergency brake shall be provided and applied to the main operating machinery. This shall be released by means of a motor-operated mechanism furnished by the Electrical Contractor, which shall hold the brake in release as long as the current is applied to the brake motor. Cutting off the current from this brake motor, or any failure of current, will result in the instantaneous application of the brake. This brake will be normally set, but will be released by the operator before starting the bridge, and be held in release during the entire operation unless an emergency condition arises requiring brake power in excess of that offered by the motor brakes, in which case it may be instantly applied by the operator. After the bridge has been closed and traffic has been resumed, this brake will again be applied. This portion of the equipment shall be designed so that it will not be injured if left in release indefinitely. Proper means shall be provided for releasing the brake mechanically when the bridge is to be operated by hand or emergency-power equipment.

189.—The emergency brake motor circuit is to be independent of the general interlocking system, and there shall be a mechanical interlocking device which will prevent the main leaf motors and the emergency brake from being used one against the other.

190.—The emergency-brake switch shall be attached to the controller stand within easy reach of the operator and proper labels shall be placed back of the switch handle to indicate "Set" and "Released" positions of the brake.

Current Supply.

191.—Unless the current supply is taken from more than one source, it shall be conducted to the switch-board in two independent conductors, one for the supply, and one for the return current.

Submarine Cables.

192.—Submarine cables, if needed, will be furnished and laid by the Railroad Company.

193.—The wiring from the collector rings for the electrical equipment of the bridge shall be furnished by the Contractor.

Qualities of Wire and Insulation.

194.—The quality of all wires and insulation shall conform to the specifications of the Railway Signal Association, as revised and adopted in October, 1911, and contained in Volume 8 of the *Proceedings* of that Association.

Conduits and Minimum Size of Wire.

195.—If wires are to be placed in conduits, the conduits shall be of ample size, sherardized, and loricated on the inside. No wire less than No. 12, B. & S. gauge, shall be used.

Condulets and Factory Ells.

196.—Conduits shall be of sufficient size to allow the wires to be easily drawn in. No joints are to be made inside of a conduit. Condulets and factory ells shall be used. Condulets, ells, and conduits shall be sherardized, and loricated inside.

Wiring, etc., to Conform to Codes.

197.—The wiring, motor installation, and the whole electric equipment must conform to the underwriter's code, and to the city code, if the bridge is subject to city authority.

Fuses. 198.—Enclosed fuses shall be used.

Minimum Stranded Wire. 199.—No wire smaller than No. 10, B. & S. gauge, stranded wire, shall be used.

Wires to be Tagged. 200.—Wires when installed shall be permanently tagged and numbered so that any wire can be traced from the switch-board to the motors, and to the source of power.

Ground Connections. 201.—Ground connections of ample area shall be provided.

Quick-Break Switch and Switch-Board. 202.—A switch, of the quick-break type, shall be provided for each supply wire. Each motor circuit and each light, signal, indicator, or other circuit shall be provided with switches which are approved by the Railway Company's Engineer. The switches shall be mounted on an enameled slate panel switch-board (not less than 1¼ in. thick, and free from metallic veins, or flaws) in the operator's house. The switch-board shall be large enough to carry the meters, switches, cut-outs, fuses, etc. Switches, cut-outs, buttons, etc., shall be provided with plates designating their use.

Automatic Circuit Breaker. 203.—An automatic circuit breaker shall be placed on the switch-board in the operating motor circuit of the bridge. Each line to the motor, each line to the electric brakes, and each lighting, signal, indicator, or other circuit, shall be protected by enclosed fuses.

204.—Any circuit whatsoever shall be protected by fuses, circuit breakers, or equivalent devices, which will insure the excessive current being cut off before any parts are damaged.

Lightning Arrester. 205.—The feeders shall be protected by a pole-switch fuse and lightning arrester mounted on a non-combustible and non-absorbent insulating base.

206.—Lightning arresters shall be placed as near as practicable to the parts to be protected, and away from combustible material. A No. 4, B. & S. gauge, wire should be used for the connection; this wire should run in a straight line to a ground plate, and not be connected to any structural parts. To avoid inductive resistances, the wire should not run through a conduit. If a choke-coil is used, it should be thoroughly insulated from the ground and other conductors.

Short Circuiting. 207.—The connections of parts in contact with track shall be such as to allow no short circuiting of track signals.

Protection of Electric Contacts. 208.—Electric contacts shall be protected from the weather or accumulations of dirt.

Housing of Motors. 209.—Motors must be housed in weather-proof metal housing. This housing must be large enough to allow the inspection and oiling of the motor. It must be readily removable so that access to the motor may be obtained. No metal in this housing shall be less than No. 16, U. S. Standard, gauge; it shall be galvanized.

Housing of Solenoids, etc. 210.—Solenoids and electrically-operated brakes shall be housed.

Indicator Lights. 211.—The Contractor shall provide and install electric light indicators for the purpose of showing the operator the various positions

of the bridge, especially the fully open, entirely closed, nearly open, and nearly closed positions of the bridge, and the fully open and fully closed positions of the rail-lock and bridge-locks.

Volt Meter, etc.

212.—A volt meter, ammeter, and watt meter shall be provided on the switch-board. The use of external multiple shunts will not be permitted.

Ground Detector.

213.—The switch-board shall be furnished with one 2-c. p. lamp for detecting ground, and a 2-c. p. lamp for illuminating the ammeter and volt meter scales.

Lamps for Lighting.

214.—In the operator's house shall be placed ten 16-c. p. lights, and additional lights about the machinery and such other lights as the Engineer may direct. For all lights in the house above ten in number, the Railroad Company will pay the regular market price or furnish them to the Contractor.

215.—Lights of 16-c. p. shall be placed outside at the head and foot of stairways or similar paths. All lights in the house shall have tungsten filaments.

Channel Lights.

216.—The Contractor shall furnish warning and channel lights and signals, in accordance with the U. S. Government requirements, or other harbor requirements.

Alternating Current Motors.

217.—Alternating motors shall be of the three-phase induction type with slip-rings, rotor-wound, 25 cycles and 220 voltage, unless otherwise specified. The resistances for varying the speed shall be in series with the rotor circuit, and shall be such as to affect evenly all three phases. Motors of 5 h.p. or less may be of the squirrel-cage type.

218.—Alternating-current motors shall be of the crane type, and be of rugged construction. The motors shall be capable of exerting momentarily a maximum torque equal to at least two and a quarter times the greatest torque shown by the torque curves for the bridge and operating machinery, even if it requires a motor having a nominal horse-power greater than that which may be found from the torque curves (Paragraph 31).

Control of Motors.

219.—The control of motors shall be electrically interlocked with each other and with the signal system, and the bridge shall be controlled in such a way that the end-locks or wedges cannot be released until the signals have gone to the danger position and the derails are set, or the bridge motor started until the end-locks and wedges have actually been released. In closing the bridge, the control shall be such as to make it impossible for the operator to move the end-locks or wedges until the bridge has been completely closed, or to set the signals at safety until the bridge has been closed and the end-locks and wedges are in place.

Railway Signal System.

220.—The company will furnish and install the railway signal system, also the master lever and all necessary devices controlling the interlock between this signal system and the bridge as a whole. The

Contractor shall furnish and install the necessary devices for interlocking the various parts of the bridge with each other and for connection to the Company's master lever.

SPECIFICATIONS FOR SPECIAL METALS USED FOR MACHINERY PARTS.

Qualities of Machinery Steel.

221.—Steel for castings may be made by the open-hearth or crucible process.

222.—All castings shall be annealed unless otherwise specified.

223.—Phosphorus ..... 0.05% maximum.
Sulphur ..... 0.05% maximum.

224.—Minimum physical qualities, as determined on a standard test specimen, of ½ in. diameter and 2 in. gauged length:

Tensile strength, in pounds per square inch.....	70 000
Elongation: percentage in 2 in.....	18
Contraction of area: percentage.....	25

225.—A test to destruction may be substituted for the tensile test, in the case of small or unimportant castings, by selecting three castings from a lot. This test shall show the material to be ductile, free from injurious defects, and suitable for the purpose intended. A lot shall consist of all castings from the same melt or blow, annealed in the same furnace charge.

Flaws in Castings

226.—Castings shall be true to pattern, free from blemishes, flaws, or shrinkage cracks. When the bearing surface of any steel casting is finished there shall be no blow-holes visible, exceeding 1 in. in any direction, nor exceeding ½ sq. in. in area. The length of blow-holes cut by any straight line laid in any direction shall never exceed 1 in. in any 1 ft.

Blow-Holes in Gear Wheels.

227.—No blow-hole exceeding one-half the above dimension and area will be allowed in any gear tooth, or in the rim at the root of the teeth.

Electric Welding.

228.—The correction of defects in castings, by welding electrically by thermit or by similar processes, will not be allowed.

Testing of Large Castings.

229.—Large castings shall be suspended and hammered all over. No cracks, flaws, defects, or weakness shall appear after such treatment.

230.—A specimen (1 in. by ½ in.) shall bend, cold, around a diameter of 1 in., through an angle of 90°, without fracture on the outside of the bent portion.

231.—The number of standard test specimens shall depend on the character and importance of the castings. A test piece shall be cut, cold, from a coupon to be moulded and cast on some portion of one or more castings from each melt or blow, or from the sink-heads (in case heads of sufficient size are used). The coupon or sink-head must receive the same treatment as the casting or castings, before the specimen is cut out, and before the coupon or sink-head is removed from the casting.

232.—Turnings from the tensile specimen, or drillings from the bending specimen, or drillings from the small test ingot, if preferred

by the inspector, shall be used to determine whether or not the steel is within the limits in phosphorus and sulphur specified in Paragraph 223 concerning chemical properties.

Steel Forgings.

Qualities of Steel Forgings.

233.—Steel forgings may be made by the open-hearth or crucible process.

234.—Phosphorus ..... 0.04% maximum.
Sulphur ..... 0.05% maximum.

235.—Minimum physical properties, as determined on a standard turned test specimen, of ½ in. diameter and 2 in. gauged length:

Tensile strength, in pounds per square inch, 55 000 to 65 000
Elongation: percentage in 2 in..... 28

236.—A specimen (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of ½ in., without fracture on the outside of the bent portion. The bending may be effected by pressure or by blows.

237.—The number and location of the test specimens to be taken from a melt, blow, or forging shall depend on their character and importance, and, therefore, must be regulated by individual cases. The test specimen shall be cut, cold, from the forging, or full-sized prolongation of the same, parallel to the axis of the forging and half way between the center and the outside; the specimens shall be longitudinal, *i. e.*, the length of the specimen shall correspond with the direction in which the metal is most drawn out or worked. When forgings have large ends or collars, the test specimens shall be taken from a prolongation of the same diameter or section as that of the forging back of the large end or collar. In the case of hollow shafting, either forged or bored, the specimen shall be taken within the finished section prolonged, half way between the inner and outer surfaces of the wall of the forging.

238.—Turnings from the tensile specimen, or drillings from the bending specimen, or drillings from the small test ingot, if preferred by the inspector, shall be used to determine whether or not the steel is within the limits in chemical composition specified in Paragraph 234.

239.—Forgings shall be free from cracks, flaws, seams, or other injurious imperfections, and shall conform to the dimensions shown on the drawings furnished by the purchaser, and shall be made and finished in a workmanlike manner.

240.—All forgings shall be annealed.

Axle Steel.

Qualities of Axle Steel.

241.—Axle steel may be made by the open-hearth or crucible process.

242.—Phosphorus ..... 0.05% maximum.
Sulphur ..... 0.05% maximum.

243.—Minimum physical properties, as determined on a standard turned test specimen, of ½ in. diameter and 2 in. gauged length:

Tensile strength, in pounds per square inch	80 000
Elongation: percentage in 2 in.	20

244.—A specimen (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of 1½ in., without fracture on the outside of the bent portion. The bending tests may be made by pressure or by blows.

245.—Turnings from the tensile test specimen, or drillings from the small test ingot, if preferred by the inspector, shall be used to determine whether the melt is within the limits in chemical composition specified in Paragraph 242.

Boiler Plates.

Qualities of Boiler Plate Steel.

246.—The steel used for boilers and fire-boxes shall be made by the open-hearth process.

247.—Phosphorus	0.04%	maximum.
Sulphur	0.04%	maximum.

248.—The physical properties required shall be as follows:

Tensile strength desired, in pounds per square inch, 60 000.

$$\text{Elongation: minimum percentage in 8 in.} = \frac{1\,500\,000}{\text{Ultimate strength.}}$$

Character of fracture	Silky.
Cold bends, without fracture	180° flat.

249.—The ultimate strength shall come within 4 000 lb. of that desired.

250.—Chemical determinations of the percentage of carbon, phosphorus, sulphur, and manganese, shall be made by the manufacturer from a test ingot taken at the time of the pouring of each melt of steel, and a correct copy of such analysis shall be furnished to the Engineer or his inspector. A check analysis shall be made from the finished material, if called for by the purchaser, in which case an excess of 25% above the required limits will be allowed.

251.—Specimens for tensile and bending tests for plates shall be made by cutting coupons from the finished product, which shall have both faces rolled, and both edges milled to the usual form of the standard test specimen, 1½ in. wide on a gauged length of at least 9 in.; or with both edges parallel.

Nickel Steel for Machine Parts.

Qualities of Nickel Steel.

252.—Nickel steel shall be made by the open-hearth process.

253.—	Plates, shapes, and bars.	Rivets.
Phosphorus shall not exceed	0.04%	0.04%
Sulphur " " "	0.05%	0.04%
Nickel, not less than	3.00%	3.25%

254.—The physical properties required shall be as follows:

	Plates, shapes, bars, and forgings, pounds per square inch. Minimum.	Rivets.
Tensile strength.....	80 000	60 000 to 70 000
Elastic limit.....	50 000	40 000 minimum

Elongation, percentage in 8 in., for plates, shapes, bars, and forgings; and also for rivets $= \frac{1\,600\,000}{\text{Ultimate strength.}} = \text{minimum.}$

Elongation, percentage in 2 in., for forgings = 25.

255.—Specimens cut from forgings (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of 1 in., without fracture on the outside of the bent portion.

256.—Specimens cut from plates, shapes, and bars shall bend, cold, 180°, around a diameter of three times their thickness, without fracture on the outside of the bent portion.

257.—Each rivet rod shall bend 180°, flat, on itself, without fracture on the outside of the bent portion.

258.—Rivet rods shall be tested as rolled.

259.—The fracture of all tension tests shall show a fine silky texture, of a uniform bluish gray or dove color, free from black or brilliant specks, and shall show no sign of crystallization.

260.—All nickel-steel forgings shall be properly annealed.

261.—Annealed eye-bars and similar members, when full-sized pieces are tested, shall comply with the following requirements:

Minimum ultimate tensile strength, in pounds per square inch	75 000
Minimum elastic limit, in pounds per square inch.	45 000
Minimum elongation in 10 ft., including fracture.	12%
The fracture shall be mostly silky, and free from crystals.	
Full-sized pieces shall bend, cold, 180°, around a diameter of twice their thickness, without fracture.	

Tool Steel.

Qualities of Tool Steel.

262.—This steel is generally used for parts which require hardening or oil tempering, such as pivots, friction rollers, ball-bearings, and springs.

263.—Tool steel shall be made by the open-hearth or crucible process.

264.—

Carbon	1.00% minimum.
Phosphorus	0.04% maximum.
Sulphur	0.04% maximum.
Manganese	0.50% maximum.

Phosphor-Bronze.

Qualities of Phosphor-Bronze.

265.—Special phosphor-bronze shall be used for high pressures and slow speed.

266.—The metal shall have a minimum elastic limit in compression of 27 000 lb. per sq. in. The permanent set at 100 000 lb. shall not exceed $\frac{1}{10}$ in.

267.—A test piece shall be cut from a coupon to be moulded and cast on some portion of each casting. Test pieces shall be 1-in. cubes, finished.

268.—Phosphor-bronze composed of the following ingredients and of the following proportions has given satisfactory results:

Copper	79.7 per cent.
Tin	10. " "
Lead	9.5 " "
Phosphorus	0.8 " "

Babbitt Metal.

Qualities of Babbitt Metal.

269.—Babbitt metal composed of the following ingredients and of the following proportions has given satisfactory results and a low coefficient of friction (0.03 to 0.04):

Copper	3.6 per cent.
Tin	89.3 " "
Antimony	7.1 " "

Purpose of the Specifications.

270.—It is the purpose of these specifications to provide a first-class structure. They are intended as an aid in designing and fabrication. The subject of machine design is so great and varied that no single work of this character can cover all points. As a further aid in securing a first-class structure, the following works will be considered authoritative, in the order named:

1. Unwin's "Machine Design," Part I, Ed. 1909.
   Unwin's "Machine Design," Part II, Ed. 1902.
2. "A Manual of Machine Design," etc., by Low and Bevis, 11th Impression.
3. Reuleaux's "Constructor," Translated by Suplee.
4. Kent's "Pocket Book," 8th Ed.

271.—Machine parts shall be designed, if practicable, by the methods of applied mechanics, but such designs shall be viewed in the light of experience. It should be borne in mind that machine design is not based on the precise methods in vogue for statical structures.

DISCUSSION

Mr. Smith.

AUGUSTUS SMITH, M. AM. SOC. C. E. (by letter).—The writer desires to add his acknowledgment of the value of the specifications for movable bridges,* by C. C. Schneider, Past-President, Am. Soc. C. E., and of the discussions contributed by other members of the Society on that subject. There was great need for definite specifications, and Mr. Leffler's valuable contribution is another important gift to the Profession.

The writer is glad to discuss a few of the details defined so unequivocally by the author, taking them up in order, as follows:

Paragraph 55.—The author apparently favors the use of tapered keys, but obviously could not attempt, in the text of a specification, to give any justification for this preference. Without rehearsing the arguments against tapered keys,† the writer would call attention to the fact that they cost more than straight keys and require considerable room on the shaft for each wheel fitted, so that it is not practicable to place a wheel close to a bearing, and, when such keys are used, it is not practicable to place two or more wheels very close together. In some cases tapered keys are necessary. The writer's practice is to use straight keys where possible, and tapered keys where straight ones are not practicable.

Paragraph 92.—Worm gearing is used frequently for transmitting power, where it is desirable to hold the load. If the angle of the thread for the worm were 20° or more, the wheel would be able to turn the worm backward. There are not many data on the limiting angle of thread which will give the maximum efficiency of a worm drive without being steep enough to permit the wheel to drive the worm. The writer has found the angle to be approximately 6°, but much depends on the nature of the thrust bearing holding the worm, and the angle would be less if first-class ball bearings were used.

Paragraph 136.—The author allows for the bending stress in the individual wires of rope bent around a sheave, and points out that this is a function of the diameter of the individual wires and not directly of the diameter of the rope, as it is sometimes apparently thought to be. The same thing has been worked out by the engineers of the Trenton Iron Company.‡ Attention is called to the fact that the minimum diameter of sheaves and drums given in the lists of all manufacturers of wire ropes has been apparently agreed on, like the price list, but it is not altogether consistent with the foregoing theory.

The writer confesses to some obtuseness in his power of conception of the action of cumulative stresses. If the bending stress in the

* *Transactions*, Am. Soc. C. E., Vol. LX, p. 258.

† Summarized in Kent's "Mechanical Engineer's Pocketbook."

‡ The results are given in the handbooks of that company.

Mr. Smith.

wires is really added to the tensile stress produced by the load on the rope, an overloaded rope should always break on a sheave or drum, and not in a straight part.

Paragraph 140.—The author's formula for determining the strength of gear teeth follows the general form advocated by Mr. Lewis, namely, by making the allowable pressure proportionate to the pitch and face multiplied together, instead of the earlier formula given by Tredgold, in which the pitch was squared. The author's formula makes due allowance for the number of teeth and the velocity, and is intended to apply to steel gearing, because, according to Paragraph 38, only cast or forged steel should be used for this purpose. He should add a formula fixing the face in terms of the tooth pressure, to provide for wear. Cast iron works with less friction, and usually with less tendency to cut, than cast steel or forged steel when running together, and the writer is doubtful about allowing much greater tooth pressure per inch of face for steel than for first-class close-grained cast iron. It will be observed that the permissible pressure on the contact surfaces between the teeth of gears given in Paragraph 140 is many times greater than that allowed in sliding contact by Paragraph 150. Unwin mentions the old rule that the pressure between teeth should not exceed 400 lb. per in. of face, in order to obtain good wearing results. The late James Christie,* M. Am. Soc. C. E., in his discussion of Mr. Schneider's paper, gives a formula naming the working pressure of the tooth in pounds per inch of face, in terms of the pitch multiplied by a constant dependent on the nature of the material, and divided by the square root of the velocity. Mr. Christie's formula, it will be observed, gives higher values for steel than for cast iron, in the ratio of 10 to 6.

Paragraph 157.—The writer would suggest adding to this paragraph a sentence to the effect that when brakes which act through the transmission machinery are used, all parts of that machinery so affected shall be designed to withstand the maximum force set up by the application of the brakes, if it should be more than that of the driving motor.

Paragraph 168.—The author limits the maximum piston speed of internal-combustion motors to 350 ft. per min. A comparison of the various speeds given by manufacturers of so-called "heavy-duty" motors would indicate an allowable piston speed of 500 ft. per min., and even higher. The writer's experience with a gasoline motor indicates perfectly satisfactory results at 500 ft. per min. One objection to putting the piston speed too low in motors of this type is the inevitable leaks past the piston rings, and at low speeds there is a marked loss in compression around the valves, so that an internal-

* *Transactions*, Am. Soc. C. E., Vol. LX, p. 318.

combustion engine does not develop the proportional power at a low speed that it would at a higher speed. Mr. Smith.

The writer would also recommend adding a provision to this paragraph limiting the ignition, if electric, to the jump-spark method, and would also advocate specifying the use of a jump-spark apparatus in which the secondary coil is made up on each spark plug as part of it, so that a low-tension current of 6 or 10 volts at the outside is all that would have to be taken care of in the wiring. He would recommend a clause prohibiting the use of any internal combustion motor in which cooling water was passed through a packing or joint designed to withstand the gases of combustion. This provision, in the case of engines in which the cylinder head is made separable from the body of the cylinder, would require the cooling water to be by-passed outside from the cylinder to the head, or brought to and from the head and cylinder separately. Preference should be given to an air-cooled motor of proven reliability.

Paragraph 177.—In this paragraph the author names the spare parts to be furnished with an electric motor. The writer thinks that certain spare parts, such as igniters and crank-pin brasses, would be advisable in the case of internal-combustion motors.

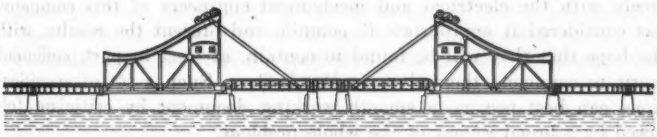

FIG. 3.

Paragraph 180.—The author specifies controllers of the reversible drum type, and while these give very good results, the writer has found that controllers of the disk type, such as are made by the Electric Controller and Manufacturing Company, give equally satisfactory results in hoisting and crane service, so that he would not advise limiting controllers to the drum type.

In the discussion of Mr. Schneider's paper, a number of leading designs of bascule bridges were brought out. Though it has no direct bearing, as part of this discussion, it might be of interest at this time to add to the various bridges brought out by Mr. Schneider's paper, a design which the writer prepared for the Stone Bridge, at Tiverton, for the State of Rhode Island, based on the old Delille type of fortification draw-bridge.

The mechanical principles involved in this bridge are obvious from Fig. 3. The advantage of the stiff connecting link between the moving bascule and the counterweight is that the bridge can be balanced at all points and forced down against a wind pressure. Another advantage is that the spans on which the counterweight moves can

Mr. Smith.

be used frequently as through truss spans, like approach spans, on each side of the draw, with some economy in metal. A third feature is that all the moving parts are high above the water, and cannot be affected by salt spray or ice. In common with many others of the bascule type, a low-level bridge is possible, and no expensive foundations for counterweight or the like are necessary. Another advantage—and it seems to the writer a very important one—is that this bridge, especially where a double-leaf bascule is used, has a more pleasing architectural effect than is commonly the case with bascule bridges.

In the Tiverton Bridge, which was designed for highway and trolley car service, no central pier was used, but the connecting rods were made of very ample cross-section so as to reduce the deflection of the bridge at the center to a negligible amount for the purpose. For railway service, a center pier of some sort would doubtless be desirable; such a pier would be built in the middle of a two-leaf span with less obstruction to traffic than would be the case if a swinging draw were used.

Mr. Mercer.

CHARLES H. MERCER, M. AM. SOC. C. E. (by letter).—The writer is connected with a company which fabricates and erects a considerable number of bridges movable in a vertical plane, and, after consulting freely with the electrical and mechanical engineers of this company, has considered it appropriate to compile and present the results, with the hope that they will be found to contain, at least in part, sufficient merit to commend themselves to Mr. Leffler. Such a set of specifications can best become a smooth working document by criticism followed by a broad review of the whole problem.

Paragraph 2.—The "Specifications of the New York Central Lines for Steel Railroad Bridges," for 1910, are made a part of the author's specifications. These specifications require the railroad company to furnish and lay the track, rails, timber floor, etc. This is logical for an ordinary steel bridge, but does not seem to be proper for a counterweighted bridge. The contractor for a bridge of this character cannot balance the bridge until the floor is laid. If the railroad does this work, the labor forces will be mixed, which is objectionable. Besides, the majority of these bridges are erected open, which tends to increase the complications if the railroad company lays the track. The specifications would be more harmonious if they required the contractor to do this work.

Paragraph 21.—The constants given in this paragraph do not seem to be sufficiently specific; thus, for rolling friction, the radius of the roller and whether one or two faces are in contact should be considered. The writer has had to do with "movable" bridges moving on rollers of 12 and 100 in., respectively, and with segmental rollers of much larger diameter. Although there is no agreement on the constant used in the several formulas for rolling friction, it would seem that

the maximum of these could be used advantageously in ascertaining the resistances to be overcome. Mr. Mercer.

The loss caused by the stiffness of wire cables depends on the sheave diameter, the number and angle of the bends, and the type of rope. The usual limitation of sheave diameter is not made in these specifications, probably because the stresses due to bending of ropes over them are taken into account. It would seem, however, that the sheave diameter should be considered in calculating the power requirements.

Paragraph 22.—The coefficient for journal friction is given as 0.07. The writer thinks this should be covered by Paragraph 21, using the same constant as for friction on trunnions, that is, $\frac{1}{3}$ for starting and $\frac{1}{16}$ for running.

Paragraph 23.—This paragraph reads: "The time to open the bridge after the ends are released shall be as specified on the proposal drawing."

The writer suggests that it be changed to: The time to open the bridge after the ends are released shall be approximately as specified on the drawings.

The writer has had to do with contracts for two bridges under these specifications with the company represented by Mr. Leffler, and there has been no thought of taking exception to this paragraph, nor need there be when the specifications are interpreted broadly by a reputable engineer; but the specification is now apt to be more widely adopted and made a part of contracts. In such a case, could not an unscrupulous representative of a buying company make the contractor suffer if the bridge required somewhat more time to open than was specified? Bascule and lift bridges are not designed by contractors, but ordinarily by the patentees, who are experts for their respective structures, and it is a proper assumption that they are more expert on these special bridges than the contractor's corps of engineers. The specifications and plans on which the contractor bids are complete, specifying in detail the requirements of the prime mover, the size of all pinions, gears, shafting, etc., and the sectional areas of all the component members, as well as the details for their connection. The contractor is told just what to do. Except for workmanship and materials, it does not appear to be equitable that he should be held responsible for results. A contract based on divided responsibility is wrong in principle; let the designer be responsible for the design and the contractor for the construction and materials. The writer feels that, in specifications of this character, the portion covering design should be separate, and the contractor should not be responsible for it if designed by any other than himself.

Paragraph 36.—The writer believes that trunnions bearing on phosphor-bronze should be of axle steel rather than structural steel. The harder steel would be less apt to cut and score.

Mr. Mercer.

Paragraph 126.—This paragraph provides for tests of trunnions on their bearings, and the test requires special apparatus, with consequent delay and expense. The paragraph might well be omitted, but if there is a demand for some such test, the results sought could be attained by placing the trunnions in their respective bearings on a surface plate.

Paragraph 156.—This paragraph states that: "All machinery parts shall be designed with sufficient strength to resist the greatest pressure which can be exerted by the motor." Paragraph 173 specifies an overload for direct-current motors of 200% for 3 min., and 400% momentarily. Apparently, this overload for the motors is simply a test of the insulation, but, taking the requirements of Paragraph 156 literally, the machinery would have to be designed for an overload of 400% with the units specified in Paragraphs 133 and 135, which results would be abnormal.

Paragraph 168.—The maximum piston speed of the gasoline engine is lower than required by standard practice. In all cases the piston speed should depend on the size of the engine. The advisability of operating the locking machinery by the gasoline engine is doubted. If operated by hand, the machinery would be much simplified, and there would be much less likelihood of jamming the lock machinery when undertaking to drive home when not in proper position.

Paragraph 169.—"Water-proof" should be changed to "weather-proof," as it is better to have a semi-open type of motor properly housed. In the case of a totally enclosed motor, the operator seldom inspects it as thoroughly as he would if he could examine the working parts without removing the cover.

Paragraph 172.—The words, "direct-current," in the first line should be omitted.

Paragraph 173.—It would be much clearer if, for each bridge, a definite statement was made as to how much torque the motor had to develop in foot-pounds for 3 min., and the exact time the motor would have to carry the normal torque of 400 per cent. These values should then be selected so that a standard motor which fulfills one will fulfill the other without a special arrangement of the winding.

The percentage of drop in voltage which will be allowed under full-load conditions, between the switch-board and the motor terminals, might be stated for each proposition.

Paragraph 175.—This paragraph is applicable to a back-geared motor. It may not be advisable to use such a motor in every case.

Paragraphs 181 and 182.—These paragraphs are slightly confusing. Paragraph 181 calls for a controller for each motor. Paragraph 182 calls for series-parallel control, which can be applied to two or more motors. It might be better to have the control specified for each case, because, where the operating machinery does not rotate with the bridge, it would seem as if a remotely controlled contact or board

could be used to advantage, especially if the operator's house is some distance from the bridge. Mr. Mercer.

Paragraph 188.—The writer believes the motor-operated, emergency brake to be too complicated for the average operator. A better brake, as far as concerns reliability, less complication, and being more nearly balanced in all positions of the bridge-leaf, is obtained with the same type as that used for the operating motors, provided the size required does not exceed the largest size manufactured. In case it does, two such brakes should be used.

Paragraph 190.—It seems to be desirable that the emergency-brake switch be in closed position, thus releasing the brake before power is available for the operating motors. In this case the switch would be electrically interlocked, but the operator would be free to apply the emergency brake at any time, regardless of the position of the controller arm.

Paragraph 192.—Submarine cables, if needed, should be furnished and laid by the contractor for almost the same reasons as those given for laying the floor, and to obviate division of responsibility due to possible delay. The trench for such cables if required, might be dredged or dug by the railroad company.

Paragraph 193.—For bridges moving in a vertical plane, the logical place at which to deliver the current to the electrical contractor is at the switch-board.

Paragraph 197.—If the electrical equipment is installed as required in these specifications, there seems to be no need of requiring everything to be in accordance with N. E. C. Standard, as this standard is devised for installations where the danger of fire is great, which is not true on a bridge. Bridges were not considered in making up the N. E. C. Standard, and its application to them is not sufficiently definite.

Paragraph 212.—In measuring currents, it seems to be standard practice to use shunts for the ammeter, thus avoiding heavy currents through the measuring instrument and the consequent impairment thereto.

Paragraph 217.—The type of the alternating-current motor will depend on the kind of current available, and need not be a 25-cycle, 220-volt, three-phase type.

Paragraphs 265 and 266.—Phosphor-Bronze.—It is well to preface any discussion on this subject with a statement of the fact that it is most difficult to obtain consistent physical results from any given phosphor-bronze alloy, and the most expert superintendence in the foundry is required to produce uniform results.

Probably on account of the comparatively small quantity of phosphor-bronze used in movable bridges, it has not received the attention from bridge engineers that its importance warrants. In look-

Mr. Mercer.

ing over bridge specifications in which the composition for phosphor-bronze is given, the writer finds that almost all specify that given in Paragraph 268 of the author's specifications, namely:

Copper	79.7	per cent.
Tin	10.0	" "
Lead	9.5	" "
Phosphorus	0.8	" "

and this composition will be referred to hereinafter as "standard."

Practically all the bearings in movable bridges may be characterized as high-pressure and slow-speed, as against low-pressure and high-speed. For the latter conditions, the "standard" composition seems satisfactory, and specimen tests will give physical results practically as follows:

Compression:

Elastic limit, in pounds per square inch	13 000 to 15 000
Permanent set from 100 000-lb. load, in inches	0.27

This elastic limit is based on a set of 0.001 in. in 1 in.

Tensile:

Yield point, in pounds per square inch	20 000
Ultimate, in pounds per square inch	25 000
Elongation, percentage in 2 in	4
Reduction	3 per cent.

After discussing this subject thoroughly with a leading metallurgist, the writer submits the following composition for high pressure and slow speed:

Copper	85.2	per cent.
Tin	14.0	" "
Phosphorus	0.8	" "

The approximate physical results from this composition on a cylinder with an area of 1 sq. in. and 1 in. long, should be:

Compression:

Elastic limit, in pounds per square inch	20 000 to 22 000
Permanent set from 100 000-lb. load, in inches	0.12 to 0.16

In tension tests, this composition will show some ductility.

The presence of lead in bridge bearings subjected to heavy pressures is objectionable, for the following reasons: Lead does not alloy with the copper-tin bronzes, but is mechanically admixed, and, being a very soft metal, it immediately lowers the elastic limit in compression, causing the bronze to become plastic and flow under pressure. It likewise, being a soft metal, tends to grip or seize the shaft under conditions of heavy pressure and poor lubrication. The harder the

bronze the less likely it will be to seize the steel shaft, providing, of course, the bronze does not exceed the steel in hardness. Mr. Mercer.

Experiments made by the late C. B. Dudley,* M. Am. Soc. C. E., indicate that the relative wear of a copper-tin alloy is one and one-half times that of the "standard" copper-tin-lead alloy.

For convenience, Table XCIII, showing the results of these experiments, is here quoted.

"TABLE XCIII.—Relative Wear of Bronze Bearings (*Dudley*).

Alloy tested.	Composition.					Relative wear.
	Copper.	Tin.	Lead.	Phosphorus.	Arsenic.	
Standard lead (phosphor) bronze S.	79.70	10.00	9.50	0.80	....	1.00
Ordinary bronze	87.50	12.50	....	....	....	1.49
Arsenic bronze, A	89.20	10.00	....	....	0.80	1.42
Arsenic bronze, B	82.20	10.00	7.00	....	0.80	1.15
Arsenic bronze, C	79.70	10.00	9.50	....	0.80	1.01
Bronze K	77.00	10.50	12.50	....	....	0.92
Bronze B	77.00	8.00	15.00	....	....	0.86

This table was determined by placing a "standard" and an experimental bearing on opposite ends of the same axle on locomotive tenders. From time to time they were removed and weighed and the wear was recorded. The copper-tin alloy also gave some trouble from heating. These experiments were conducted about 1892.

These results as to relative wear were confirmed by Clamer about 1903, and are set forth on page 426 of the book:

"He used a specially designed friction-testing machine, with test-bearings, measuring $3\frac{1}{2}$ inches x $\frac{1}{2}$ inch. In each experiment the journal ($3\frac{3}{4}$ inches in diameter) made 100 000 revolutions at a speed of 525 revolutions per minute, the same pressure (1 000 lbs. per square inch), oil, and method of lubrication being used throughout. It was found that the rate of wear diminished, though the friction and temperature increased, as the percentage of tin in the bronze was decreased and the percentage of lead increased (see Table XCIV)."

"TABLE XCIV.—Relative Friction and Wear of Lead-Bronze Bearings (*Clamer*).

	Copper.	Tin.	Lead.	Friction, lbs.	Temperature above room, °F.	Wear, in grms.
1	85.76	14.90	.....	13	50	0.2800
2	90.67	9.45	.....	13	51	0.1768
3	95.01	4.95	.....	16	52	0.0776
4	90.82	4.62	4.82	14	53	0.0542
5	85.12	4.64	10.64	18½	56	0.0380
6	81.27	5.17	14.14	18½	58	0.0327
7	75. ?	5. ?	20. ?	18½	58	0.0277
8	68.71	5.24	26.67	18	58	0.0204
9	64.34	4.70	31.22	18	64	0.0130

* "Lubrication and Lubricants," by Leonard Archbutt and R. Montford Deeley, p. 425.

Mr. Mercer.

It is to be particularly noted from this table (XCIV) that the friction on copper-tin-lead alloys is approximately 50% greater than on copper-tin alloys, which approximate the writer's composition for high-pressure and slow-speed bearings.

The results, as set forth in the Clamer's Table XCIV, were confirmed later by Spare, from experiments made on the same friction testing machine, namely, the Cornell machine.

The conditions under which the experiments were made by Dr. Dudley, and Messrs. Clamer and Spare differed widely from those which exist in a bearing with a load of, say, from 1 600 to 3 000 lb. per sq. in. and supporting a trunnion which revolves only through 80° during the operation of the bridge. The amount of wear on the copper-tin alloy bearing with 100 000 revolutions, as reported by Clamer, was not appreciable from a practical standpoint. With an average of ten openings per day, for 250 days per year, it would take 40 years for 100 000 operations of a bridge. Therefore, the problem for high pressure and slow speed is entirely different from that covered by the experiments. It has not been overlooked that the frictional area for a certain number of revolutions varies with the size of the journal or trunnion.

It seems obvious that, for high-pressure and slow-speed bearings, stiffness combined with a low frictional resistance is essential, and the wear is unimportant. Stiffness is shown in the composition submitted by a high elastic limit in compression, while sufficient ductility is retained.

To summarize: the writer recommends for movable bridge bearings a copper-tin alloy with a maximum content of 1% of phosphorus (other alloys in excess of one-half of 1% will not be permitted), with physical results specified as follows:

Compression:

Elastic limit, in pounds per square inch. . 19 000 to 23 000

Permanent set from 100 000-lb. load, in inches ..... 0.12 to 0.16

Tension:

The yield point, ultimate, and elongation in 2 in. to be recorded.

The compression test should be made on a cylinder having an area of 1 sq. in. and 1 in. long and the tension test on a specimen having a diameter of $\frac{1}{2}$ in. The compression elastic limit should be determined by the load that gives a permanent set of 0.001 in. It may be noted that the physical tests proposed by the writer are nearly a mean between the physical requirements of Paragraph 266 and the physical

results which may be expected from the "standard" composition given in Paragraph 268. Mr. Mercer.

The writer acknowledges his indebtedness to Mr. C. R. Spare, Holmesburg, Philadelphia, Pa., for information on the subject of phosphor-bronze.

P. J. REICH, M. AM. SOC. C. E. (by letter).—Mr. Leffler's "Specifications for Bridges Movable in a Vertical Plane" are quite complete. In the following the writer suggests a few insertions which would eliminate possible misunderstandings; questions the advisability of a number of unusual limitations; and brings up one general question—the greatest power to be assumed as being exerted by the motors, in the calculations of the machinery to hold it, a point on which there seems to be no uniformity. Mr. Reich.

MANNER OF BIDDING.

The classification of the materials in detail for payment is very good, and is to be recommended in preference to the more general classifications that are frequently used. It would be advisable in Paragraph 3 to exclude from the machinery—in addition to the electric motors—all gas and steam engines, together with their equipments. These are usually purchased by the bridge contractor, ready for operation. As the weights are not ordinarily at hand for estimating, it would be preferable and more convenient to place a lump-sum price on each, with its equipment.

Paragraphs 6 and 7.—It would generally be preferable to omit "sockets" from Paragraph 7, and include them in Paragraph 6, with wire ropes, as they are furnished and attached to the rope by the wire rope sub-contractor.

Paragraph 8.—It is probably the intention of Paragraph 8, taken in connection with Paragraph 3, that attached machined parts, such as cast-steel sleeves, bronze bushings, etc., for movable joints in links and similar members, be weighed separately and classified as machinery. A note added to this paragraph would prevent any misunderstandings.

Similarly, in Paragraph 10, it is advisable to add that "tread-plates" are to be included with the segmental and horizontal girders.

Several minor items not mentioned for payment are: Operator's house with its fixtures, machinery housings, and lumber, each of which should be paid for at separate lump-sum prices. (Structural steel in operator's house, or machinery housings should be classed with structural steel.)

Gas-pipe railings, which are usually expensive, should be paid for at a separate price per pound, the size of railing being specified.

Mr. Reich.

Operating Machinery.

Paragraph 36.—"Trunnions, pins, and shafting more than 3½ in. in diameter shall be of forged structural steel." It is questionable whether enough good comes from this low limitation to warrant the additional expense and delays incident to getting them. The writer has used the rolled rounds up to 5 and 5½ in. with entire satisfaction.

Paragraph 39.—In limiting pinions to forged steel, it would be necessary to make exceptions for those of unusual size, allowing them to be cast. Exceptions should also be made to the cutting; and cast teeth should be required when the pinions mesh with cast teeth, as would be the case where pinions mesh with the racks.

Paragraph 48.—"Nuts shall be secured by split pins put through the bolt." This may be interpreted in two ways: As a general note for all bolts; or only for those where nuts are apt to work off. To make it a general requirement would be an unnecessary expense, and it is suggested that they be used in special cases only where requested by the engineer.

Paragraphs 55 to 59.—Proportions, etc., of Keys.—As many of the bridge companies have standards for keys, to which they are accustomed, and which approximate very closely those outlined, it would be preferable to make the specifications a little more flexible, permitting their use when acceptable to the engineer. This should not be objectionable, as the theoretical requirements are taken care of under Paragraph 56. Gib heads on keys are not always reliable, as they frequently break off. Further, gib-head keys are not as simple to make and fit as those without. Much better results would be obtained by requiring keys to be placed so that they can be backed out, using the gib-head keys only where this cannot be done.

Paragraph 62.—"Keys shall be held in place by set-screws." This seems to be an unnecessary general requirement, in view of the fact that the machinery ought to be in charge of a competent man who should go over it frequently enough to detect any key which might be working out. It is doubtful if a key that would work loose would be held long by a set-screw. Where keys might readily drop out, should they become loose, as in the case of a vertical shaft, effective means should be used for holding them.

Paragraph 68.—This paragraph limits the use of Babbitt metal to shafts 3 in. or less in diameter. When the working pressures do not exceed 500 lb. per sq. in., Babbitted bearings are entirely satisfactory for the larger ones, are easy running, economical, and simple to replace.

Paragraph 77.—"Dust covers shall be provided for principal bearings, in particular for trunnions" (where shown on general plans). It is very desirable, from a contractor's point of view, to have

these at least indicated where required, and it is suggested to modify this paragraph by adding the words: "Where shown on general plans." This is also referred to when discussing Paragraph 93a. Mr. Reich.

Paragraph 86.—Taking care of the effect of key-ways, could also be excepted for overhanging shafts, in which case the maximum moment is at the center of the bearing where no key-ways are cut.

Paragraph 88.—This paragraph limits gear teeth to 20° involute. The differences and relative advantages of the 15 and 20° involute teeth over one another are not sufficient to exclude one or the other. In the past, the 15° involute was the more commonly used, and hence more bridge shops are equipped to cut them. A change means a large expense, which is out of proportion to the advantages gained.

Paragraph 92.—This paragraph limits the angle of thread of worm gearing to 20° as a minimum. As far as wear and efficiency are concerned, an angle of thread of from 13 to 15° gives very satisfactory results, and ought to be permitted. The use to which the worm gearing is put also governs, to some extent. If the span were coasting, a wheel in the main train of gearing would of necessity turn the worm. The writer has no data as to just what this angle would be.

Paragraph 92a.—The writer has frequently used 24-toothed worm wheels, and knows of some 21-toothed wheels in service, working satisfactorily. It would seem that 28 as a minimum might be high.

Paragraph 93a.—The contractor should be asked to furnish only such safety guards as are shown on the general plans. To include all, from a general clause such as this, may mean much or little, depending on the engineer in charge. The addition of these, or changes in their location after the detailed plans are completed, almost invariably costs the contractor more, in his drafting department, than it would to take care of it entirely at the bridge site after the erection of the work. It would be far more satisfactory to the contractor if the safety guards referred to in Paragraph 93a, the dust covers in Paragraph 77, and railings in general which are not shown on the plans, were taken care of entirely by the purchaser. In the end, it would be the more economical to the purchaser, would ordinarily avoid delays, by removing uncertainties, and they would unquestionably be more suitably placed.

Workmanship.

Paragraph 121.—Although it is not definitely permitted, the writer would infer from this paragraph that racks with their pinions are to have cast teeth.

Motors.

Paragraph 156.—"* * * the motor shall be of ample capacity to move or turn the bridge at the required speed. All machinery parts shall be designed with sufficient strength to resist the greatest pressure

Mr. Reich.

which can be exerted by the motor." It is very desirable that a method of obtaining the horse-power of the motors from the torque curves of Paragraph 31, be fixed by the specifications; and, further, if any additional allowance of power is to be made for a margin of safety, it should be stated. The fixing of this is essential to another important requirement: The designing of the machinery to enable it to resist the greatest pressure which can be exerted by the motor.

The assumptions to be made for calculations to take care of holding the motor are many, and it would be advisable to have it fixed by the specifications. It is very desirable to have it definitely fixed how the over-loads which the motors must stand should be taken care of in the machinery, giving permissible increases in the unit stresses, etc. These over-loads for which the motors are good are large, as given in Paragraph 173.

The design of the machinery is largely dependent on the assumptions made for these two items, they being somewhat dependent on each other. It is very desirable, therefore, that they be given explicitly in the specifications.

A common method of taking care of the two items is to make the horse-power of the motors sufficiently large, using the maximum torque, as given by Paragraph 31, and the maximum speed as a basis for getting the horse-power. All machinery is proportioned for the normal torque of the motor, and, as low unit stresses are used for the machinery, there is no doubt that the machinery will hold the motor. There may be times, if electrically operated, that the higher starting torque may increase the unit stresses used, but this can be regulated by having the automatic circuit breaker arranged so that the time for opening or closing will approximate the calculated time.

More accurate methods may be devised, depending on the actual torque curves of the motors, but this is objectionable, as the motors are usually the last thing ordered and wanted; and, further, it would delay the progress of the design too much to get these at the start.

Paragraphs 166 to 168.—The last sentence of each of these paragraphs requires the contractor to furnish a work-bench with a full set of machinist's tools, etc. It would be preferable to have these furnished by the purchaser, as the exact needs could then be taken care of, this being dependent, to some extent, on the operator and the proximity of a good machine shop. It is objectionable to the contractor to furnish these, as the final cost is an uncertainty, because of uncertain requirements; further, when they are furnished with the bridge, they are usually carried away by some one before bridge is taken over.

Paragraphs 197 and 216.—Any special requirements by city codes for the electric installation, if the bridge is subject to city authority, or any Government or other harbor special requirement for channel lights and signals, should preferably be furnished by the purchaser at

the time of asking bids. The purchaser is usually in a better position to get this information, and it means a saving of considerable trouble to each of the bidders. Mr. Reich.

Paragraphs 160 to 220.—It would be very desirable, from a contractor's point of view, if Paragraphs 160 to 220, covering power and operator's house equipment, were divided into three distinct and separate clauses: One for steam-engine equipment, one for internal-combustion motor equipment, and one for electrical equipment. The specifications are nearly in this order at present. The separation is desired for simplicity and to make it unnecessary to pick out the parts that might be interpreted as being required.

These specifications cover a first-class bridge which would be used on a main line of a railroad over a stream where navigation requires frequent opening. A supplement might profitably be added, waiving certain restrictions in the design and workmanship of the machinery and equipment, for economical purposes, for bridges not on a main line, or for those which are not opened frequently.

In conclusion, the writer would add that one essential feature to the success of movable bridges, to which not enough attention is ordinarily given, is the erection. Many of the troubles ordinarily credited to other sources would be eliminated entirely if a good competent machinist, familiar with this class of work, were added to the regular forces, to superintend the installation of the machinery.

B. R. LEFFLER, M. AM. SOC. C. E. (by letter).—The writer desires to express his appreciation of the discussion of his paper, and offers the following notes on some of the points brought out. Mr. Leffler.

As a result of the discussion and the writer's experiences since the paper was written, the specifications have been revised and are presented in separate form.

Taking up Mr. Smith's discussion:

Paragraph 55.—The writer sees no objection to other forms of keys, provided they are of the right proportions. However, a tapered key with a moderate slope, and held by a set-screw through the hub, is quite adequate. The specifications have been modified to allow the use of other keys.

Paragraph 92.—The writer believes that the only justification for using a worm gear, in the bridges covered by the specifications, is for the purpose of getting a large reduction in a limited space where a train of gears could not be used. For this case, efficiency is of more importance than the holding power of the worm. In swing bridges the worm has been used to raise the ends of the bridge; here the holding power is of much importance.

Paragraph 136.—The writer does not believe it advisable to look to the handbooks of wire rope makers for the proper diameter of

Mr. Leffler.

sheaves for counterweight cables. It seems that a rational theory which gives safe design is preferable to tabulated empirical data.

The writer's knowledge concerning wire rope is not extensive enough to say just where a rope will break. Apparently, it should break where it starts to bend over the sheave. Over the sheave, the frictional resistances of the rope on the sheave groove probably strengthens the rope. Over the sheave, the rope is subject to radial forces which modify the conditions.

Paragraph 140.—The character of the stresses in gear teeth at their contact is unknown. Line contact with sliding is found; the intensity of the stresses between any two bodies pressed together on a line is not known. This is the problem of designing a roller for heavy loads. The best pair of meshing gears, according to the writer's experience, is that of a wooden-toothed bull-wheel and cast-iron pinion.

Teeth designed by the Lewis formula seem to be satisfactory. In the writer's experience, teeth seem to break instead of wearing out. Recently, in the horizontal rack of a rolling lift bridge under the writer's care, several teeth were broken on account of the sudden application of the brakes; the material was cast steel.

For other points by Mr. Smith, the specifications have been modified.

Referring to Mr. Mercer's discussion, the following views are presented:

Paragraph 21.—In rolling bascule bridges, pure rolling is not found. For the full roller, a flange is used; for the segmental roller, teeth in the track. Hence, there is some sliding friction. Moreover, there is considerable deformation, which becomes partly permanent. In one case under the observation of the writer, the rolling structure refuses to close without the application of extra torque; this is due to permanent deformation at the end of the track. Some rolling structures are not precise in their movements; the free end is forced sidewise into its closed position by guides. In lieu of more exact knowledge, the coefficient of $\frac{1}{12}$ is a workable one. A coefficient for pure rolling is added.

The coefficient for stiffness of wire rope is not well known. The efficiency of a wire rope belt over two pulleys may be equal to 96%, including journal friction. *Eytelwein's formula for stiffness is $R = \frac{Kd^2}{D} P$, in which K is a constant; d is the diameter of the rope, and D is that of the sheaves, both in inches. P is the weight lifted. The pull, which lifts the weight, must equal $R + P$. K can be taken at $\frac{1}{3}$. The specifications are revised accordingly.

* References: Church's "Mechanics of Engineering," 1890, p. 193.
Kennedy's "Mechanics of Machinery," 4th Ed., Art. 80.

Mr. Leffler.

The ratio of the diameter of the sheave to that of the rope in the Halsted Street lift at Chicago is 90. After 18 years of service, the ropes were still in use. A high ratio should be used to limit the friction, and consequent wear, between the wires. A paragraph has been added to the specifications to cover this. According to Rankine, for ratios above 140, the effect of rigidity is negligible.

Paragraph 22.—Journals are not subject to the high pressure found in trunnions; the coefficient at starting is not as great. Again, there is some play in a train of gears, and the motor overcomes the initial journal friction before the initial trunnion friction comes into play.

Paragraph 23.—It is desirable to define clearly the line between the designer and the fabricator. The writer accepts a revision. However, the writer has found it necessary to make specifications for the designers.

Paragraph 36.—The writer recommends the use of a softer phosphor-bronze instead of a harder steel.

Paragraph 168.—The writer has one swing bridge operated by a gasoline engine. The rail-locks are of the sliding-sleeve type, and are actuated by the engine. The gasoline engine is not a suitable type of prime mover for a bascule bridge; it does very well for a lift, if placed on the moving span, and in this position it can be made to operate end-locks for rails and ends of span.

For bridges of the type herein discussed, sliding rail-locks may be dispensed with. The writer has devised a lock which holds securely the ends of the rails, and bridges the gap between the shore rail and the bridge rail, and no machinery is necessary for its operation.

Paragraph 192.—The writer is not prepared to give a specification for submarine cables. It is the practice of the railroad company with which he is connected to furnish the cable, because such cable contains the wires for signal, telegraph, light, and telephone services, as well as power wires for the bridge.

Paragraph 197.—The writer believes that the National Electric Code represents good practice. Every bridge has an operator's house, or power station, in which part of the electric equipment is installed. Obviously, the installation in the house should be first class, from a fire-protection standpoint.

There are many excellent provisions in the Code which should be used in any first-class electric installation. The character and installation of circuit breakers, fuses, switches, motors, etc., are important. To cover all these points in a specification would be a useless repetition of what is already recognized as first-class practice. Hence, a mere reference to the Code should be sufficient.

Paragraph 266.—The writer believes that the suggestions for phosphor-bronze are excellent. The physical qualities of phosphor-bronze suitable for heavy bearings seem to be somewhat unknown.

Mr. Leffler.

The writer has under observation a trunnion which became abraded. The phosphor-bronze showed a permanent set of 0.06 in. on a 1-in. cube under a 100 000-lb. load. Another, and similar, case has occurred. Hence, it seems that a somewhat softer phosphor-bronze is more suitable. The specification suggested is adopted.

The writer has not commented on all the points raised by Mr. Mercer. Nearly all those omitted have been adopted in the revised specification.

Referring to Mr. Reich's discussion, the suggestions are excellent, and the writer has adopted most of them in the revision.

Paragraph 68.—Babbitt metal gives good results if properly poured, but where accuracy of alignment and correct relative position of the machinery parts are to be maintained, bronze and brass linings are better.

Paragraph 88.—The proper angle of obliquity in involute teeth is still unsettled, although the matter has been before the American Society of Mechanical Engineers for several years. For an angle less than 20°, it is necessary to modify the outline, to avoid interference. Even for 20°, a slight change must be made for a pinion of 17 teeth or less meshing with a rack.

The writer finds that the special gear-cutting concerns readily undertake to cut gears of any obliquity without much extra expense. *The present trend is toward an angle of 20° as a standard.

Paragraph 92.—For worm gears, used in bridges of the character specified, efficiency is of more importance than holding power. An angle of thread of 20° is about the lowest limit for a loss of 30 per cent.

Paragraph 156.—The writer has attempted in the revision to clear up the question of designing for excess torques.

The use of the term "Horse-power" is somewhat misleading. It is better to specify the capacity of a motor by naming the variable torque it should exert for a given time, say twice the normal variable torque shown on the torque curves for a cycle of operation.

The writer believes that the torque curves should be worked up as quickly as possible. This is necessary for the correct determination of the gear ratio, and the capacity of the storage battery, if this is intended as the source of power.

Regarding a specification for bridges of minor importance; it is the writer's experience that such bridges give the most trouble in maintenance. Any power-operated bridge should be opened at least once a week, in order to keep the parts in smooth running condition. A movable bridge, to fulfill its purpose, must be in first-class condition continually, even if seldom moved. After a number of years of experience in maintaining movable bridges, it is the writer's opinion that it is impossible to keep a power-operated bridge too efficient.

* In the "American Machinist Gear Book," pp. 20 to 26, the subject is fully discussed.

Mr. Leffler.

The writer begs to submit a demonstration of the formula for the bending of wires, given in Paragraph 38. This is largely of academic interest. The Trenton Iron Company, in its "Wire Rope Book," gives a formula which is intended to serve the same purpose.

In attempting to reduce the Trenton formula, it was found to be erroneous. *Further investigation led to the derivation of the formula given in Paragraph 38. In the deduction a slightly different limiting value of the angle is adopted. This gives a closer approximation.

The Deduction of the Value of R in Paragraph 138.—

Proposition.—A wire is bent over a sheave through a small angle. Determine the least radius of curvature, R, of the bend.

Let Fig. 4 represent the conditions, considerably distorted for purposes of reasoning.

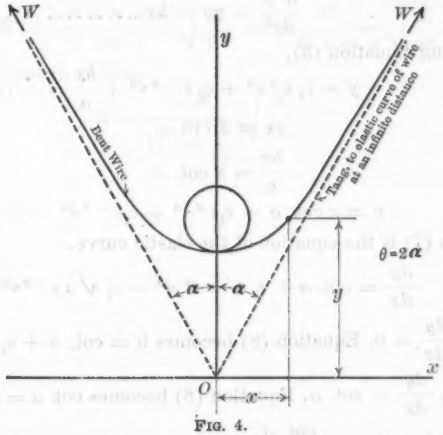

FIG. 4.

For practical purposes, θ is the angle between the straight parts of the wire.

Let I = Moment of inertia of the wire.
M = Bending moment in the wire at any point.
E = Modulus of elasticity.
W = Pull on wire.
S = Length of curve, measured from the y axis.
$RM = EI$.

Now, by calculus,

$$R = \left(\frac{ds}{dx}\right)^3 \cdot \frac{dx^2}{d^2y} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

$$M = W\,(y - x \cot.\ \alpha) \sin.\ \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

* Private correspondence, dated May 21st, 1912, with Mr. William Hewitt.

Mr. Leffler.

Now, as α is to be a large angle, it will be assumed to be not less than 65 degrees. In Equation (1) $\frac{ds}{dx}$ can never exceed cosec. α in value, or be less than 1; its cube will be practically a constant, say b.

Then $$R = b\,\frac{dx^2}{d^2y} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

hence, $$b\,\frac{dx^2}{d^2y}\,W\,(y \sin.\ \alpha - x \cos.\ \alpha) = EI.$$

$$\frac{d^2y}{dx^2} = \frac{b\,W\,(y \sin.\ \alpha - x \cos.\ \alpha)}{EI}.$$

Put $$\frac{b\,W \sin.\ \alpha}{EI} = a, \text{ and } \frac{b\ W \cos.\ \alpha}{EI} = h, \text{ then}$$

$$\frac{d^2y}{dx^2} = ay - hx \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Integrating Equation (3),

$$y = c_1\,e^{x\sqrt{a}} + c_2\,e^{-x\sqrt{a}} + \frac{hx}{a} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

$$e = 2.718 +$$

Now, $$\frac{hx}{a} = x \cot.\ \alpha,$$

hence $$y = x \cot.\ \alpha + c_1 e^{x\sqrt{a}} + c_2 e^{-x\sqrt{a}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Equation (7) is the equation of the elastic curve.

$$\frac{dy}{dx} = \cot.\ \alpha + c_1\sqrt{a}\ e^{x\sqrt{a}} - c_2\sqrt{a}\,e^{-x\sqrt{a}} \quad \ldots\ldots\ldots\ldots (8)$$

For $x = 0$, $\frac{dy}{dx} = 0$, Equation (8) becomes $0 = \cot.\ \alpha + c_1\sqrt{a} - c_2\sqrt{a}$.

For $x = \infty$, $\frac{dy}{dx} = \cot.\ \alpha$, Equation (8) becomes $\cot.\ \alpha = \cot.\ \alpha + c_1 \infty$.

Hence, $c_1 = 0$, and $c_2 = \frac{\cot.\ \alpha}{\sqrt{a}}$.

Equation (7) now becomes

$$y = x \cot.\ \alpha + \frac{\cot.\ \alpha\, e^{-x\sqrt{a}}}{\sqrt{a}}.$$

For $x = 0$, $y = \frac{\cot.\ \alpha}{\sqrt{a}}$, this is the value of y where the curve crosses the y axis.

Equation (1a) now becomes, for R at the y axis, by putting $x = 0$, and $y = \frac{\cot.\ \alpha}{\sqrt{a}}$ in Equation (3),

$$R = \frac{b}{\cot.\ \alpha\ \sqrt{a}} = \frac{\sqrt{b}}{\cos.\ \alpha}\sqrt{\frac{EI \sin.\ \alpha}{W}}.$$

This is the least value of the radius of curvature. Mr. Leffler.

As the limiting values of $\frac{ds}{dx}$ are 1 and cosec. $\alpha = 1.10$, we will assume as an average value for $\frac{ds}{dx}$, 1.05, hence, as $\left(\frac{ds}{dx}\right)^3$ was called b, $\sqrt{b} = 1.08$.

Again, as α is never less than 65°, the average value of its sine can be taken at 0.953.

$$\text{Then } R = \frac{1.08 \times 0.976}{\text{cos. } \alpha}\sqrt{\frac{EI}{W}} = \frac{1.054}{\text{cos. } \alpha}\sqrt{\frac{EI}{W}}.$$

Again, $$I = \frac{\pi\, d^4}{64},$$

hence $$R = \frac{1.054\ \sqrt{\pi}\ d^2}{8 \text{ cos. } \alpha}\sqrt{\frac{E}{W}} = \frac{d^2}{4.27 \text{ cos. } \alpha}\sqrt{\frac{E}{W}}.$$

It is close enough to take

$$R = \frac{4\, d^2}{17 \text{ cos. } \frac{\theta}{2}}\sqrt{\frac{E}{W}}.$$

REVISED SPECIFICATIONS FOR RAILROAD BRIDGES MOVABLE IN A VERTICAL PLANE.

Scope. 1.—These specifications are intended to cover bascule bridges, which are such as rotate about a horizontal axis; and vertical lifts, which are those in which successive positions are parallel.

Deck. 2.—The Contractor shall place and fasten permanently all ties, rails, guards, and other deck material. Usually, the Railroad Company will furnish all the deck material except rail-locks, rails which must be fabricated to fit locks, and special devices to hold the deck in place.

Responsibility. 3.—If complete general proposal plans are furnished to the Contractor, he shall be responsible for only the material and character of the workmanship and installation. However, for any parts of the design not covered by the proposal plan, and for which the Contractor is to make a design, he shall be wholly responsible.

Electrical Equipment. 4.—Unless otherwise specified, the electrical equipment shall include all electrical parts up to, and including, the switch-board. Electrical equipment carrying the current to the switch-board from the source of power will be covered by separate contract.

5.—The specifications of the New York Central Lines for Steel Railroad Bridges, for 1910, shall apply to movable bridges, except as noted herein.

Manner of Bidding.

Parts Classified as Machinery. 6.—Drums, cylinders, eccentrics, trunnions, and their cast supports, shafting, pistons, gear wheels, racks, boxings, bearings, couplings, disks, cast sheaves and wheels, worm gearing, valves, pins about the axis of which the connecting members rotate, whistles, ram screws, end bridge-locks, rail-locks, indicators, cranks, axles, hooks, wrenches, and similar parts of machinery which require machine-shop work, shall be classified as machinery and be paid for at a common price per pound. Electric motors, or other prime movers, are not classified as machinery. (11).

Sheaves. 7.—The large sheaves of vertical lift bridges the webs and diaphragms of which are built up with plates, angles, and rivets, shall be paid for at a separate price per pound of finished weight, including casings and fastenings to trunnions.

Air Compressor Boilers. 8.—Air compressor tanks and steam boilers shall be paid for at a separate price.

Wire Ropes and Cables. 9.—Wire ropes and cables and their sockets shall be paid for at a separate price per pound.

Pins, Levers, etc. 10.—The pins, equalizing levers, and cable attachments to the trusses and counterweights shall be paid for at a separate price per pound.

Structural Steel Parts. 11.—Structural steel supporting the machinery proper, counterweight frames, counterweight trusses, steel in operator's house, towers,

and links, shall be classified as structural steel and be paid for at the same price per pound as for the span itself. Attached machine parts, such as sleeves, bushings, etc., shall be classified as machinery. (6).

Operator's House.

12.—The operator's house, except for the structural steel therein, shall be paid for on a lump-sum basis.

13.—Structural steel which can be fabricated by the common shop methods, as punching, reaming, drilling, shearing, planing, etc., as is usually done for stationary structures, shall be classified as structural steel and be paid for at the same price per pound as for the span itself.

Segmental Girders.

14.—Segmental girders in rolling bascule bridges and the horizontal girders on which they roll shall be paid for at a separate price per pound. This does not include any bracing, floor system, or other structural members which may be attached. Track plates shall be included.

Hand-Rail.

15.—Hand-rail shall be paid for at a separate price per pound.

Electrical Equipment.

16.—Electrical equipment, such as wiring, switch-boards, controllers, lights, blow-outs, cut-offs, solenoids, switches, motors, etc., shall be paid for on a lump-sum basis.

Engines.

17.—Internal-combustion engines and steam engines shall be paid for on a lump-sum basis.

18.—Cast-iron parts used in counterweights shall be paid for at a separate price per pound.

19.—Concrete in counterweights shall be paid for at a price per cubic yard in place.

Extra Parts, etc.

20.—It is to be understood that if any extra parts are needed, or any question arises, all difficulties shall be settled on the pound price basis as quoted and accepted for the parts in question.

General Details in Designing.

Self-Centering Devices.

21.—Self-centering and seating devices shall be used on the free ends of the moving span. Holding and forcing-down devices shall be used for the free ends of each truss.

Rail-Locks.

22.—Designs for bridging the gap between the shore rails and moving rails shall be furnished by the Railroad Company. Loose rails will not be allowed.

Air Buffers.

23.—Air buffers shall be furnished at the free ends of the moving span.

Counterweights.

24.—The counterweights shall be easily adjustable. Usually, this shall be done by adding or taking away cast-iron parts, or small concrete blocks.

Stairways.

25.—Metal stairways, with 1½-in. hand-rail, shall be provided for access to the machinery, trunnions, and counterweights. The pipe shall weigh 2.68 lb. per ft.

Girders in Rolling Bridges.

26.—The reinforcements of webs in the segmental girders and track girders of rolling bridges shall be symmetrical about the center planes of the webs. The center planes of the segmental webs shall coincide with the corresponding center planes of the webs of the track girders. That part of an outstanding leg of an angle, which is beyond the outside face of the upstanding leg, shall not be considered as reinforcement. The width of contact between the segmental webs (including the reinforcements) and the back of the tread plates, shall be equal to the width of the corresponding contact in the track girder.

Coefficients of Friction for Moving Span and Attached Parts.

27.—In calculating the resistances to be overcome by the machinery, the resisting forces shall be reduced to a single force acting between the pinion and operating rack, or in the operating cable. In determining this force, the following coefficients shall be used in starting the span, and, except for the stiffness in cables, shall be reduced one-half after motion is begun. (44):

For trunnion friction..... $\frac{1}{8}$

For rolling friction of bridges having rollers with flanges, or built-up segmental girders..... $\frac{1}{12}$

For stiffness of wire rope per 180° of bending: d = diameter of rope, in inches; D = diameter of sheaves, in inches..... $\frac{d^2}{3D}$

Coefficients of Friction.

28.—For a solid cast roller, without flanges, in contact with one surface only, the coefficient of rolling friction shall be taken equal to $\frac{15}{1\,000\,r}$, in which r is the radius of the roller, in inches.

29.—In figuring the machinery losses between the operating rack or operating cable and the motor, the following coefficients shall be used:

For the efficiency of any pair of gears, journal friction not included.....	0.99
For journal friction.....	0.06
Losses in a worm gear for an angle of thread of 20° or more.....	0.30

30.—For sliding friction between plane surfaces intermittently lubricated, such as guides on tower posts, the coefficient of friction shall be taken equal to 0.08.

Time to Open.

31.—The time to open the bridge after the ends are released shall be approximately as specified on the proposal drawing.

Inertia.

32.—The force necessary to overcome the inertia and produce acceleration and retardation for the time of opening shall be considered. The machinery shall be capable of stopping the bridge in 6 sec.; for this purpose, the coefficient of friction in the friction brake shall be taken at not less than 25 per cent.

Impact in Structural Parts.

33.—In calculating the dead-load stresses in the moving structural parts, for the various positions of the open bridge, such stresses shall be increased 25% as allowance for impact. For stationary structural parts (as towers, and supporting girders in rolling bridges), to which moving structural parts are attached, or on which such parts roll, 15% of the static stress shall be added as impact.

34.—In structural steel parts, where a percentage of the dead load or static stress is added for impact, the unit stresses for stationary structures shall be used; the impact percentages are an allowance similar to that provided by an impact formula for stationary railroad bridges.

Reversal of Stress.

35.—In structural members subject to reversal on account of the motion of the span, the effect of reversal shall be neglected. The member shall be designed for the stress giving the larger section. For riveted connections, the number of rivets shall be increased 25% over that required for the static stress plus impact stress.

Impact for Machinery Parts, etc.

36.—The allowance for impact in trunnions, cables, cable attachments, machinery parts, and structural parts supporting the machinery, is taken care of by lowered unit stresses.

Wind Pressure.

37.—The wind pressure to be assumed in proportioning the machinery or moving parts shall be 15 lb. per sq. ft. on the exposed surfaces of the moving parts as projected on any vertical plane. The machinery shall be strong enough to hold the moving parts in any position for this pressure, and be capable of opening the bridge in the specified time at 10 lb. per sq. ft. wind pressure.

38.—The structure shall be strong enough to resist a wind pressure of 15 lb. per sq. ft. on any surface as projected on any vertical plane for any open position of the moving span. The structure shall be strong enough to resist a wind pressure of 25 lb. per sq. ft. when the moving span is in the closed position.

Least Wind Pressure.

39.—The least wind pressure to be assumed on the floor of the moving span shall be 2½ lb. per sq. ft. for any position of the span. For the vertical lift, this shall be taken as acting throughout the movement.

40.—On the ordinary open-floor bridge with ties, the exposed surface to wind shall be taken equal to 80% of a full quadrilateral having a width equal to the distance from center to center of trusses and a length equal to that of the moving span.

Detailed Drawings.

41.—The Contractor shall make complete detailed drawings of the machinery, so that any other shop can take them and duplicate the machinery. No reference to patterns or individual shop practices will be considered in lieu of the complete drawings. These drawings shall show a general outline of the assembled machinery. The drawings shall be made on tracing cloth, each sheet 24 by 36 in. in outside dimensions. These drawings shall become the property of the Railroad Company on the completion of the job.

Outline Drawing of Machinery.

42.—The Contractor shall furnish an outline drawing of the machinery, on which are shown the forces acting on the gear teeth, the twisting moment and bending moment on shafts, and other necessary information for checking the strength of the machine parts. A tabulation of the formulas and methods of calculation shall be shown complete enough to allow them to be checked.

Torque Curves.

43.—The Contractor shall show by a drawing of curves the torque to be exerted by the motor or prime mover, as follows:

1. A torque curve for acceleration and retardation;
2. A torque curve for the frictional resistance;
3. A torque curve for any unbalanced condition of the structure;
4. A torque curve for the wind load;
5. A torque curve showing the greatest combination of resistances acting at any one time.

44.—In figuring the friction at starting (this being twice the running friction), no acceleration of the moving mass shall be considered. This friction shall be considered as reduced to the running friction in the first second after the power is applied. (27).

Capacity of Wires, etc.

45.—If the Contractor is to furnish the design for the electrical equipment, such as wiring, switches, etc., he shall show by a curve the current required by the motor to overcome the various resistances. This is for the purpose of checking up the carrying capacity of wires and other parts, and determining the storage battery capacity.

Center of Gravity.

46.—The Contractor shall check the location of the center of gravity of the moving span, including all parts attached thereto, and also the location of the center of gravity of the counterweights, including counterweight girders and trusses, by computations based on accurate weights calculated from shop plans. He shall submit duplicate sketches and copies of these computations accompanied by weight bills to the Railroad Company for approval.

Hand Operation.

47.—All bridges shall be equipped with hand-operating mechanism. The number of men and the time required to operate shall be estimated on the assumption that the force one man can exert on a lever is 40 lb. with a speed of 160 ft. per min. developing about $\frac{1}{3}$ h.p. For calculating the strength of the machinery, the power of one man shall be assumed as 125 lb.

Operating Machinery.

48.—The parts shall be simple in design, and easily erected, inspected, adjusted, and taken apart. The fastenings shall hold the parts in place securely after they have been set.

Kind of Material.

49.—Rolled or forged steel shall be used for bolts, nuts, keys, cotters, pins, axles, screws, worms, piston rods, trunnions, and crane hooks, if any.

50.—Trunnions, pins, and shafting more than 4½ in. in diameter, shall be of forged structural steel. Shafting 4½ in. or less in diameter may be of cold-rolled steel.

51.—Forged or cast steel shall be used for levers, cranks, and connecting rods.

52.—Cast steel, or forged steel, shall be used for couplings, end shoes, racks, toothed wheels, brake wheels, drums, sheaves, and hangers where the supported weight will cause tensile stresses. Large sheaves may be built of structural steel.

53.—Pinions shall be made of forged steel and cut from the solid metal, unless such pinions are too large for forgings.

54.—Sockets used for holding the ends of wire ropes shall be forged without welds from the solid steel. The equalizing levers, connecting the ropes to the counterweights, or moving span, shall be of forged steel.

Cast Iron.

55.—Cast iron may be used in boxes for shafts 2 in. or less in diameter, and which obviously carry light loads. Other boxes shall be of cast steel.

56.—Cast iron may be used in eccentrics, cylinders, pistons, flywheels, and parts of motors which are usually made of cast iron. Cast iron shall not be used for any trunnion or axle supports.

Metal for Bushings.

57.—Phosphor-bronze, brass, and Babbitt metal shall be used for the bushing or lining of journal bearings and other rotating or sliding surfaces, to prevent seizing.

58.—Phosphor-bronze, only, shall be used for bushing for the trunnions of bascule and lift bridges, or in any large bearing carrying heavy loads.

59.—The bushings for large bearings, such as for trunnions and similar parts, shall be held from rotating in their casings. The force tending to cause rotation shall be taken as one-eighth of the load on the trunnion or bearing, and as acting at a tangent to the surface between the back of the bushing and casing; this force shall not be considered as counteracted by any frictional resistances between bushing and casing. It shall be practicable to take out the bushing when the trunnion is slightly lifted.

Castings.

60.—Castings which are to be attached to rough unfinished surfaces shall be provided with chipping strips. The outer unfinished edges of ribs, bases, etc., shall be rounded off, and inside corners filleted.

Bolts and Nuts.

61.—Bolts and nuts, up to 1½ in. in diameter, shall have U. S. Standard V-threads. Nuts and exposed bolt heads shall be hexagonal in shape, and each nut shall be provided with a washer. If the nut will come on an inclined surface, a special seat, the top surface of which is at right angles to the bolt, shall be cast or built up to receive the nut. Bolt heads which are countersunk in castings shall be square.

62.—Nuts which are subject to vibration and frequent changes of load shall have locking arrangements to prevent the gradual unscrewing of the same. If double nuts are used for that purpose, each nut shall be of the standard thickness. Nuts subject to vibration shall be further secured by split pins through the bolt.

Screws.

63.—Screws which transmit motion shall have square threads.

Tap-Bolts, Set-Screws, etc.

64.—Tap-bolts and stud-bolts shall not be used, except by special permission.

65.—Set-screws shall not be used for transmitting torsion to shafts or axles.

Collars.

66.—Collars shall be used wherever necessary to hold the shaft from moving horizontally. Each collar shall have at least two set-screws at an angle of 120 degrees.

Shaft Couplings.

67.—Shaft couplings, unless of the flexible kind, shall be of the flange type, or split muff with bolt heads and nuts countersunk.

68.—For large shafts, couplings such as are used for rolling mill shafting may be used.

69.—Couplings shall be keyed to shaftings.

Keys.

70.—If practicable, hooked and tapered keys shall be used. The taper shall be $\frac{1}{8}$ in. per ft. The width of the key shall be one-fourth of the diameter of the shaft; the height, at mid-section of the tapered length, shall be three-fourths of the width. The length of the hook, measured parallel to the shaft, shall be equal to the width of the key.

71.—If tapered keys are not practicable, parallel-faced keys of about the above proportions shall be used.

72.—Tapered keys shall bear on top, bottom, and sides; parallel-faced keys shall bear on sides only.

73.—The length of any key shall be not less than that of the hub.

74.—The foregoing dimensions are approximate. The shape of the key shall be such as to have unit stresses in shear and bearing not exceeding those allowable in the table.

75.—If practicable, the keys and grooves shall be made so that the keys may be backed out.

76.—Keys shall be sunk in grooves in both hub and shaft. The depth of a groove shall be such that the bearing will not exceed the allowable unit stress.

Set-Screws, etc.

77.—Keys shall be held by set-screws or equivalent means. In vertical shafts, bands clamped about the shaft, or other devices, shall be placed below the key.

Hub.

78.—If practicable, the length of the hub shall be not less than two diameters of the shaft, and its thickness not less than one-third of the diameter of the shaft. The hub shall have a light driving fit on the shaft.

79.—The groove in the hub shall be made on the center line of an arm.

80.—Hubs shall be bored truly at the center of the wheel.

Keys in Trunnions.

81.—For trunnions and similar parts, which are designed chiefly for bending and bearing, the keys, key-ways, and bolts shall be designed to hold the trunnions from rotating. The force tending to cause rotation shall be taken at one-fifth of the load on the trunnion, and shall be taken as acting at the circumference of the trunnion.

Journals.

82.—Journals shall be proportioned to resist, not only the various stresses to which they are subjected, without exceeding the permissible fiber and bending stresses, but also to prevent a tendency to heat and seize.

83.—Divided journal and trunnion bearings shall be used, and the cap shall be fastened to the base with turned bolts recessed into the base. The nuts and heads shall bear on finished bosses cast on the bearing. There shall be $\frac{1}{8}$ in. clearance between the lining of the base and the cap or its lining, to allow for expansion.

Bushings.

84.—Steel bearings carrying steel shafts or journals shall be lined with bronze or brass. If shafts are 3 in. or less in diameter and of a slow motion, Babbitt metal may be used. Bearings of steel on steel for moving surfaces will not be allowed.

Boxes.

85.—In cast-iron boxes carrying light shafts, no lining is needed.

86.—The bearings of shafts shall be placed as near to the points of loading as possible.

87.—The foot-steps of vertical shafts shall be of axle or tool steel, and shall run on bronze disks.

Lubrication.

88.—Provision shall be made for the effective lubrication of journals, or any other sliding surfaces. Closed oil or compression grease cups shall be used. Grooves shall be cut in the surface of the trunnion to provide for the proper distribution of grease or oil. Grease and oil cups must hold the lubricant for any position of the moving parts.

Grease Grooves.

89.—The grooves in large trunnions shall approximate to a U shape; the size shall be such that a wire $\frac{5}{16}$ in. in diameter may lie wholly within the groove. The edge of the U shall be rounded to a radius of $\frac{1}{4}$ in.

90.—The grooves shall be straight, running parallel to the axis of the trunnion. They shall be not less than three in number, and located so that all parts of the bearing surface of the bushing will be swept by the contained lubricant, in an opening, and in a closing of the bridge. The grooves must allow of being cleaned with a wire.

Grease Cups.

91.—In any trunnion bearing, or similar heavy bearings, strong compression grease cups shall be used for the grooves.

92.—Oil and grease ducts shall be located so that the lubricant will flow by gravity toward the bearing surface.

Dust Covers.

93.—Dust covers shall be provided for the principal bearings, in particular for trunnions where shown on plans.

Shaft Supports and Couplings.

94.—Line shafts, extending from the center of the bridge to the end, shall not be continuous, but shall be connected with claw couplings. Each length of shafting shall rest in not more than two bearings, with the couplings close to the bearings.

95.—If shaft supports are connected to the floor-beam, in bridges having long panels, intermediate supports shall be used; these shall be adjustable, and are intended merely to prevent the shaft from sagging.

Equalizing Gears.

96.—Equalizing gears or devices shall be used to insure equal action at the pinions and operating racks.

Unsupported Length of Shafts.

97.—The unsupported length of shafts shall not exceed $L = 80^3\sqrt{d^2}$ for shafts supporting their own weight only; $L = 50^3\sqrt{d^2}$ for shafts carrying pulleys, gearing, etc., where L = length of shaft between center of bearings, in inches; and d = diameter of shaft, in inches.

98.—Line shafts connecting machinery at the center to that at the ends shall run at fairly high speed. The speed reduction shall be made in the machinery near the end.

99.—In designing circular shafting, trunnions, and axles, the greatest unit fiber stress in tension or compression due to bending shall be calculated by the following formula:

$$f = \frac{32}{\pi d^3}\left(\frac{3}{8}M + \frac{5}{8}\sqrt{M^2 + T^2}\right).$$

Formulas for Shafts.

100.—The maximum unit shear shall be calculated by the following formula:

$$S = \frac{16}{\pi d^3}\sqrt{M^2 + T^2}.$$

101.—In these formulas, f = unit fiber stress in tension or compression; S = unit shear; d = diameter of shaft; M = the simple bending moment; and T = the simple twisting moment.

102.—If a shaft, trunnion, or axle has one key-way cut, at the section where the maximum stresses occur, f and S shall be increased by one-sixth; if two key-ways are cut, increase by one-fourth. If the shaft is enlarged through the hub, this does not apply.

Distance between Shaft Supports.

103.—In calculating the bending moment on shafts, trunnions, and journals, the distance from center to center of bearings shall be taken.

Style of Gear Teeth.

104.—Gear teeth shall be of the involute type, with an angle of obliquity of 20 degrees. The roots below the clearance line shall be filleted.

105.—The width of the teeth may be as great as four times the pitch, but not more, except for wheels running at a very high velocity, as in motors where abrasion is to be considered.

Strength of Beveled Gear Teeth.

106.—In estimating the strength of teeth in bevel wheels, the pitch at the middle section shall be taken.

Pitch Circle.

107.—For the purpose of setting gear teeth accurately in the field erection, the pitch circle shall be scribed on the ends of the teeth.

Worm Gearing.

108.—Worm gearing, for transmitting power, shall have an angle of thread not less than 20 degrees. The worm shall run in oil. A bronze or brass collar shall be used at the end of the worm and at the end of the wheel axle, to take care of the end thrust. The wheel shall be of bronze. If a nut engages the worm, the nut shall be of bronze.

109.—Worms which are to be used for actuating signals, indicators, or other minor parts, may have an angle of thread less than 20 degrees.

Number of Teeth in Worm Gears.

110.—Worm wheels shall have not less than twenty-six teeth.

Number of Pinion Teeth.

111.—Pinions shall have not less than fifteen teeth.

Diameter of Sheaves.

112.—For the purpose of keeping down the wear between the individual wires in counterweight rope, the diameter of the sheave shall be at least ninety times that of the rope.

Safety Guards.

113.—Machinery parts near which workmen may be while the parts are in motion, shall be designed so that safety guards may be added. These guards will be furnished and installed by the Railroad Company.

Counterbalancing, Operating Ropes, and Attachments.

Wire Ropes and Cables.

114.—Wire rope shall be made by a manufacturer approved by the Engineer.

115.—The counterbalance ropes shall be of plow-steel wire, and shall consist of six strands, of nineteen wires each, laid around a hemp center.

116.—Ropes shall be laid up in the best manner, and shall be thoroughly soaked in an approved lubricant during the process of manufacture.

117.—The counterbalance ropes shall be made from wire which has been tested in the presence of an inspector designated by the Engineer, and which, for sizes from 0.076 to 0.150 in. in diameter (the limiting values used in counterbalance ropes), exhibits the following physical properties:

a.—The tensile strength shall be not less than 225 000 lb. per sq. in. for wire from 0.150 to 0.126 in. in diameter, nor less than 230 000 lb. for wire from 0.125 to 0.101 in. in diameter, nor less than 235 000 lb. for wire from 0.100 to 0.076 in. in diameter.

b.—The total ultimate elongation, measured on a piece 12 in. long, shall be not less than 2.4 per cent.

c.—The number of times a piece 6 in. long can be twisted around its longitudinal axis without rupture shall be not less than 1.4 divided by the diameter, in inches.

d.—The number of times the wire can be bent 90°, alternately to the right and to the left, over a radius equal to twice its diameter, without fracture, shall be not less than six. This test shall be made

in a mechanical bender constructed so that the wire actually conforms to the radius of the jaws and is subjected to as little tensile stress as possible.

Ultimate Strength of Cables.

118.—The rope shall be made in one piece, if possible. Its breaking strength, as determined by test described in Paragraph 121, shall be not less than

4 900	lb.	if	$\frac{1}{4}$	in.	in diameter.
11 800	"	"	$\frac{3}{8}$	"	" "
20 600	"	"	$\frac{1}{2}$	"	" "
32 400	"	"	$\frac{5}{8}$	"	" "
45 000	"	"	$\frac{3}{4}$	"	" "
70 000	"	"	$\frac{7}{8}$	"	" "
79 200	"	"	1	"	" "
100 800	"	"	$1\frac{1}{8}$	"	" "
120 600	"	"	$1\frac{1}{4}$	"	" "
148 000	"	"	$1\frac{3}{8}$	"	" "
173 000	"	"	$1\frac{1}{2}$	"	" "
200 000	"	"	$1\frac{5}{8}$	"	" "
230 000	"	"	$1\frac{3}{4}$	"	" "
264 000	"	"	$1\frac{7}{8}$	"	" "
297 000	"	"	2	"	" "
325 000	"	"	$2\frac{1}{8}$	"	" "
374 000	"	"	$2\frac{1}{4}$	"	" "
465 000	"	"	$2\frac{1}{2}$	"	" "

119.—In case the physical qualities of the rope, or its individual wires, fall below the values cited above, the entire length from which the test pieces were taken shall be replaced by the manufacturer with a new length, the physical qualities of which come up to the specifications.

120.—The dimensions of the sockets shall be such that no part under tension shall be loaded higher than 65 000 lb. per sq. in. when the rope is stressed to its ultimate strength, as named above. The sockets must be attached to the rope by a method which is reliable and will not permit the rope to slip in its attachment to the socket.

121.—In order to show the strength of the rope and fastenings, a number of test pieces, not more than 10% of the total number of finished lengths which will ultimately be made, nor less than two from each original long length, and not more than 12 ft. long, shall be cut, and shall have sockets, selected at random from those which are to be used in filling the order, attached to each end. These test pieces are to be stressed to destruction in a suitable testing machine. Under this stress the rope must develop the ultimate strength given in Paragraph 118.

122.—If, in testing, slipping in the sockets should occur, then the method must be changed until slipping is avoided. The sockets themselves shall be stronger than the rope with which they are used; if one should break during the test, then two others shall be selected and attached to another piece of rope and the test repeated; and this process shall be continued until the inspector is satisfied of their reliability, in which case the lot shall be accepted. If, however, 10% or more of all the sockets tested break at a load less than the minimum ultimate strength of the rope, as given in Paragraph 118, then the entire lot shall be rejected.

Length of Rope.

123.—The length of each rope, from inside of bearing to inside of bearing of socket, shall be determined, and a metal tag having the said length stamped thereon shall be attached securely to the rope.

Testing Rope Connections.

124.—One-third of the wire rope connections, selected at random, shall be tested (after attachment to the ropes are made) up to 0.4 of the ultimate strength of the rope. If any connection is weak, the remainder of the connections shall be tested. The weak connections shall be rejected and replaced. Not less than four connections shall be tested.

Facilities for Testing Rope.

125.—The manufacturer shall provide proper facilities for making the tests, and shall make at his own expense all the tests required. Tests shall be made in the presence of an inspector who represents the Engineer.

Shipment of Rope in Coils.

126.—Ropes shall be shipped in coils the minimum diameter of which is at least thirty times that of the ropes, and they shall be uncoiled for use by revolving the coil, not by pulling the rope away from the stationary coil.

Workmanship.

127.—For the parts of the operating machinery of movable bridges which are usually exposed to the weather, the finish shall be confined to the bearing, rotating, and sliding surfaces, and wherever it is required to produce accurate fits and precise dimensions.

128.—Equalizing levers in rope connections shall be neatly finished, and shall conform to the dimensions shown on the drawings.

129.—Castings shall be cleaned, and seams and other blemishes removed.

130.—Drainage holes, not less than $\frac{3}{4}$ in. in diameter, shall be drilled in places where water is likely to collect.

Play of Unfinished Bolts.

131.—Unfinished bolts may have a play of $\frac{1}{16}$ in. in the bolt holes. Turned bolts must have the diameter of the shank at least $\frac{1}{16}$ in. larger than the diameter of the threaded portion, and must have a driving fit in the bolt hole.

Racks and Contact Surfaces.

132.—The backs of racks and surfaces in contact shall be planed.

Sheaves. 133.—The bearing surfaces, at the junction of the cast rim and structural parts in built-up sheaves, shall be planed to give full contact throughout the circumference of the sheave.

Grooves in Sheaves. 134.—The grooves in the circumference of sheaves carrying wire ropes shall be turned to a radius that will fit the rope. This is to be done after the sheave is completely assembled and permanently riveted up.

Tread-Plates. 135.—The top and bottom of the tread-plates and surfaces in contact in rolling bridges shall be planed to fit. A full bearing must be made.

136.—The periphery and the ends of teeth which mesh with shrouded teeth shall be planed, and the pitch line shall be scribed thereon.

Finishing of Trunnions, etc. 137.—Journals and trunnions shall be turned with a fillet where the section changes. Journals shall have a collar at each end. Trunnions and journals 8 in. in diameter and greater shall have a hole, 1½ in. in diameter, bored through on the longitudinal axis. Journals, trunnions, and bushings must be polished after being turned. The use of a cutter which trembles or chatters will not be allowed.

138.—The joints between the caps and bases of journal and trunnion bearings shall be planed. The ends of the bases and surfaces in contact with the supports shall be planed. Bolt holes for holding the cap to the base and for holding the base to its support shall be drilled.

Grooves. 139.—The grooves in the surfaces of trunnions or similar large bearings shall be machine cut. Chipping and filing will be allowed only for removing small inequalities. The grooves shall be smooth, especially the rounded corners.

Hubs. 140.—Hubs of wheels, pulleys, couplings, etc., shall be bored to fit close on the shaft axle. If the hub performs the function of a collar, the end next to the bearing shall be faced. Holes in hubs of toothed gear wheels shall be concentric with the pitch circle.

Cut Gears, etc. 141.—The periphery of gear wheels shall be turned. Gear wheels and racks which are part of the train which actuates the moving span shall be cut. Other gears, except beveled gears, shall be machine moulded.

142.—If any moulded gears are shrouded, chipping or other means shall be used at the junction of the shrouding and teeth to insure proper meshing.

Beveled Gears. 143.—Beveled gears shall be cut. The cutting shall be done by a planer having a rectilinear motion to and from the apex of the cone. Rotating milling cutters shall not be used.

144.—Threads on worms, and the teeth of worm wheels shall be cut, and shall fit accurately. Point contact shall be avoided.

145.—Any two surfaces which slide, or roll, or bear on each other, shall be planed or turned to fit.

Assembling of Machinery.

146.—Machinery parts shall be assembled on the supporting members in the shop, and shall be aligned and fitted, and holes in the supports drilled, and with the members in correct relative position. The members shall be match-marked, both to the supports and to each other, and re-erected in the same relative position.

Holes for Sheaves for Vertical Lift Bridges.

147.—The holes in the girders and columns for the bolts connecting the main sheave bearings to their supporting girders shall be drilled from the solid through cast-iron or steel templates on which the bearings were set and accurately lined when the holes in the bearing were bored. The bolt holes and the bolts shall be turned to the same diameter, and the bolts shall be driven to place without injury to them, the bearings, the girders, or the columns.

Testing of Trunnion Bearings.

148.—Trunnions shall be turned to a diameter of $\frac{1}{50}$ in. less than that of the bushing. Before shipping, the trunnions shall be placed in their bearings and given two full rotations. If any grinding or hard turning is found, it must be remedied. The tests shall be made in the presence of the Railroad Company's inspector.

Facing of Couplings.

149.—Faces of flange and split muff couplings shall be planed to fit. The couplings shall be keyed to the shaft.

150.—A special effort to secure good workmanship on keys and keyways shall be made.

Coating of Surfaces.

151.—Machined surfaces shall have a coating of white lead applied to them.

152.—Machinery which is of the regular standard manufactured type, such as steam, gasoline, electric motors, pumps, air compressors, etc., shall be guaranteed by the manufacturer as to efficiency, and shall be subject to the approval of the Engineer. Motors shall be tested to prove that they fulfill the specified requirements and develop the desired speed, power, and torque.

153.—The rating of a prime mover shall be the horse-power determined by the brake test.

Unit Stresses.

Normal and Excess Loads.

154.—Machinery parts shall be designed for the normal loads used in determining the torque curves, using the unit stresses herein specified. For the excess torque specified for the prime mover, twice the normal unit stresses will be allowed. (178) (205) (208).

Braking.

155.—If brakes act through the machinery, the unit stresses produced by braking shall not exceed by more than 50% those caused by the normal torque of the prime mover.

156.—The following unit stresses, in pounds per square inch, shall be used for parts in which main stresses are not increased by impact:

Stresses in One Direction.

Material.	Tension.	Compression.	Fixed Bearing.	Shear.
Machinery steel...	9 400	$9\,400 - 40\frac{l}{r}$	11 000	6 200
Structural steel....	8 500	$8\,500 - 36\frac{l}{r}$	.....	5 600
Steel castings.....	7 000	$8\,000 - 35\frac{l}{r}$	.....	5 000
Phosphor-bronze..	6 600	.....	.....	4 600
Cast iron.....	3 000	8 000	.....	3 000
	Shear on keys....	4 900		
	Bearing on keys..	8 800		

157.—The maximum unit tension in plow-steel cables shall be one-sixth of the ultimate. The maximum unit tension is equal to the direct unit stress plus the extreme fiber unit stress in the individual wire due to bending over the sheave.

Reversal of Stresses.

158.—For stresses which are reversed at the rate of ten or more times per minute, use one-half of the above unit stresses.

159.—If wire rope is bent over a sheave, the bending stress and permissible load on the rope shall be calculated as follows:

Let P = the total pull or permissible load on the rope, in pounds;
K = extreme unit fiber stress in greatest individual wire;
E = modulus of elasticity = 28 500 000;
a = cross-sectional area of rope, in square inches;
d = diameter of thickest wire, in inches;
D = diameter of sheave to center of rope, in inches;
S = greatest unit tension allowable;
α = angle of helical wire with axis of strand;
β = angle of helical strand with axis of rope;
c = diameter of rope.

$$\text{Then } K = \frac{Ed \cos.^2 \alpha \cos.^2 \beta}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$P = a\left(S - \frac{Ed \cos.^2 \alpha \cos.^2 \beta}{D}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

For rope having six strands of nineteen equal wires each,

$$P = a\left(S - \frac{1\,800\,000\, c}{D}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

because $\cos.^2 \alpha \cos.^2 \beta = 0.95$, $d = \frac{c}{15}$.

160.—For haulage rope, six strands of seven wires each, take $d = \frac{c}{9}$.

161.—If a rope is in contact with a sheave over a small arc, the actual radius of curvature may be greater than that of the sheave. (See figure.)

Let R = The actual radius of curvature;
θ = the angle between the directions of the rope;
W = pull on individual wire, equal to P divided by the number of wires if all wires are of equal diameter.

$$\text{Then } R = \frac{4\,d^2}{17 \cos. \frac{\theta}{2}} \sqrt{\frac{E}{W}}.$$

162.—If R is greater than the radius of the sheave, $2R$ should be used in place of D in Formulas (1), (2), and (3). The formula is only valid for values of θ between 130 and 180 degrees.

163.—The strength of cut gear teeth shall conform to the following formula, one tooth only taking pressure: Strength of Gear Teeth.

$$P = fpb\left(0.154 - \frac{0.912}{n}\right)\frac{600}{600 + v}, \text{ in which}$$

P = pressure on tooth, in pounds;
f = permissible unit stress = 17 000 lb.;
p = pitch, in inches;
b = face or breadth of tooth, in inches;
n = number of teeth in gear;
v = velocity on pitch circle, in feet per minute.

164.—The strength of machine-moulded teeth shall be calculated by the foregoing formula, taking f = 15 000 lb.

165.—The foregoing formula is for involute teeth having an angle of obliquity equal to 20 degrees.

166.—The pressure, in pounds per linear inch, on rollers at rest shall be, for rolled and cast steel, 600 d, where d equals the diameter of the roller, in inches. Pressure on Rollers.

UNIT STRESSES FOR BEARING ON ROTATING AND SLIDING SURFACES.

167.—Maximum bearing values for rotating and sliding surfaces, in pounds per square inch:

Bearings on which the speed is slow and intermittent:

	Pounds per square inch.
Trunnion bearings on bascule bridges: machinery steel on phosphor-bronze	1 500
Wedges: Cast steel on cast steel or structural steel	500
Screws which transmit motion on projected area of thread	200

	Pounds per square inch.
For ordinary cases, parts moving at moderate speeds: Hardened steel on hardened steel	2 000
Hardened steel on bronze	1 500
Tool steel (not hardened) on bronze	900
Structural steel on bronze	600
Cast iron on structural steel	400
On cross-head slides, speed not exceeding 600 ft. per min	50

168.—In order to prevent heating and seizing at higher speeds, the pressure on pivots or foot-step bearings for vertical shafts and journals shall not exceed:

On pivots $p = \frac{40\,000}{n\,d}$ per square inch.

On journals $p = \frac{300\,000}{n\,d}$ per square inch.

Where n = number of revolutions per minute;
d = diameter of journal or pivot, in inches.

169.—For crank pins and similar joints with alternating motion, the limiting bearing values given in the above formula may be doubled.

Stresses on Rollers.

170.—Permissible pressure, in pounds per linear inch of roller in motion:

For cast iron	$p = 200d$
For steel castings	$p = 400d$
For machinery steel	$p = 500d$
For tool steel	$p = 800d$
For hardened tool steel	$p = 1\,000d$

Where p = pressure per linear inch of roller,
and d = diameter of roller, in inches.

171.—The foregoing values are for rollers and bearing surfaces of the same material; if rollers and bearing surfaces are of different materials, the lower value shall be used.

Power Equipment.

General Requirements.

172.—The kind of motor best adapted to any particular case depends on local conditions, and should be left to the judgment of the Engineer.

Mechanical Power.

173.—If the bridge is operated by mechanical power, the motor shall be of ample capacity to move or turn the bridge at the required speed. No matter what mechanical power is used, all bridges shall also be provided with hand-power operating machinery.

Friction Brakes.

174.—Friction brakes, to be operated by hand or foot, shall be provided where the motor is located in the operator's house. They shall have sufficient capacity to stop or hold the moving span in any position, under all conditions.

Operator's House.

175.—If mechanical power of any kind is to be used for operating a movable bridge, a suitable house shall be provided for the operator. The house shall be of such dimensions as required for the purpose for which it is to be used. It shall be placed in a position where the operator can observe the signals and see the approaching vessels and trains, and with enough windows of sufficient size, so that his view will not be obstructed. If the operator's house is above or below the floor of the bridge, suitable steel or iron stairs with railings shall be provided to lead from the floor of the bridge to the floor of the operating house. The house shall be of fire-proof construction, consisting of a steel frame, steel floor joists and a fire-proof floor. If the house contains motors and machinery, the floor shall preferably consist of steel plates, but, if the motors are located elsewhere, the floor between the joists may be of concrete construction. The sides and roof shall be of metal, concrete, or any other non-combustible material. The hand-rail for stairways and other places shall be made of 1½-in. gas pipe.

Heating of Operator's House.

176.—Whenever climatic conditions require it, provision shall be made for heating the operator's house. If steam power is used, the house shall be heated by a steam coil or radiator fed from the boiler. If electric power is used, the heat may be supplied by electricity. If gasoline is used, or any other power which cannot be utilized for heating, a coal, wood, petroleum, or gas stove, as directed by the Engineer, shall be provided.

Whistle.

177.—A whistle, having a bell 5 in. in diameter and 12 in. long, shall be installed complete. If operated by air, the compressor and air tank shall conform to the following specifications: The compressor shall be motor driven, the motor and compressor being on one frame, and geared. All working parts shall be completely enclosed, and self-lubricating. The compressor shall have a piston displacement of from 25 to 30 cu. ft. per min. when working against a tank pressure of 90 lb. per sq. in. The compressor shall be provided with strainer, and automatic governor and switch, in order that the compressor may start and stop automatically at any predetermined tank pressure. The air receiving tank shall be 36 in. in diameter and 8 ft. long, or of equal capacity. The tank shall be galvanized, and good for a working pressure of 100 lb. per sq. in. It shall be provided with pressure gauge and pigtail, pop-valve and drain cock, and have standard flanges bushed for 1½-in. pipe. The Contractor shall furnish all pipe, pipe fittings, and valves, and all shall withstand a working pressure of 100 lb. per sq. in.

Greatest Torque.

178.—A prime mover shall be capable of exerting twice the greatest torque shown on the torque curves for the normal loads. (154).

Steam Power.

Steam Engine. 179.—If a steam engine is used, it shall consist of a double-cylinder, reversing engine, the piston speed of which shall not exceed 200 ft. per min.; it shall develop the desired power and speed with a steam pressure of 50 lb. per sq. in. The engine shall be connected to the operating machinery by an approved friction clutch, arranged so that the moving and locking machinery can be operated alternately or stopped without stopping the engine.

Steam Separator. 180.—In the steam supply pipe, and close to the steam chest, shall be placed a steam separator. This separator, under test with quality of steam as low as 66%, shall show an average efficiency of 85% in five tests.

Boilers. 181.—The steam shall be generated by one or two upright, tubular boilers, each of which shall have twice the capacity of the engine. The boilers shall be designed for a steam pressure of 150 lb. per sq. in., and adapted to the kind of fuel specified by the Engineer; they shall be of open-hearth steel, in accordance with the specifications for boiler plates appended hereto. They shall be encased in asbestos and covered with Russia iron.

182.—The boilers shall also be in accordance with the specifications of the Mechanical Department of the Railroad Company, and shall conform to the civil laws.

Flues of Boilers. 183.—Vertical boilers shall have submerged flues at the top.

Horse-power of Boilers 184.—The total horse-power of the boilers shall be twice that of the engine, and shall be computed by the following rule: Calculate the inside area of the tubes, the area of the tube sheet next to the fire, and the sides of the fire-box where this is in contact with the fire. Take the sum of these areas in square feet and divide by fifteen. The intention is to allow 15 sq. ft. of heating surface per horse-power. At least $\frac{1}{2}$ sq. ft. of grate surface shall be provided per horse-power.

Equipment of Engine-Room. 185.—The engine-room shall be provided with a steel water tank of sufficient capacity; a duplex, steam feed-pump; and an injector for each boiler, with necessary pipes and connections for feeding boilers separately or together; steam water-lifters with necessary strainers, flexible hose, and piping to lift the water from the river into the tank; a coal hoist and a steel coal-bin of sufficient capacity. The engine-room shall be provided with a suitable indicator for recording the positions of the moving span in turning and locking.

Internal-Combustion Engines.

Gasoline Motor, etc. 186.—If an internal-combustion engine is used, one of the most substantial kind shall be selected, the maximum piston speed of which shall not exceed 500 ft. per min. The engine shall have a reversing gear provided with approved friction clutches, to be operated by a hand-wheel. The countershaft connecting the engine with the operat-

ing machinery shall be provided with disengaging couplings, arranged so that the moving and locking machinery can be operated alternately and in either direction without stopping the engine. Motors of 10 h.p. or more shall be started by compressed air. The fuel tank shall be located outside of the engine-house. The engine-room shall be provided with indicators for recording the positions of the moving span, and lifting and locking apparatus.

Engine Cooling.

187.—For bridges which are to be opened at intervals of 10 min. or less, and about six times per hour, the engine shall be water-cooled. For longer intervals, the engine shall be air-cooled. For this purpose, the outside cylinder shall have deep flanges about which a forced circulation of air is maintained by a fan.

Ignition.

188.—The ignition shall be of the jump-spark kind in which the secondary coil is made up on each spark plug as part of it, so that a low voltage current of not more than 10 volts will be sufficient.

Extra Parts.

189.—Two extra igniters and two extra crank-pin brasses shall be furnished.

Electric Equipment.

A. I. E. E. Rules.

190.—The electric equipment shall conform to the Standardization rules of the American Institute of Electrical Engineers, as adopted June 21st, 1907, or subsequent revisions.

N. E. C.

191.—The National Electric Code shall apply to the electric construction and installation, except as may be noted hereinafter.

Wires and Insulation.

192.—The quality of the wires and insulation shall conform to the specifications of the Railway Signal Association, as revised and adopted October, 1911. (See Volume 8 of the *Proceedings* of that Association.)

Tests.

193.—Any motor under test shall develop the required horse-power and torque at the armature shaft. Characteristic curves showing the results of the test shall be furnished by the manufacturer.

194.—Motors shall be tested for one-half their normal voltage between the brushes. An efficiency curve shall be shown.

195.—Motors, generators, automatic circuit breakers, solenoids, brakes, and other electric mechanism shall be tested at the factory by the manufacturer in the presence of the Railroad Company's inspector.

196.—If the motor is enclosed in a case, as mill motors are, small openings of sufficient size shall be provided in the case for the inspection, removal, and replacing of brushes.

197.—One cast-steel cut gear, bored and key-seated for attachment to the countershaft, shall be furnished with the motor. The gear and pinion shall be covered by a sheet-steel or malleable-iron split gear case, supported by the motor frame and completely covering the gear and pinion. An opening, with a hinged cover, shall be provided in

the gear case for inspection and oiling. The gear ratio shall be such that the full speed of the countershaft will not be more than 125 rev. per min.

Motor Pinions. 198.—Motors shall have a forged-steel cut pinion, out of one piece, keyed to the end of the armature shaft and secured by a lock-nut.

Spare Motor Parts. 199.—For each size of motor furnished, the Contractor shall supply the following spare parts: One armature, one field coil, one pinion, one gear, and one set of brushes. These parts shall be finished and fitted in such a manner as to admit of being installed in their respective places without further fitting or adjustment.

Mounting Motors. 200.—The motors shall be mounted in such a manner as to admit of easy access for inspection and repairs; they shall be supported securely by brackets or suitable foundations.

201.—If the machinery and motors are on the moving span, they shall be capable of being operated satisfactorily in any position of the span.

Housing of Motors. 202.—Motors must be housed in weather-proof metal housing. This housing must be large enough to allow the inspection and oiling of the motor. It must be readily removable so that access to the motor may be obtained. No metal in this housing shall be less than No. 16, U. S. Standard, gauge; it shall be galvanized.

D. C. Motor. 203.—Direct-current motors and generators shall be of the railway series, or mill, interpole type, water-proof, with slotted-drum armature and form-wound armature coils. They shall be of a standard commercial type in common use.

Testing of Motors. 204.—The rating of a direct-current motor is the horse-power output at the armature shaft which gives a rise of temperature above the surrounding air (referred to a room temperature of 25° cent.) not exceeding 90° cent. at the commutator and 75° cent. at any other part after a continuous run of 1 hour at its rated voltage, on a stand with the motor covers removed and with natural ventilation. The rise in temperature is to be determined by thermometer, but the resistance of no electric circuit in the motor shall increase more than 40% during the test.

Excess Motor Loads. 205.—Direct-current motors shall be capable of exerting continuously for two cycles twice the normal torque shown on the torque curves for the moving span and machinery. One cycle is an opening and closing of the bridge in a specified time. (154) (224) (226).

A. C. Motors. 206.—Alternating-current motors shall be of the three-phase, induction type, with slip-rings, rotor-wound, 25 or 60 cycles, and 220 or 440 voltage, unless otherwise specified. The resistance for varying the speed shall be in series with the rotor circuit, and be such as to affect evenly all three phases. Motors of 5 h.p. or less may be of the squirrel-cage type.

207.—Alternating-current motors shall show, in a run for heat test, the following maximum temperature rises above 25° cent. for

the surrounding room: for continuous run under a nominal load, 40° cent.; for 2 hours' run under 25% overload and a 1 min. run under 50% overload 55° cent.

208.—Alternating-current motors shall be of rugged construction. The sum of the starting torques of the motors shall be at least equal to twice the greatest torque shown by the torque curves for the bridge operating machinery. The pull-out torque shall be at least equal to 1½ times the starting torque. (154) (224) (226).

Controllers.

209.—The controllers for motors shall be located in the operating-house. The controllers shall be of the reversing drum type, or flat type, with magnetic blow-out, and shall be capable of varying and maintaining the speed of the motors throughout the entire range desired, without injurious sparking, and without shock due to sudden variation in speed. The controllers shall be capable of doing their work for the usual loads, and excess loads, that may come upon the motors, with a temperature rise not exceeding that specified for the motors.

Controller Steps.

210.—The controller shall have a sufficient number of notches or steps, such that the minimum or maximum motor torque will not differ by more than 10% from the average torque required for uniform acceleration.

211.—One controller shall be furnished for the operation of the main motors, one for rail-lock motors, and one for bridge-lock motor. These controllers shall be designed so that the operation of any motor can be cut out by pulling a switch on the switch-board, without affecting the operation of any of the other motors.

212.—The controllers for the two main motors, if for direct current, shall be of the series-parallel type; or of the type in which the field is varied, as may be done for the interpole type of motor.

Control of Motors.

213.—The control of motors shall be electrically interlocked with each other and with the signal system, and the bridge shall be controlled in such a way that the end-locks cannot be released until the signals have gone to danger position and the derails are set; and the bridge motor cannot be started until the end-locks have actually been released. In closing the bridge, the control shall be such as to make it impossible for the operator to move the end-locks until the bridge has been completely closed, or to set the signals at safety until the bridge has been closed and the end-locks are in place.

Master Controller.

214.—For currents too large for the usual type of controller, the motor circuits shall be made by contactors mounted on panels or frames. These contactors shall be operated by solenoids which are controlled by a master controller.

Automatic Control.

215.—For large structures, automatic control may be used, but this is too complicated to be covered by a specification. This should be taken up for special consideration with the Engineer.

Resistance.

216.—Resistances shall be of the cast-grid type, and of such capacity that the motor can be operated continuously at any point of the controller when developing full-load torque, or for 10 min. when developing 50% over-load torque, without sufficient rise in temperature of the resistance to cause deterioration of any part. The resistance shall be mounted so as to admit of free ventilation and be without injurious vibration.

Electric Brakes.

217.—The main operating motors, rail-lock motors and bridge-lock motors shall be provided with approved post brakes which are held in set position by a spring with such force as to overcome not less than 50% of the maximum torque required. The friction surfaces are to be of materials not affected by moisture. The brakes are to be released by solenoids of ample power and heating capacity whenever the motors are taking current, and are to be set automatically whenever the current fails or is cut off from the motors. Water-proof motors shall be provided with water-proof solenoids. Brakes shall be provided with a foot-switch release for coasting purposes. Means shall be provided for mechanically releasing the brakes when the bridge is to be operated by hand or other equipment.

Emergency Brakes.

218.—An additional emergency brake shall be provided and applied to the main operating machinery. This shall be released by solenoids or motors which shall hold the brake in release as long as the current is applied to the brake motor. Cutting off the current from the solenoids or motors, or any failure of current, will result in the instantaneous application of the brake. This brake will be normally set, but will be released by the operator before starting the bridge, and be held in release during the entire operation unless an emergency condition arises requiring brake power in excess of that offered by the motor brakes, in which case it may be instantly applied by the operator. After the bridge has been closed and traffic has been resumed, this brake will again be applied. This portion of the equipment shall be designed so that it will not be injured if left in release indefinitely. Proper means shall be provided for releasing the brake mechanically when the bridge is to be operated by hand or emergency-power equipment.

219.—The emergency brake circuit shall be independent of the general interlocking system, and there shall be a mechanical interlocking device which will prevent the main leaf motors and the emergency brake from being used one against the other.

220.—The emergency brake switch shall be attached to the controller stand within easy reach of the operator, and proper labels shall be placed back of the switch handle to indicate "Set" and "Released" positions of the brake.

Automatic Cut-offs.

221.—An automatic cut-off or short-circuiting device shall be provided which will throw out the circuit breakers, cut off the current

from the operating motors, and set their brakes when the bridge is 5° from its open position, and its closed position. Spring switches shall be provided which, if closed and held closed, will put the cut-offs out of commission and thus enable the bridge tender fully to close or open the bridge.

222.—The bridge-lock motors, and rail-lock motors, shall be stopped and the brakes set automatically at each end of the travel.

Size of Switches.

223.—Switches shall be designed to carry not more than 900 amperes per sq. in. of cross-sectional capacity.

Excess Current.

224.—Electrical parts, such as wires, switches, etc., shall be designed for the currents which are needed for the excess torques in motors. (205) (208).

225.—Ground connections of ample area shall be provided.

226.—Circuit breakers and fuses shall be designed to act when the current exceeds 2½ times the current required in the motors to exert their greatest normal torque and horse-power for the specified time. (205) (208).

Fuses.

227.—Enclosed fuses shall be used.

Minimum Stranded Wire.

228.—No wire smaller than No. 10, B. & S. gauge, stranded wire, shall be used.

Wires to be Tagged.

229.—Wires when installed shall be permanently tagged and numbered so that any wire can be traced from the switch-board to the motors, and to the source of power.

Lightning Arrester.

230.—The feeders shall be protected by a pole-switch fuse and lightning arrester mounted on a non-combustible and non-absorbent insulating base.

Quick-Break Switch and Switch-board.

231.—A switch, of the quick-break type, shall be provided for each supply wire. Each motor circuit and each light, signal, indicator, or other circuit, shall be provided with switches which are approved by the Railroad Company's Engineer. The switches shall be mounted on an enameled slate panel switch-board (not less than 1¼ in. thick, and free from metallic veins, or flaws) in the operator's house. The switch-board shall be large enough to carry the meters, switches, cut-outs, fuses, etc. Switches, cut-outs, buttons, etc., shall be provided with plates designating their use.

Automatic Circuit Breaker.

232.—An automatic circuit breaker shall be placed on the switch-board in the operating motor circuit of the bridge. Each line to the motor, each line to the electric brakes, and each lighting, signal, indicator, or other circuit, shall be protected by enclosed fuses.

233.—Automatic circuit breakers shall be placed near the top of the switch-board, with the other instruments below.

234.—Any circuit whatsoever shall be protected by fuses, circuit breakers, or equivalent devices, which will insure the excessive current being cut off before any parts are damaged.

Lightning Arresters.

235.—Lightning arresters shall be placed as near as practicable to the parts to be protected, and away from combustible material. A No. 4, B. & S. gauge, wire should be used for the connections; this wire should run in a straight line to a ground plate, and not be connected to any structural parts. To avoid inductive resistances, the wire should not run through a conduit. If a choke-coil is used, it should be thoroughly insulated from the ground and other conductors.

Short Circuiting.

236.—The connections of parts in contact with track shall be such as to allow no short circuiting of track signals.

Protection of Electric Contacts.

237.—Electric contacts shall be protected from the weather or accumulations of dirt.

Coils.

238.—Coils shall be impregnated.

Solenoids, etc.

239.—Solenoids and electrically-operated brakes shall be housed.

Indicators.

240.—The Contractor shall provide and install electric light indicators for the purpose of showing the operator the various positions of the bridge, especially the fully open, entirely closed, nearly open, and nearly closed positions of the bridge, and fully closed and fully open positions of the rail-lock and bridge-locks.

Volt Meter, etc.

241.—A volt meter, ammeter, and watt meter shall be provided on the switch-board.

Ground Detector.

242.—The switch-board shall be furnished with one 2-c.p. lamp for detecting ground, and a 2-c.p. lamp for illuminating the ammeter and volt meter scales.

Lamps for Lighting.

243.—In the operator's house shall be placed ten 16-c.p. lights, and additional lights about the machinery and such other lights as the Engineer may direct. For all lights in the house above ten in number, the Railroad Company will pay the regular market price or furnish them to the Contractor.

244.—Lights of 16-c.p. shall be placed outside at the head and foot of stairways or similar paths.

245.—All lights in the house shall have tungsten filaments. Outside lights shall have weather-proof sockets.

Channel Lights.

246.—The Contractor shall furnish warning and channel lights and signals, in accordance with the U. S. Government requirements, or other harbor requirements. The Railroad Company will furnish a copy of the U. S. Government regulations.

Railroad Signal System.

247.—The Company will furnish and install the railroad signal system, also the master lever and all necessary devices controlling the interlock between this signal system and the bridge as a whole. The Contractor shall furnish and install the necessary devices for interlocking the various parts of the bridge with each other and for connections to the Company's master lever.

248.—Emergency switches shall be provided which will free the various motors from the interlocking, in emergencies. These switches shall be mounted on the switch-board, but covered by a sealed glass case.

Current Supply.

249.—Unless the current supply is taken from more than one source, it shall be conducted to the switch-board in two independent conductors, one for the supply, and one for the return current.

Submarine Cables.

250.—Submarine cables, if needed, will be furnished and laid by the Railroad Company.

Conduits and Minimum Size of Wire.

251.—If wires are to be placed in conduits, the conduits shall be of ample size, sherardized, or loricated on the inside. No wire less than No. 12, B. & S. gauge, shall be used.

Conduits and Factory Ells.

252.—Conduits shall be of sufficient size to allow the wires to be easily drawn in. No joints are to be made inside of a conduit. Conduits and factory ells shall be used. Condulets, ells, and conduits shall be sherardized, or loricated inside.

Specifications for Special Metals Used for Machinery Parts.

Steel Castings.

Qualities of Steel Castings.

253.—Steel for castings may be made by the open-hearth or crucible process.

254.—All castings shall be annealed, unless otherwise specified.

Phosphorus	0.05% maximum.
Sulphur	0.05% maximum.

255.—Minimum physical qualities, as determined on a standard test specimen of ½ in. diameter and 2 in. gauged length:

Tensile strength, in pounds per square inch	70 000
Elongation: percentage in 2 in.	18
Contraction of area: percentage	25

256.—A test to destruction may be substituted for the tensile test, in the case of small or unimportant castings, by selecting three castings from a lot. This test shall show the material to be ductile, free from injurious defects, and suitable for the purpose intended. A lot shall consist of all castings from the same melt or blow, annealed in the same furnace charge.

Flaws in Castings.

257.—Castings shall be true to pattern, and free from blemishes, flaws, or shrinkage cracks. When the bearing surface of any steel casting is finished, there shall be no visible blow-holes exceeding 1 in. in any direction, nor exceeding ½ sq. in. in area. The length of blow-holes cut by any straight line laid in any direction shall never exceed 1 in. in any 1 ft.

Blow-Holes in Gear Wheels.

258.—No blow-hole exceeding one-half the above dimensions and area will be allowed in any gear tooth, or in the rim at the root of the teeth.

Electric Welding.

259.—The correction of defects in castings, by welding electrically by thermit or by similar processes, will not be allowed.

Testing of Large Castings.

260.—Large castings shall be suspended and hammered all over. No cracks, flaws, defects, or weakness shall appear after such treatment.

261.—A specimen (1 in. by ½ in.) shall bend, cold, around a diameter of 1 in., through an angle of 90°, without fracture on the outside of the bent portion.

262.—The number of standard test specimens shall depend on the character and importance of the casting. A test piece shall be cut, cold, from a coupon to be moulded and cast on some portion of one or more castings from each melt or blow, or from the sink-heads (in case heads of sufficient size are used). The coupon or sink-head must receive the same treatment as the casting or castings, before the specimen is cut out, and before the coupon or sink-head is removed from the casting.

263.—Turnings from the tensile specimen, or drillings from the bending specimen, or drillings from the small test ingot, if preferred by the inspector, shall be used to determine whether or not the steel is within the limits in phosphorus and sulphur specified in Paragraph 254 concerning chemical properties.

Steel Forgings.

Qualities of Steel Forgings.

264.—Steel forgings may be made by the open-hearth or crucible process:

Phosphorus	0.04% maximum.
Sulphur	0.05% maximum.

265.—Minimum physical properties as determined on a standard turned test specimen of ½ in. diameter and 2 in. gauged length.

266.—Tensile strength, in pounds per square inch, 85 000 to 65 000

Elongation: percentage in 2 in. 28

A specimen (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of ½ in., without fracture on the outside of the bent portion. The bending may be effected by pressure or by blows.

267.—The number and location of the test specimens to be taken from a melt, blow, or forging shall depend on their character and importance, and, therefore, must be regulated by individual cases. The test specimens shall be cut, cold, from the forging, or full-sized prolongation of the same, parallel to the axis of the forging and half way between the center and the outside; the specimens shall be longitudinal, *i. e.*, the length of the specimen shall correspond with the direction in which the metal is most drawn out or worked. When forgings have large ends or collars, the test specimens shall be taken from a prolongation of the same diameter or section as that of the forging back of the large end or collar. In the case of hollow shafting, either forged or bored, the specimen shall be taken within the finished section prolonged, half way between the inner and outer surfaces of the wall of the forging.

268.—Turnings from the tensile specimen, or drillings from the bending specimen, or drillings from the small test ingot, if preferred

by the inspector, shall be used to determine whether or not the steel is within the limit in chemical composition.

269.—Forgings shall be free from cracks, flaws, seams, or other injurious imperfections, and shall conform to the dimensions shown on the drawings furnished by the purchaser, and shall be made and finished in a workmanlike manner.

270.—All forgings shall be annealed.

Machinery Steel.

Qualities of Machinery Steel.

271.—Machinery steel shall be made by the open-hearth or crucible process.

Phosphorus.....0.05% maximum.
Sulphur.....0.05% maximum.

272.—Minimum physical properties, as determined on a standard turned test specimen of ½ in. diameter and 2 in. gauged length:

Tensile strength, in pounds per square inch.....80 000
Elongation: percentage in 2 in..... 20

273.—A specimen (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of 1½ in., without fracture on the outside of the bent portion. The bending tests may be made by pressure or by blows.

274.—Turnings from the tensile test specimens, or drillings from the small test ingot, if preferred by the inspector, shall be used to determine whether the melt is within the limits in chemical composition.

Boiler Plates.

Qualities of Boiler Plate Steel.

275.—The steel used for boilers and fire-boxes shall be made by the open-hearth process.

Phosphorus.....0.04% maximum.
Sulphur.....0.04% maximum.

276.—The physical properties required shall be as follows:

Tensile strength desired, in pounds per square inch...60 000.

$$\text{Elongation: minimum percentage in 8 in.} = \frac{1\,500\,000}{\text{Ultimate strength.}}$$

Character of fracture.....Silky.
Cold bends, without fracture.....180° flat.

277.—The ultimate strength shall come within 4 000 lb. of that desired.

278.—Chemical determinations of the percentages of carbon, phosphorus, sulphur, and manganese, shall be made by the manufacturer from a test ingot taken at the time of the pouring of each melt of steel, and a correct copy of each analysis shall be furnished to the Engineer or his inspector. A check analysis shall be made from the finished material, if called for by the purchaser, in which case an excess of 25% above required limits will be allowed.

279.—Specimens for tensile and bending tests for plates shall be made by cutting coupons from the finished product, which shall have both faces rolled, and both edges milled to the usual form of the standard test specimen, 1½ in. wide on a gauged length of at least 9 in.; or with both edges parallel.

Nickel Steel for Machine Parts.

Qualities of Nickel Steel.

280.—Nickel steel shall be made by the open-hearth process.

	Plates, shapes, and bars.	Rivets.
Phosphorus shall not exceed	0.04%	0.04%
Sulphur	0.05%	0.04%
Nickel, not less than	3.00%	3.25%

281.—The physical properties required shall be as follows:

	Plates, shapes, bars, and forgings. Pounds per square inch. Minimum.	Rivets.
Tensile strength	80 000	60 000 to 70 000
Elastic limit	50 000	40 000 minimum.

Elongations: percentage in 8 in., for plates, shapes, bars, and forgings; and also for rivets $= \frac{1\,600\,000}{\text{Ultimate strength.}} =$ minimum.

Elongation: percentage in 2 in. for forgings = 25.

282.—Specimens cut from forgings (1 in. by ½ in.) shall bend, cold, 180°, around a diameter of 1 in., without fracture on the outside of the bent portion.

283.—Specimens cut from plates, shapes, and bars shall bend, cold, 180°, around a diameter of three times their thickness, without fracture on the outside of the bent portion.

284.—Each rivet rod shall bend 180°, flat, on itself, without fracture on the outside of the bent portion.

285.—Rivet rods shall be tested as rolled.

286.—The fracture of all tension tests shall show a fine silky texture, of a uniform bluish gray or dove color, free from black or brilliant specks, and shall show no sign of crystallization.

287.—All nickel-steel forgings shall be properly annealed.

288.—Annealed eye-bars and similar members, when full-sized pieces are tested, shall comply with the following requirements:

Minimum ultimate tensile strength, in pounds per square inch	75 000
Minimum elastic limit, in pounds per square inch	45 000
Minimum elongation in 10 ft., including fracture	12%

The fracture shall be mostly silky, and free from crystals.

Full-sized pieces shall bend, cold, 180°, around a diameter of twice their thickness, without fracture.

Tool Steel.

Qualities of Tool Steel.

289.—Tool steel is generally used for parts which require hardening or oil tempering, such as pivots, friction rollers, ball-bearings, and springs.

290.—Tool steel shall be made by the open-hearth or crucible process.

Carbon	1.00% minimum.
Phosphorus	0.04% maximum.
Sulphur	0.04% maximum.
Manganese	0.50% maximum.

Phosphor-Bronze.

Qualities of Phosphor-Bronze.

291.—Special phosphor-bronze shall be used for high pressure and slow speed.

292.—Phosphor-bronze shall be a copper-tin alloy. The phosphorus shall not exceed 1 per cent. Other alloys, up to one-half of 1%, will be permitted, except that no sulphur will be allowed.

Compression:

Elastic limit, in pounds per square inch	19 000 to 23 000
Permanent set, under 100 000 lb., in inches	0.12 to 0.16

293.—The compression is to be made on a cylinder having a height of 1 in. and an area of 1 sq. in. The elastic limit is to be the load which gives a permanent set of 0.001 in.

Tension:

The yield point, ultimate strength, and elongation in 2 in. are to be recorded. The tension specimen is to have a diameter of ½ in.

294.—For every heat, at least two tests shall be made. A chemical anaylsis shall be furnished.

Babbitt Metal.

Qualities of Babbitt Metal.

295.—Babbitt metal composed of the following ingredients and of the following proportions has given satisfactory results and a low coefficient of friction (0.03 to 0.04):

Copper	3.6 per cent.
Tin	89.3 " "
Antimony	7.1 " "

Purpose of the Specifications.

296.—It is the purpose of these specifications to provide a first-class structure. They are intended as an aid in designing and fabrication. Machine design and kindred subjects are so great and varied that no single work of this character can cover all points. As a further aid in

securing a first-class structure, the following works will be considered authoritative, in the order named:

1. Unwin's "Machine Design," Part I, Ed. 1909.
   Unwin's "Machine Design," Part II, Ed. 1902.
2. "A Manual of Machine Design," etc., by Low and Bevis, 11th Impression.
3. Reuleaux's "Constructor," Translated by Suplee.
4. Kent's "Pocket Book," 8th Ed.

297.—Machine parts shall be designed, if practicable by the methods of applied mechanics, but such designs shall be viewed in the light of experience. It should be borne in mind that machine design is not based on the precise methods in vogue for stationary structures.

Paper No. 1252

A BRIEF DESCRIPTION OF A MODERN STREET RAILWAY TRACK CONSTRUCTION.*

By A. C. Polk, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. E. R. Tratman, Walter C. Howe, Louis A. Mitchell, William J. Boucher, C. B. Vorce, and A. C. Polk.

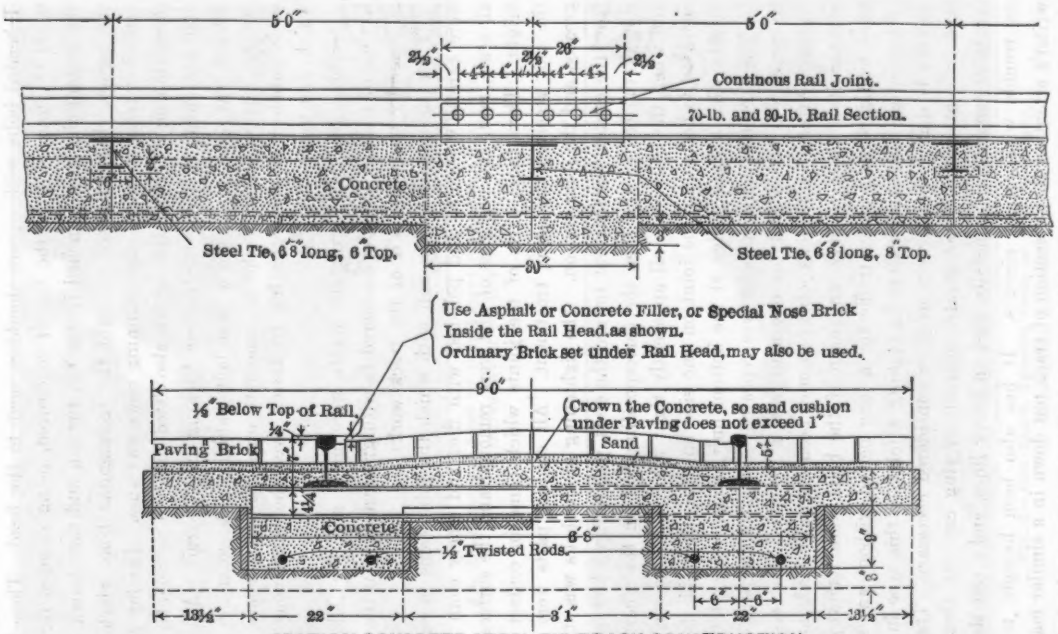
With the increasing demands made on various traction companies throughout the country to provide good service, the matter of securing a permanent roadbed in the busy and paved sections of a city has become a serious problem. When the work is poorly done originally, and is not on a proper foundation, the cost of maintenance is increased, the paving along the poor roadbed becomes cracked and ruined by the movement of the track, unfavorable public comment on it arises, and the company finds itself face to face with one of two propositions, either the entire rebuilding of the roadbed or the attempt to surface and repair the old one. Either alternative is expensive, as the work will have to be done on a busy street and will interfere with car schedules, with consequent loss of revenue to the company and inconvenience to the public. Therefore, when the paving is done originally, the permanent roadbed should be substantial and effective.

In this paper the writer has attempted to give a general description of the methods and materials used at Springfield, Mo., in rebuilding the Springfield Traction Company's lines on streets which were being paved by the City during 1911.

* Presented at the meeting of October 16th, 1912.

The Company's franchise stipulates that it shall pave the space between its rails and for 2 ft. outside of the rails, when the City paves on the various streets occupied.

The work was done by the Company, under the writer's supervision, and aggregated more than 3 miles of new tracks.



It was desired to secure as permanent a roadbed as possible, in fact, one which would outwear the rail itself and allow its replacement without disturbing the roadbed if so desired. Fig. 1 shows the general cross-section and detail of the work as put in.

General Features.—The general features of the structure were, a 7-in., 70-lb. T-rail section, 62 ft. long, laid on steel ties, and, directly under each rail, longitudinal concrete beams, each reinforced with two ½-in. twisted steel rods, and a 5-in. concrete mat over the beams and the center of the tracks for a paving foundation.

In this case the city contractors were allowed to place the street pavement first, except where it was of asphalt. After the paving on each side of the track had been completed, the old track was moved to one side or the other on the completed pavement, and excavation between the tracks was commenced, as shown on Figs. 2 and 3.

Excavation.—The standard depth below the finished pavement to which the general excavation was made over the whole 9-ft. space was 10 in., as shown by Fig. 1. Then two trenches were excavated to exact dimensions, a depth of 9 in. more, and running with the rail. At the joints these trenches were connected by cross trenches, 30 in. wide, at an additional depth of 3 in., so that each joint tie would be thoroughly embedded and have a good thickness of concrete under it. Around each intermediate tie shallow trenches were excavated so that there would be at least 2 in. of concrete under the tie and 4 in. around its sides.

Ties.—All ties were punched at the proper gauge to take 7-in., 70-lb. or 80-lb. T-rails, but the 70-lb. rail was used principally. There were two types of ties, one under the joints which came opposite one another, and the other intermediate between them. The joint tie was an I-beam section, weighing 20 lb. per ft., 6 ft. 8 in. long, having an 8½-in. top, on which the joint rested, and a 4½-in. base. The intermediate ties were of the same length, but weighed 14.5 lb. per ft. and had a 6-in. top and a 4-in. base. All ties were spaced 5 ft. apart, or as near that as the distance between joints would permit.

SECTION CONCRETE STEEL TIE TRACK CONSTRUCTION.

FIG. 1.

Fastenings.—The rail was fastened to the tie by special lugs and T-headed bolts with square shoulders next to the head. These bolts could be inserted from the top, if so desired, being dropped through the rectangular hole punched in the tie, turned, and then raised until the square shoulder fitted up into the rectangular hole, which prevented it from turning while running down the nuts. The lug had a projection on its under side which also fitted into the rectangular hole and prevented it from turning or backing off the rail. A socket wrench was used to run down these bolts rapidly. The joint ties were heavier and wider than the intermediate ones, as noted above, and were punched to allow the lug to fasten over the continuous joint which was used.

Joints.—Six-bolt continuous joints were used, and the following method of making them was adhered to with greatest care, as the joint is generally the weak part of the track work:

First, those parts of the rail with which the joint came in contact were carefully cleaned and polished with files and emery cloth until all scale, rust, and particles of dirt were removed and the surface was bright. Then those parts of the joints which came in contact with the rail received the same treatment. All contact parts were then greased and the joint put on. The tightening of the bolts was started from the center, working out toward the ends, pulling up a bolt on one side of the center and then the corresponding bolt on the other side, and when the bolts were all apparently tight a heavy sledge was held against the bottom of the joint on one side and the other side tapped briskly with a light sledge at the bottom only, and *vice versa*.

Then the tightening process was repeated until nothing more could be gotten out of the bolts by one man with a wrench having a 30-in. handle. After a continuous joint has once been carefully made in this manner it is there to stay, and even if the bolts were removed the joint would remain under traffic for a long period without any signs of loosening. Another feature in making a joint of this type in this manner is that no bonds were used, or considered necessary. The net area in contact has a far greater current-carrying capacity than the No. 0000 copper bond generally used on heavy lines, and a test showed no trouble with return circuits. It has also been brought to the writer's attention that a section of track put down in a similar manner showed a first-class negative return circuit after two years under traffic.

FIG. 2.—STREET AS LEFT BY CITY PAVING CONTRACTOR READY FOR STARTING WORK ON CAR TRACK.

FIG. 3.—OLD TRACK THROWN OVER ON NEW PAVEMENT, EXCAVATION STARTED.

Surfacing and Preparing for Concrete.—The track, having been put together as described, was supported on small piers of old brick placed under every other tie, and centering under the rail. The final surfacing was done with oak wedges on top of these piers, and both the piers and wedges were concreted in.

Two ½-in. twisted steel rods were placed in the bottoms of the trenches about 6 in. apart. These also were supported at intervals on top of a brick which held them about 2½ in. off the ground. Under each joint two extra 4-ft. lengths of these steel rods were placed, to give additional strength at this point, which is usually considered the weak spot of track construction. This is shown on Fig. 4.

The track was then given its first surfacing raise, being brought approximately to grade. Afterward, a second finishing surface and true grade was secured by driving up the oak wedges. This final surface, however, was only kept a short distance ahead of the mixer on account of the difficulty in keeping the skeleton track in correct line, variations in temperature kinking it.

Concrete.—Concreting was next started, two types of mixers being used on this particular work at different times: One was mounted on car trucks and driven with a 10-h.p. motor; it occupied the temporary old tracks which had been previously placed at one side, and was supplied by a regular work train which delivered the concrete material on flat cars. The other type was mounted on wide-tired wheels, driven with a 15-h.p., 500-volt, D. C. motor, and was equipped with a charging bucket. All materials for the latter were hauled in wagons to the streets and dumped ahead of the mixer in such manner that they were about in the right proportions. These materials were cleaned up as the mixer progressed.

Of the two methods, the latter was found to be by far the more satisfactory, as there were frequent delays in the delivery of materials to the first mixer by the work train, and the temporary track was blocked for traffic beyond the point where concreting was in progress and, on single-track work, passengers had to transfer around the obstruction.

In the second method, all material could be delivered on the street for a considerable distance ahead of the mixer, and there was no reason for the mixer to be idle at any time on this account.

The concrete was composed of 1½-in. (maximum size) crushed limestone, Kaw River sand, and chats from the Aurora Zinc Mine district, the proportions being one of cement, two of sand, two of chats, and three of crushed stone, this making a very good mixture. The concrete was mixed very wet, dumped into movable chutes from the mixer, and deposited directly by them on the track. Great care was taken at all times to keep all loose material in the excavation cleaned up ahead of the concrete and to maintain the twisted steel rods in their proper positions. The concrete was puddled carefully under and around all ties with shovels, and finally crowned, when it reached grade, with a special board or templet made for the purpose.

When the material through which excavation had been made was of a very loose character, or if bad weather had caved in the sides of the trench, forms were placed where necessary to hold the concrete to the exact dimensions of the roadbed. After the concrete had set for 48 hours, and in the majority of cases longer, the brick paving was done.

Paving.—The paving was of first-class paving blocks, laid on a 1-in. sand cushion, and grouted. The method of laying it differed somewhat from the usual practice. Along each rail, and snug up against it, was laid a 2 by 4-in. piece of timber. A stretcher course of bricks was then laid against it paralleling the rail, the tops of the bricks being only ½ in. below the top of the rail. The headers across the tracks were then laid and all the bricks were thoroughly rolled and rammed.

Before grouting, the 2 by 4-in. piece was removed and the space thus left was filled with concrete to a plane 1 in. below the top of the rail, forming the flangeway for the wheels. After this had set, the whole pavement was grouted thoroughly and carefully. When filled up, the grout remaining over the top of the pavement was allowed to stand until it had attained a set and was fairly stiff, then dry sand was sprinkled over it and the whole was swept thoroughly with wire brooms, thus removing all surplus grout sticking to the tops of the bricks and presenting a very neat, clean surface. It was noticeable, too, how very much the paving contractor improved in the character of his work, when this specification of cleaning off the top of the brickwork was strictly enforced. By this method all irregularities

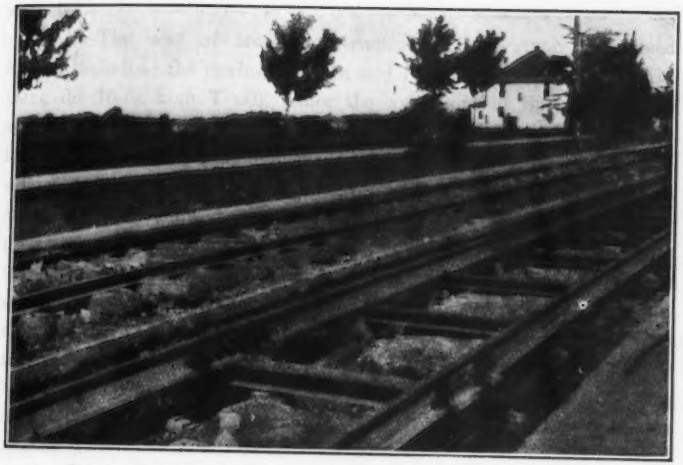


FIG. 4.—REINFORCEMENT AT JOINTS, AND GENERAL CONSTRUCTION.

FIG. 5.—CONCRETE AND TRACK WORK COMPLETE, READY FOR BRICK PAVING.

of laying and surfacing are strongly brought out, and easily seen and corrected.

Cost.—The cost of track construction of this type for paved streets, including the paving between and for 2 ft. outside of the rails, using the 70-lb. high T-rail, under the conditions at Springfield, was approximately $5 per ft. of single track. This cost may seem to be high, but, when the permanent character of the work is taken into consideration, and the cost of doing street work under other methods is analyzed and compared, it will be found to be very reasonable. It possesses several advantages over some of the methods in vogue. It takes less concrete than the old method of filling under and around wooden ties. It places the concrete and the strength where it is most needed, and, when properly put in, it is certainly permanent, and the roadbed will easily outwear two or more sets of rails under heavy traffic. The rail can be changed without disturbing the roadbed in the least, if proper provisions have been made in the steel ties originally.

On one section of similar track construction, known to the writer, not the slightest sign of any motion could be detected after 3 years' operation, and it is reported to be in as good condition as the day it was built.

The writer trusts that the foregoing brief description may prove of interest to members of this Society and bring out some discussion on work of this class, concerning which very little has appeared in the technical press.

The work was done by the Springfield Traction Company, owned and operated by the Federal Light and Traction Company, of New York, and was executed under the general direction of Mr. W. A. Haller, Chief Engineer, the writer being in immediate and full charge of all construction matters at Springfield, Mo.

DISCUSSION

Mr. Tratman.

E. E. R. TRATMAN, ASSOC. M. AM. SOC. E. (by letter).—An interesting point suggested by this paper is the shape of the flangeway groove along the rail. It appears to be a rather wide, rectangular groove, having a flat bottom, vertical face, and sharp corner. It will be of interest to know whether this vertical face stands up under traffic, or whether the wheels of vehicles crush and crack it to an approximately beveled outline. The more usual method of forming the groove is to use nose-brick laid as headers with the top surface next the rail beveled so as to fit beneath the rail head. Still another plan is to use ordinary bricks (also laid as headers), tilted so that one end fits under the rail head while the top surface lies approximately in the contour of the crowning of the pavement between the rails. A third plan is to use a rectangular stretcher under the rail head (and projecting beyond it) and a higher bevel-edged stretcher level with the paving. In all these methods the groove or flangeway is of beveled or triangular section rather than rectangular.

In the Springfield work, the crowning of the paving between the rails, as shown in Fig. 1, appears to be unduly high, interfering with the normal cross-section of the street, and making an irregular contour. This is especially the case as the paving is $\frac{1}{2}$ in. below the rail head on the inside and $\frac{1}{4}$ in. below it on the outside, so that each rail forms a distinct ridge in the pavement. This construction does not seem to be desirable in connection with a well-paved street surface, and it would be of interest to know whether the city authorities or the public have made any objection to it.

In regard to the wide spacing of the ties, experience has shown that the concrete immediately beneath the rail disintegrates or crushes, in some cases, due to the vibration and slight deflection of the rail, in spite of the fact that, theoretically, the rail has a continuous solid bearing.

Mr. Howe.

WALTER C. HOWE, ASSOC. M. AM. SOC. C. E. (by letter).—This paper is both interesting and instructive. The writer has found very few published data on work of this class, although it is one of the most important features in the construction of modern pavements. Municipal engineers are often at a disadvantage in drawing up ordinances and specifications governing the control of paving in the excepted portion occupied by street railways.

The writer was Commissioner of Streets of Oakland, Cal., for a number of years, and observed that the initial point of failure of all asphalt streets was that portion immediately contiguous to the rails of the street railways, of both steam and electric roads. The asphalt surface adjoining the tracks was in a continual state of disrepair and

FIG. 6.—ASPHALT PAVING, TWENTY-SECOND STREET, OAKLAND, CAL. GIRDER-RAILS, STEEL TIE-PLATES, WOODEN TIES, CONCRETE TO BASE OF TIE, BASALT BLOCK LINERS ON 1½-IN. SAND CUSHION.

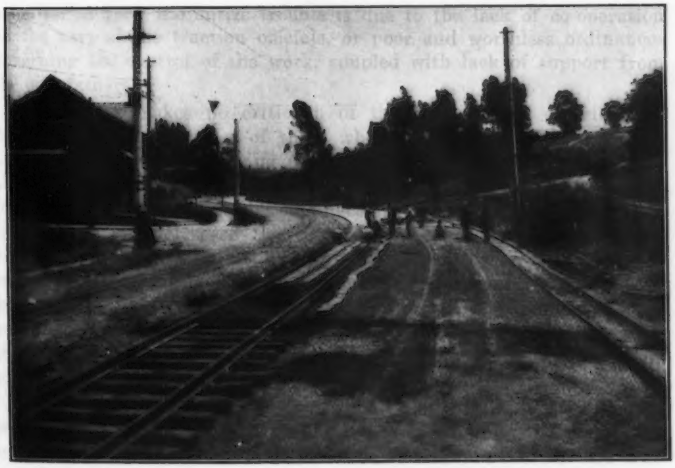

FIG. 7.—ASPHALT PAVING, FOURTH AVENUE, OAKLAND, CAL. VITRIFIED BRICK LINERS. ASPHALTIC CONCRETE BETWEEN TIES, INSTEAD OF HYDRAULIC CONCRETE.

disintegration. The failure of the pavement gradually extended outside of the railroad's portion and into that of the city. These conditions gradually became so serious that it was found necessary to adopt new and drastic ordinances governing the type of construction to be done by steam and traction lines occupying city streets. Few, if any, rails of modern type had been used by the companies previous to this action. A type of construction somewhat similar to that described by Mr. Polk was considered. The concrete extended to a depth of 6 in. under and completely across the length of the ties, but no steel reinforcement was used in the foundation. Strong opposition to this type of construction was made by the railway companies, and, as a compromise, rock ballast 6 in. deep was substituted for the 6 in. of concrete under the ties. There is no doubt that the class of construction shown by Mr. Polk is far superior, embodying, as it does, steel ties and a solid reinforced concrete foundation under them, thus affording extreme rigidity with a naturally decreased vibration. Its cost, however, is such as to preclude its use except in the case of street railway companies who are in excellent financial condition and whose officials are disposed and ready to meet with the municipality and adopt the most modern type of rail and foundation. Mr. Howe.

In many instances the official in charge of paving construction in a municipality is blamed for the dilapidated condition of paving, both adjoining and between the tracks of street railways, when, as a matter of fact, the entire trouble is due to the lack of co-operation on the part of the traction officials, or poor and worthless ordinances governing the control of the work, coupled with lack of support from the city fathers.

The writer makes no criticism of the construction described by Mr. Polk, but in the case of those who are about to go through the unenviable struggle of forcing public service corporations to use suitable construction to obviate ruined and dilapidated pavements adjoining railroad tracks, it may become necessary to follow an intermediate course, and in such case the construction described herein can be put down with good results. This type is not new by any means, but it embodies several unique features, such as a modern, 141-lb., 9-in. girder rail, with steel tie-plates and light concrete foundation; the substitution of asphaltic concrete for hydraulic concrete in some cases; the laying of paving blocks on their broad flat faces instead of on edge, etc., etc.

Previous to 1907, 90% of the asphalt and bituminous pavements contiguous to street railways in Oakland were in the condition shown in Fig. 6. From time to time, efforts had been made by the traction lines to tooth the rails with basalt blocks in order to avoid this disintegration. No results were secured, as the asphalt surface broke up outside the line of the blocks. The condition was due simply

Mr. Howe.

to excessive vibration caused by the light T-rail used, coupled with lack of foundation and inferior roadbed. Under the existing State laws and the ordinances of the municipality, railway companies were required to pave their portion of the street, and for a distance 2 ft. outside of the outer rail, with the same class of pavement as that on the remainder of the street. Specifications governing new asphalt streets called for a concrete base of 6 in., a binder course 2 in. deep, and an asphalt wearing surface of 1½ in., making a total depth of 9½ in. for the completed pavement. Most of the rails laid throughout the city were the old type of light T-rail, ranging between 5 and 7 in. in depth. This gave approximately 2½ to 4½ in. of concrete below the top of the tie. The question as to whether the company could be compelled to increase the depth of the concrete between the ties and also line the rails with blocks, when the State laws required "that paving should be similar in all respects to the remainder of the street" was a legal one, the traction companies taking the stand that they were not re-

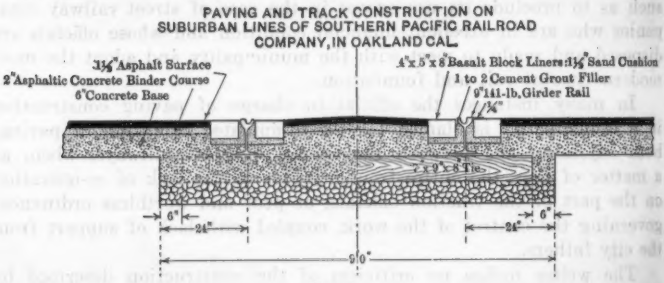

FIG. 8.

quired to do more than was called for by the State law. After many conferences and considerable discussion on the part of the city and traction officials, ordinances were drafted requiring the companies to line their tracks with types of paving brick or stone blocks satisfactory to the city, and to lay concrete the full depth of the ties. This type of construction was subjected to considerable criticism at the time. It was argued that the rigidity desired could not be secured unless the foundation concrete was carried to a depth of at least 6 in. under the ties. The ordinance was adopted despite the criticism, and work was done on many miles of streets. The results have been uniformly satisfactory, notwithstanding the apparently cheap construction.

Fig. 7 shows the west half of a completed asphalt street with basalt block liners toothing the rails. The concrete foundation on the right is complete and ready to receive the binder and surface materials. The open space adjoining the rails is ready to receive the block liners. The concrete was carried the full depth of the

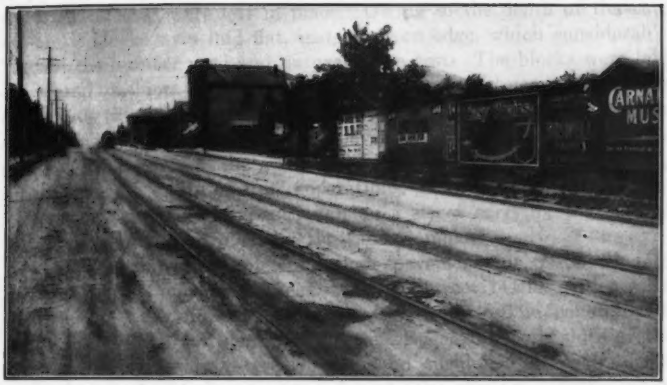

FIG. 9.—CONDITION OF ASPHALT PAVEMENTS ADJOINING CAR TRACKS WHERE NO LINERS ARE USED. OLD TYPE T-RAIL, AND LIGHT CONCRETE FOUNDATION BETWEEN TRACKS.

FIG. 10.—ASPHALT PAVING, BROADWAY, OAKLAND, CAL. BASALT BLOCK LINERS TOOTHING THE RAILS.

ties, practically encasing the wooden tie in a concrete body. Many of the ties showed signs of dry rot; the worst were removed, but many not badly affected were left in place. Owing to the depth of the rail, the basalt blocks were laid flat, instead of on edge, which considerably lessened the number used and naturally the cost. The blocks were laid on a sand cushion about 1 in. deep, and a 1:2 cement grout was swept into the joints. During the process of concreting, the traffic was carried on one track only, cross-overs being built at intermediate points. This allowed the concrete to set thoroughly before being subjected to the strain of traffic operations. This type of construction has proven very successful, although on a street carrying the cars of four branch lines controlled by the same company. Mr. Howe.

Fig. 9 shows the completed asphalt pavement up to the line of the Key Route Company's tracks. On this street 141-lb. girder rails, 9 in. deep, were laid, with tie-plates as shown. The concrete extended only to the full depth of the tie. Spaces on both sides of the track are shown ready to receive the sand cushion and basalt blocks before laying the binder course and asphalt surfacing. Heavy interurban trains operate over this line.

Fig. 8 shows the type of construction on the Southern Pacific interurban lines. Girder rails of the same type were used, with basalt blocks set on edge. These blocks ranged in depth from 5 to 6 in.

Fig. 10 shows the type of construction used on Fourth Avenue, Oakland. Vitrified brick liners were used in place of basalt blocks, and the space between the ties and to their full depth was filled with a rich asphaltic concrete instead of hydraulic concrete. The old type of T-rail used is shown. As this line was single-tracked for a considerable distance, it became necessary to maintain traffic during the paving operations. For this reason, it was thought inadvisable to put in hydraulic concrete and operate the cars at the same time. To overcome this, asphaltic concrete was substituted and thoroughly tamped between the ties, being finally rolled with a 2½-ton tandem roller. This type of construction had been used on a number of other streets, but had not proved entirely successful. This work has been completed for several years, and when seen by the writer a few months ago was in very good condition, considering the type of rail used.

Asphalt oil bricks, similar to the Eastern type of asphalt blocks, were used as liners on several streets, but proved to be a failure. These bricks soon pounded into a uniform mass under turnout traffic from teaming, and thereby lost their individuality, taking on the general appearance of the asphalt surface adjoining. They proved to be inferior to the asphalt surface, as disintegration invariably occurred after the heavy rains, continuing during the heavy weather until the remain-

Mr. Howe. ing portion of the block had to be removed. Asphalt blocks of better quality may obviate the earlier failures.

The construction described herein is not recommended for adoption wherever the more modern type can be secured. The best is none too good, as far as paving operations are concerned.

This type of construction has been generally adopted in Oakland, Cal., after a most successful experience covering a period of about 4 years.

Mr. Mitchell. LOUIS A. MITCHELL, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest because similar problems are constantly coming up to be solved.

In the writer's experience, concrete beam construction, of which that described by Mr. Polk is a type, has not been very satisfactory for railroad tracks in paved streets. Its failure, however, has not been due necessarily to the type of construction nor to the area of the cross-section of the beam; though there is no doubt that some failures have been caused by the provision of insufficient bearing, and the fact that the loads have been too great. Most failures, however, have probably been due to loose joints which allow a slight movement of the rails when a wheel passes over them. This movement starts a hammer which the concrete will not stand, and, ultimately, the beam breaks under the joint.

By placing a steel tie directly under, and thus supporting, the joint, Mr. Polk has taken a step in advance in concrete beam construction, which, no doubt, will lengthen the life of the foundation. This support will prevent the working of the ends of the rails and the hammer on the concrete. The writer believes that the life of the joint will be greatly lengthened if the support under it is increased, at least, to the full length of the joint-bar, or longer. He has used steel ties constructed of 4-in. channels, 36 in. from center to center, and connected at the ends with $\frac{3}{16}$-in. steel plates. The rails rested on these steel plates, and the joint was placed in the center so that the rails were supported for a distance of 18 in. back from the joint. Simple joint-bars 26 in. long, with six bolts, were used. These ties were fastened to the rail by castings which fitted over the base of the rail and through the steel plates (which had been previously punched) and under the rail. These castings were held in place on one side of the rail by pieces of $\frac{3}{16}$-in. plate, which were placed back of the casting and extended through the plate. The steel tie and the base of the rail were then concreted in the usual manner. This type of construction has proved very satisfactory for tracks on which 45-ton cars are operated.

The work described by Mr. Polk does not deal with the most important part in the making of a good joint for paved streets, although he may have taken care of this properly. When bolts are

used, the holes in the web of the rail and in the joint-bars should be of the same size as the bolt, and machine-bolts should be used, making a driving fit. The ends of the rails should be ground so that they will fit tightly, especially at the ball. The drilling should be such that when the bolts are in place the ends of the rails will fit tightly together. This type of joint allows for no change of length in the rail due to change in temperature; but this is not necessary owing to the fact that in paved streets only a small portion of the rail is exposed to extreme changes in temperature, and the tendency to change in length is taken up in internal stresses. Mr. Mitchell.

Any open joint will permit the wheels of a car to pound, and this will increase until the ball of the rail is ruined. This pounding may be maintained at a minimum, even in open joints, by keeping the rails ground so that they are of the same height at the joint.

Another cause of pounded joints, and one which will produce failure just as surely as an open or loose joint, is difference in the height of the rails. Specifications for rails allow for a possible variation in height of $\frac{3}{64}$ in. at any joint, and even if the joint is tight in the bolts and the rails well fitted, a pound will start, and there will be cupped rails in the track in a surprisingly short time. For this reason, the joints of new track should be ground to an even surface just as soon as possible after the work is completed.

In track constructed as described, the writer has seen joints which were ground soon after the work was completed, and it required a rather close inspection of the ball of the rail even to find where they were.

The writer's work, however, is not of concrete beam construction; in some cases there is concrete under the whole track, and in others the track is on broken-stone ballast with concrete from the bottom up to 2 in. above the top of the ties. The track constructed by both these methods and with joints of the type previously described, has required no maintenance whatever since it was installed 1½ years ago, but it was found that, in some cases, even with the tight joints, the rails had cupped, due to the difference in height, and it was necessary to grind the joints to an even surface.

Another method of constructing a tight joint is similar to that described, except that rivets are used instead of bolts, thus assuring a tight fit between the rail and splice-bar.

WILLIAM J. BOUCHER, ASSOC. M. AM. SOC. C. E.—In 1907, the franchises of many, practically all, of the street railway lines in Chicago had expired, and, through neglect of maintenance, mismanagement, and difficulties in financial affairs, the tracks and equipment were in a miserable and dilapidated condition. By popular vote, new franchises were granted, and by the ordinances of February 11th, 1907, the city became a partner in the street railway business, receiving 55% of the net receipts, and the Board of Supervising Engineers was created. The Mr. Boucher.

Mr. Boucher.

duties of this Board, as the name indicates, consisted of complete supervision of all the work necessary (including purchase of materials) to place the roadbed, tracks, cars, car-houses, power-houses, and sub-stations in first-class working condition.

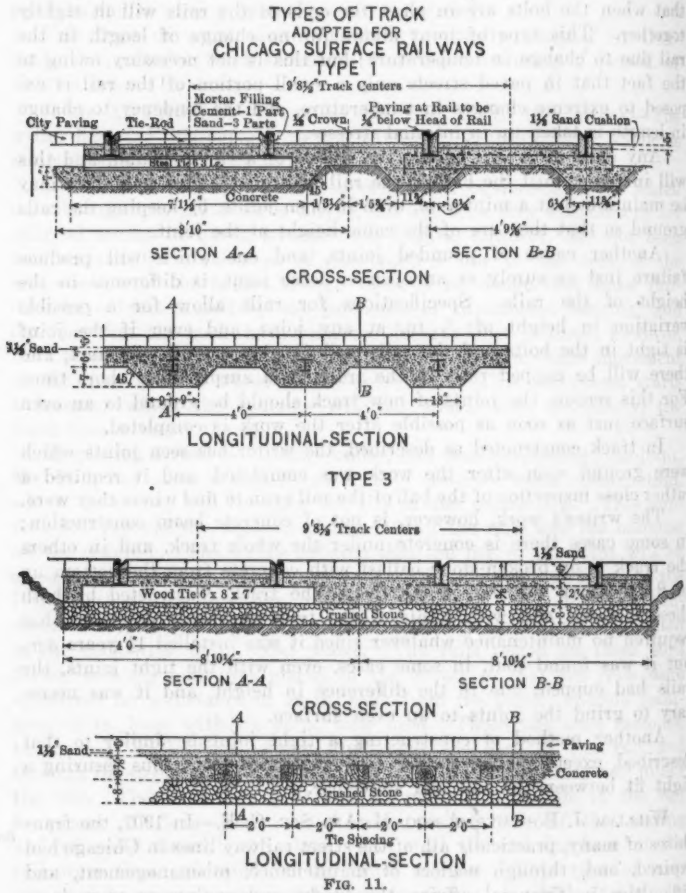

FIG. 11.

The track work was completely remodeled. The first design, known as Type 1 (Fig. 11) was very similar to that described by Mr. Polk. It consisted of steel beam ties, embedded in concrete, which was of greater thickness beneath the ties and rails than between them, where

Mr. Boucher.

the original earth was left in mounds, undisturbed. The ties were originally placed 4 ft. from center to center. The concrete embedding the ties was brought up flush with the surface of the top flange, which was wider than the bottom flange. These ties are 4¼ in. high, 6 ft. 3 in. long, and weigh 14½ lb. per ft. The tie is used merely to hold the rails down and to line and gauge; it is not depended on to transmit the car load to the soil, that function being performed by the concrete immediately in contact with the rail. A special form of fastening was designed in order to permit the removal of the rail for renewals without disturbing the tie. After the rail was fastened in place on the tie, mortar filling was placed over its flange and upward on each side of the web, and packed under the head of the rail. Tie-rods, with two nuts at each end, pass through the webs of the rails. These rods are 2 by $\frac{5}{16}$ in. in section, which permits paving, of granite or wood blocks, between the tracks, the rods being placed in the usual spaces between the blocks.

Type 2 was a modification of the preceding, and differed from it mainly in the substitution of 6 by 8-in. oak or yellow pine ties, 7 ft. long. Tie-plates are placed under the rails, and the latter are secured to the ties by screw-spikes.

Type 2-A was designed from Type 2, and in it the ties are of wood. They are 3 ft. from center to center, and the excavation has been changed to a uniform section, replacing the mounds of earth between the ties with concrete and permitting the rolling of the excavated trench before placing the concrete. This type is now standard for all new work in all parts of the city beyond the limits of the "Loop" section.

Type 3 (Fig. 11) is used in the business or "Loop" section, where car, vehicle, and pedestrian traffic is very heavy and congested, and where the necessary time cannot be given for concrete to set properly, and also for the reason that the streets in this section are likely to be torn up frequently for conduit, water pipe, or sewer work or subway construction. In this type the sub-grade is rolled and on it is placed 1½- or 2-in. broken stone. This stone is well tamped, on it are laid wooden ties, 2 ft. from center to center, and the usual track structure is built.

For all types the straight track rail weighs 129 lb. per yd. It is a girder rail 9 in. high, with 6-in. bottom flange and ½-in. web. Guard and curve rails are of similar dimensions, but weigh 145 lb. per yd. The chemical composition is as follows:

For the straight rail:

Carbon	0.50 to 0.60	per cent.
Sulphur, not to exceed	0.08	" "
Phosphorus, not to exceed	0.10	" "
Silicon, not to exceed	0.20	" "
Manganese	0.80 to 1.10	" "

Mr. Boucher.

For the guard-rail:

Carbon	0.45 to 0.50	per	cent.
Phosphorous	0.10	"	"
Sulphur, not to exceed	0.08	"	"
Silicon, not to exceed	0.20	"	"
Manganese	0.70 to 1.00	"	"

Wood ties treated with preservatives have been used extensively in the newer types of tracks.

All joints on straight track are electrically welded. This work is done under contract by one of the rail-rolling companies with its own equipment mounted on special cars, which run on the new track, and current is obtained from the trolley wire. The ends of the rails are butted carefully, but not welded. The weld is accomplished by placing against each side of the webs of the abutting rails, a steel bar, about 1 by 3 by 7 in., on each end of which is a boss, about $\frac{1}{2}$ in. high, the object of the latter being to insure good contact against the web. The bars are held rigidly against the web by heavy jaws operated by hydraulic pressure, and when thus held, a flux is applied and electric current of low voltage and exceedingly high amperage is turned on, the weld being completed in from 3 to 4 min. The heads of abutting rails are afterward smoothed down by a carborundum wheel. The conductivity of the joints must be equal to that of the rails joined.

This construction forms the smoothest running track the speaker has ever ridden over on any street surface railway.

Mr. Vorce.

C. B. VORCE, M. AM. SOC. C. E. (by letter).—The writer has read Mr. Polk's paper with much interest, and is glad that a matter of such vital importance to so many members has been brought to the attention of the Society.

As an expenditure of many thousands of dollars is involved, a very careful study should be made before a type of permanent track construction is adopted. In many cases, failure has occurred by reason of a lack of study of the character of the foundations, and a type not at all suitable to existing conditions has been chosen simply because other railroads have used that type successfully.

The writer has had very poor results with the girder type of construction adopted by Mr. Polk. This type was the standard when the writer became connected with the British Columbia Electric Railway Company, Limited, of Vancouver, but, on account of poor foundations, the girders had broken badly, with most disastrous results to both pavement and track.

After a careful study, the writer recommended, and the management adopted, the type of construction shown on Fig. 12. Since that time about 15 miles of double track of this type have been laid, and as yet no signs of failure can be seen.

Mr. Vorce.

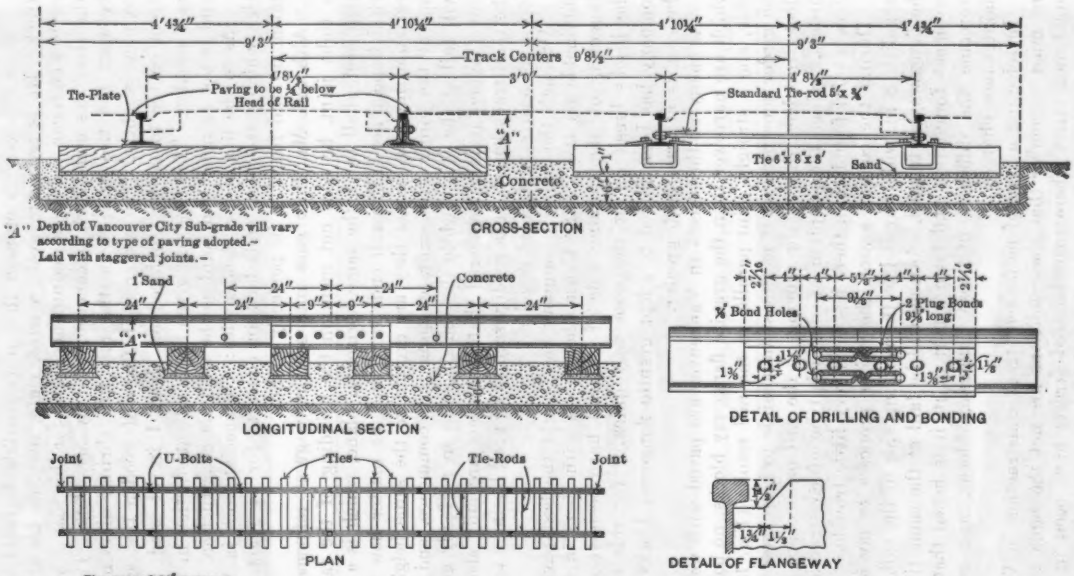

FIG. 12.

Mr. Vorce.

It is the writer's opinion that it is possible to build too rigid a track. He is trying to avoid a hard, rigid, inelastic track, which increases both car and track maintenance, and for this reason he criticizes the steel ties embedded in concrete used by Mr. Polk. The concrete between the ties and under the rail will shrink, allowing the rail to move slightly. The writer is in favor of wooden ties, spaced 2 ft. from center to center, surfaced on about 1 in. of sand, which acts as a cushion. This type has given excellent satisfaction in Vancouver, and is not as noisy and rigid as the steel tie construction.

As to the life of the wooden ties: On special work in Vancouver, ties which have been embedded in concrete for 14 years have been taken up and found to be perfectly sound.

Although Mr. Polk goes into seemingly great refinement to get a tight joint, he does not mention the grinding of the rail ends so that each shall be in the same horizontal plane, which is a matter of vital importance. The rail ends vary, and, no matter how slight this variation may be, unless they are ground to the same height, pounding at the joints will occur, cupping will commence, and the track will fail at the joints while the remainder is in perfectly good condition. When it is remembered that the joints are only about 6% of the total track length, it is readily seen to be good business to make the joints as nearly perfect as possible.

Although the writer's company has bought the best paving bricks obtainable on the Pacific Coast, the results with them in forming a flangeway on the running side of the rail have been very poor, as the bricks break off at the nose very quickly; for this reason the company has been forced to adopt granite flangeway blocks, although the cost is at least 50% greater.

As many of the streets in Vancouver are paved with wood blocks, which are narrower than the granite flangeway blocks, no bond is possible, and a straight joint parallel to the rail results (Fig. 13). With the girder construction, it is almost impossible to keep these flangeway blocks in place, due to the moving of the rail on account of broken girders. Since the adoption of the slab type of construction, which gives a solid foundation, there has been very little trouble.

During the coming season the writer proposes to lay a concrete monolith, 8 in. wide, parallel to the running side of the rail, in which the flangeway is formed. As this will be laid at the same time as the pavement foundation and form a part of it, it is hoped that this will overcome the difficulty of loose flangeway blocks, and reduce the maintenance charges.

In selecting a type of permanent track construction in Vancouver, one must remember that the conditions are not the same as in older established cities where macadamized streets have been in existence for years and a good foundation is available. Owing to the poor founda-

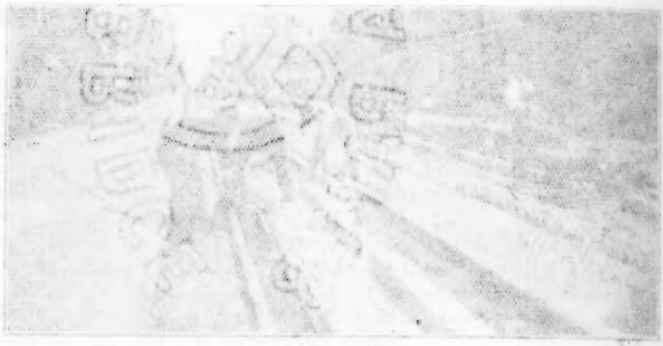

FIG. 13.—LAYING GRANITE FLANGEWAY BLOCKS ON GRANVILLE ST., VANCOUVER, B. C.

FIG. 14.—TRACKS REMOVED—GRADING IN PROGRESS—TEMPORARY TRACK ON LEFT.

FIG. 15.—GRADING COMPLETED. TEMPORARY TRACK ON RIGHT, BROADWAY, VANCOUVER, B. C.

Mr. Vorce.

tion, the streets were first planked and then macadamized, the macadam seldom being renewed before laying the permanent pavement on a concrete base. For this reason the foundation is very poor, and the problem has been the selection of a type of construction to meet the existing conditions.

On paved streets, the company always lays a double track, and, as the City pays for all paving for the entire width between the curbs, including foundation, the railway company's liability covers only whatever construction it decides to put in below it. Before the writer took charge of this work, although under the franchise the company could do its own portion of the work, it had been the practice to let it to the paving contractor. Such poor results were obtained that the writer organized and equipped a construction department, and, with few exceptions, the company now does all its own work. At the suggestion of the writer, in order to facilitate the work, the company entered into an arrangement with the City to do all the work in the track allowance, about 18½ ft. wide, the City paying for its share at the same rate as was paid to the contractor for the remainder of the street. This enabled the railway company to do its portion of the work first, the contractor following up and bringing his work to the grade established by the rails. This plan has given most satisfactory results.

The work is carried on in the following manner: A temporary track is laid, outside of the track allowance, to take care of the traffic during construction, thus enabling the company to build both tracks at once. When the traffic is turned over to the temporary tracks, the old track is torn up and the ties and rails are piled on the side of the street, ready to be picked up by the work train, grading is then started (Fig. 14), and the cut is taken out to rough grade; forms are then set by the company's engineer to the proper grade for the top of the slab, and a small gang of fine graders follows up the rough graders; in the meantime the gravel for the slab is delivered along the side of the excavation (Fig. 15). As soon as a block has been rough-graded, work on the concrete slab is commenced, the material being shoveled directly into the hopper, on which a line has been drawn to insure the right proportions. The aggregate is then run through the mixer and delivered into a bucket which travels along a 30-ft. boom cable swinging through 180° (Fig. 16). This method reduces the number of men around the mixer to the minimum, which is an important item, as common labor is paid 37½ cents per hour. All the company's mixers are of this type, and can mix about 80 cu. yd. per 10 hours, or about 250 lin. ft. of completed slab 18½ ft. wide and 6 in. deep. The rails are distributed by an electric derrick car and the ties by the company's motor car. As soon as the slab has set for 24 hours, ties are distributed, T-rails (70-lb., 264, Lorain Section, or 87-lb., 399, Lorain Section) are

Mr. Vorce.

laid, and the track is surfaced to grade with sand (Fig. 17). The standard plan calls for 1 in. of sand under the tie, but, owing to irregularities in the concrete, the thickness varies from ¾ to 1¼ in. After the track has been surfaced, the sand is scraped out from between the ties, the flat wheels on the mixer are replaced by flanged wheels, so that the mixer can run on the track, and the final concrete course is laid (Fig. 18).

It will be seen that the four operations, grading, laying the slab, laying the track, and putting in the final concrete course, are all carried on at the same time, resulting not only in speed but in economy.

Each section of track laid represents a new problem, and from time to time the writer has had to design special machinery in order to do the work quickly and economically. On Granville Street, the principal business street, though the paving was in good condition, about ½ mile of track was in such bad repair that it had to be renewed. The Board of Public Works allowed the company to abandon traffic on this street on condition that it would be restored in 22 days. As this period included 10 days for the last concrete laid to set, it meant that all work, except paving, had to be completed in 12 days. In order to be sure of carrying out the work on time, a progress chart, Fig. 20, was prepared, and was followed so closely that the work was finished 1 hour ahead of time.

The street was paved with wood blocks laid on a 6-in. concrete base, and each rail of the double track was carried on a concrete girder, 24 in. wide and 15 in. deep. The reconstruction of the track called for the removal and replacing of the following quantities: 5 100 sq. yd. of wood block paving; 10 200 ft. of rail; 1 800 cu. yd., or 5 100 sq. yd., of concrete; 600 cu. yd. of earth; the laying of 2 400 cu. yd. of concrete; ½ mile of double track; 850 sq. yd. of concrete flangeway blocks; and 4 250 sq. yd. of wood block paving. The quantity of concrete to be removed was so great, and the time allowed so short, that some mechanical means for breaking it up had to be devised, as the schedule called for the removal of about 32 sq. yd. per hour. The dipper arm was taken off the electrically-driven shovel owned by the company, and pile-driver leads, 20 ft. long, were hung from the end of the boom, being held in place by two braces running back to the main frame of the shovel. A 2 600-lb. hammer was specially cast, having a wedge-shaped cutting edge, about 8 in. deep, running parallel to the track. The cutting edge was placed in this way in order that it would not injure the remaining concrete in the street. This scheme worked excellently, and no trouble whatever was found in breaking up the concrete and adhering to the schedule. The concrete breaker, which would swing through 360°, was placed on one track, and on the other track was placed the derrick car, having a 60-ft. boom which would also

Mr. Vorce.

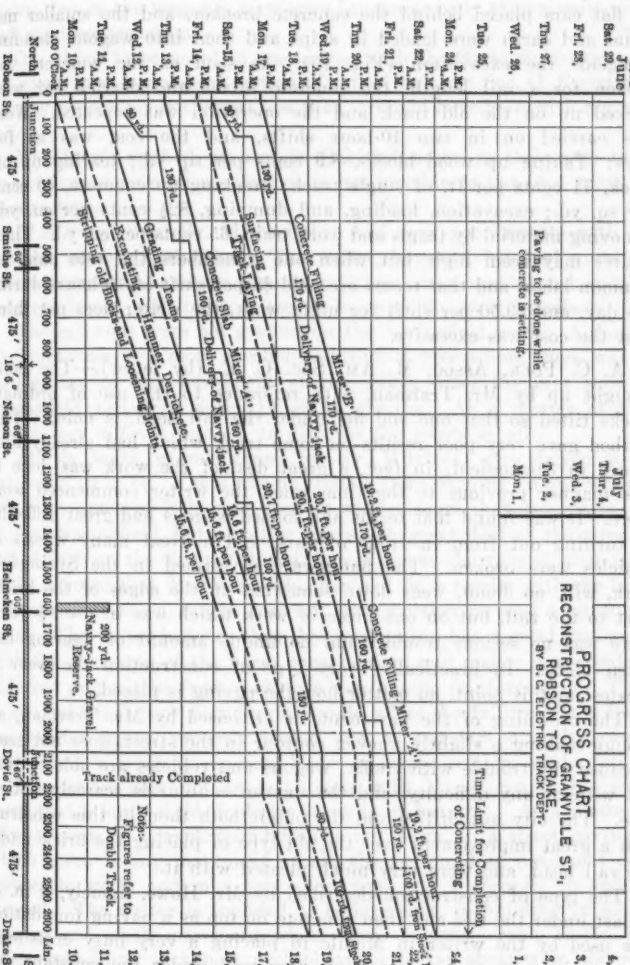

FIG. 20.

Mr. Vorce. swing through 360°, and could move itself along the track. The larger pieces of concrete were picked up by the derrick and loaded on flat cars placed behind the concrete breaker, and the smaller material and earth were loaded in skips and then into wagons standing alongside the excavation (Fig. 19). As soon as the concrete was broken for a rail length, the concrete mixer and derrick car were backed up on the old track and the operation was repeated. Work was carried on in two 10-hour shifts, and the cost was as follows: Taking up wood blocks, 8.9 cents per sq. yd.; tearing up old track, 11 cents per ft. of single track; breaking up concrete, 40 cents per sq. yd.; excavation, loading, and dumping, 82½ cents per cu. yd.; removing material by teams and work train, 65 cents per cu. yd. These figures may seem high, but when one remembers the rate paid for common labor, and that teams are paid $8 per shift of 10 hours during the day, and $9.50 per shift for night work, the writer does not think that the cost was excessive.

Mr Polk. A. C. Polk, Assoc. M. Am. Soc. C. E. (by letter).—The point brought up by Mr. Tratman, with reference to the use of ordinary bricks tilted so that one end fits under the rail head, is noted. This method gave very poor results on some track which had already been placed in Springfield; in fact, a great deal of the work was done in this manner previous to the time when the writer commenced work there. It was found that teams and loaded wagons had great difficulty in turning out from in front of cars, and a great many wheels of vehicles were broken. The flangeway, as formed in the Springfield work, will, no doubt, wear down somewhat on the edges of the bricks next to the rail, but on one piece of work which was in use 1½ years there was no serious trouble, and no undue amount of wearing had taken place. In practically every type of construction the wear is greatest at this point, no matter how the paving is placed.

The crowning of the pavement, as criticised by Mr. Tratman, although making a slightly uneven contour in the street, does not seem to cause any trouble with traffic; wagons and vehicles are able to turn out without any difficulty, and the uneven contour is scarcely noticeable. The city authorities and the public both thought this construction a great improvement over the old type of placing the brick under the rail head, and were very much pleased with it.

The type of construction described by Mr. Howe, namely, 6 in. of ballast under the ties and then concrete on top as a paving foundation, was used by the writer in Mobile in placing a very busy cross-over. Reports indicate that it stood up very well under the constant and heavy traffic, and the writer has no doubt that, as a cheaper method of construction, this type answers very well, but he would not consider it as of a permanent nature.

Mr. Polk.

The decision to put in the type used in the Springfield work was arrived at from previous experience with cheaper types, where it was shown that in the long run they were far more costly than a permanent and rigid construction.

One thing to be noted in connection with the Springfield work was the adoption of a standard section of rail of the Am. Soc. C. E. pattern. This, of course, made the cost less than it would have been with a girder rail.

Mr. Howe's method, as used in Oakland, seems to the writer to be an excellent compromise, where it is not possible to put in a more expensive type.

It is noted that Mr. Mitchell has had very poor results with the concrete beam construction. The writer, however, has had quite the contrary experience where the concrete beam has been placed and has been reinforced with twisted steel rods, as in the type described.

The rail ends were not ground on the Springfield work. Although, no doubt, this is a most excellent additional precaution, there was no visible sign of any movement at the joints, after the first work at Springfield had been down 12 or 14 months. As a matter of fact, it was very difficult, indeed, to discover the joints at all.

All the bolts, as mentioned by Mr. Mitchell, were driven to an extremely tight fit. There was no trouble from cupping on any work of this class, some of it having been in service more than two years, not only at Springfield, but at other places. A great deal of the strength and rigidity of the Springfield joints was due to the type of plate used.

It is noted that Mr. Vorce also has had poor results with the beam type of construction, but he does not state whether he used a reinforced beam. The writer believes that this reinforcing has a greal deal to do with the character of the beam construction, and makes it a decidedly different proposition from a beam which has no reinforcement. There is no doubt that poor foundations would affect the failure of the beam, but reinforcement, properly placed and in sufficient quantity, would hold where a straight concrete beam of larger section would fail.

The writer does not agree entirely with Mr. Vorce in his statement that a hard, rigid, inelastic track is undesirable. As a matter of fact, as soon as a track foundation is put down, in a street paving in which there is any movement at all, the surrounding pavement commences to work, and in a very short time will be broken up and destroyed. The writer is inclined to believe that, in building in an expensive and costly pavement where there is considerable traffic, and where rebuilding is almost prohibitive, it is far cheaper in the long run to put down a solid, heavy roadbed.

The wooden ties would probably be satisfactory, but the writer is of the opinion that, if they are to be used in a permanent structure, it

Mr. Polk. would be desirable to place tie-plates on them, which would, no doubt, add to the life and reinforcement of the track.

The writer has mentioned the criticism as to the grinding of the rail ends, and although it may be that the matter is of more vital importance than he considers it, his experience on two previous construction jobs, of the character illustrated in the paper, did not show that planing off the rail was nearly as essential as the proper placing of the joints and of the concrete around the ties, with a big, heavy tie under the joint, also the additional reinforcement at this point.

Mr. Vorce's description of the work in Vancouver is certainly most interesting, and should be of considerable value to any one interested in this particular type of work.

The writer is very much pleased to have heard from the various members who have discussed his paper, and to have had other views than his own expressed in this matter.

Paper No. 1253

THE SANITATION OF CONSTRUCTION CAMPS.*

By Harold Farnsworth Gray, Jun. Am. Soc. C. E.

With Discussion by Messrs. R. C. Hardman, Spencer Miller, Frank E. Winsor, W. E. Britton, F. W. Austin, Harry G. Payrow, and Harold Farnsworth Gray.

A problem which often confronts the engineer or contractor engaged in work which requires the establishment of a camp is the keeping of labor steadily on the job in such physical and mental condition that each man puts forth his best efforts. This is especially true when work is prosecuted in new and unpopulated country, where life at its best must be rough and at times hard. The engineer in charge may have to carry on the work with a labor force depleted by sickness. As a result, many may leave permanently, and many of those who remain may be in such poor health that their physical efficiency is greatly impaired. A shifting or half-sick labor force cannot be efficient.

The writer has seen camps where a considerable proportion of the men were laid off because of intestinal disorders, due largely to poor sanitation, and where the efficiency of the force was reduced perhaps one-half. He has been in camps in malarial regions where the reduction in efficiency of the force was known to be at least one-quarter, and at times was probably greater. Such conditions represent a serious loss to the contractor, a loss which can be almost entirely eliminated by the observance of a few simple rules based on the present knowledge of disease prevention. In the fol-

* Presented at the meeting of December 18th, 1912.

lowing the writer proposes to set forth briefly some of the principles of sanitation which are applicable to camp conditions, in the hope that he may convince the Engineering Profession that good camp sanitation is an economy, and not an expense.

Camp Location.—The matters of site and soil conditions are not of prime importance. Even under the poorest natural conditions, good health may be maintained in the camp if the proper sanitary measures are taken, but the better the natural conditions, the fewer and less costly will be the sanitary measures required.

Preference should be given to an even surface with a slight natural slope. An even surface promotes convenience and accessibility, and a slight slope gives a quick run-off for possible rain water. In cool climates a sunny exposure should be selected, and, in hot climates, the shady side of a valley, if possible. Low places, swamps, and wet areas should be avoided, as these may be breeding places of malaria-bearing mosquitoes. A light, porous soil is an advantage, not that disease lurks in the emanations from damp ground, but because of the added comfort of dry quarters.

Housing.—The form of housing will depend largely on the duration of operations and on transportation facilities. Whether tents, portable houses, or the more permanent wooden bunk-houses are used, ample provision for the free entrance of air and sunlight should be made. If wooden bunk-houses are used, the window space should be ample, and the windows swung inward on hinges at the side of the frames. In warm climates, in summer, and especially in fly and mosquito regions, the doors and windows should be screened, as described later.

One or more able-bodied men, as required, should be assigned to janitor duty. Each day all quarters should be opened as widely as possible for several hours during the morning for ventilation, and thoroughly cleaned by the janitor. Dirty conditions and violations of the camp rules should be reported by him, and the offender warned, disciplined, or discharged, according to the magnitude and frequency of the offense. With proper cleanliness, disinfectants are not required, except in unusual circumstances.

In cold climates, and during the winter, stoves (of a type which carries the products of combustion out of the room) should be provided, and fuel supplied to the men.

Mess-House.—The mess-house and kitchen should be especially well ventilated, but all doors, windows, and other openings should be screened with a copper or bronze wire of No. 18 mesh screen. Doors should be provided with springs to keep them closed. In order to prevent the entrance of insects around the edges of screens, the frames should close flush against wood strips nailed to the casing.

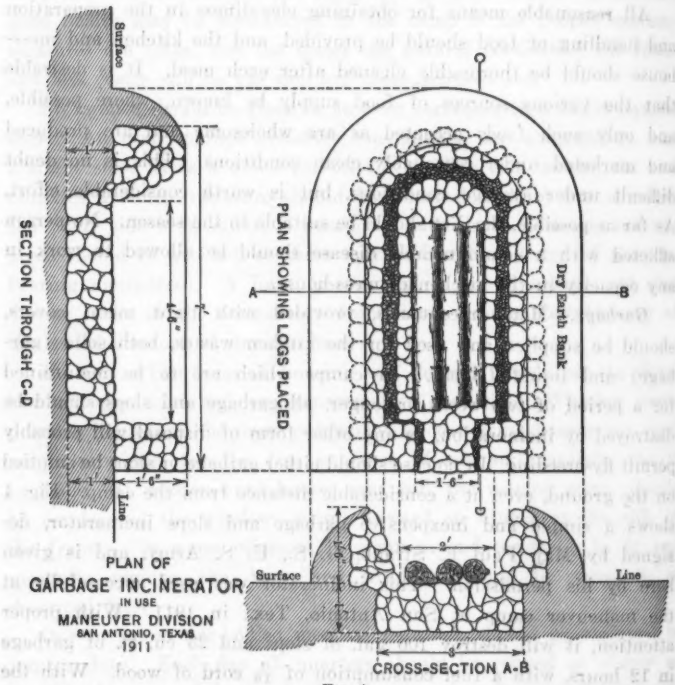
All reasonable means for obtaining cleanliness in the preparation and handling of food should be provided, and the kitchen and mess-house should be thoroughly cleaned after each meal. It is desirable that the various sources of food supply be known, where possible, and only such foods accepted as are wholesome and are produced and marketed under reasonably clean conditions. This is no doubt difficult under average conditions, but is worth considerable effort. As far as possible, the diet should be suitable to the season. No person afflicted with a communicable disease should be allowed to work in any capacity in the kitchen or mess-house.

Garbage.—Metal receptacles, provided with tight metal covers, should be supplied and used for the kitchen wastes, both solid (garbage) and liquid (slops). In camps which are to be maintained for a period of two weeks or longer, all garbage and slops should be destroyed by incineration, as any other form of disposal will probably permit fly-breeding. In no case should either garbage or slops be emptied on the ground, even at a considerable distance from the camp. Fig. 1 shows a simple and inexpensive garbage and slops incinerator, designed by Maj. Paul F. Straub, G. S., U. S. Army, and is given here by his permission. This incinerator was used successfully at the maneuver camp at San Antonio, Tex., in 1911. With proper attention, it will destroy 100 gal. of slops and 23 cu. ft. of garbage in 12 hours, with a fuel consumption of $\frac{1}{16}$ cord of wood. With the ordinary attention which would be given in a construction camp, lacking in rigid military discipline, the fuel consumption would be greater, but $\frac{1}{8}$ cord per day should be ample for the destruction of all garbage and slops created in the preparation of food for 100 men.

The liquid slops are evaporated by being poured slowly along the walls of the incinerator, and the garbage is placed on top of the fuel. If rock for the construction of the incinerator is not available, a trench of the same form and capacity may be dug in the ground,

and operated in the same manner. Great care should be taken to see that the garbage is thoroughly consumed; otherwise, fly-breeding may ensue if the incinerator is not used constantly.

Latrines.—Indiscriminate defecation and urination in the vicinity of the camp should be prohibited, and a sufficient number of latrines constructed at convenient places. A two-hole seat with a urinal



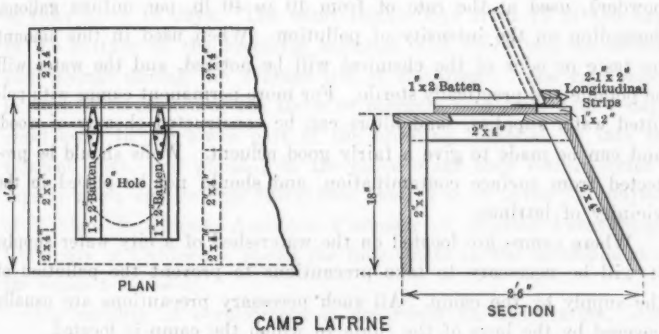


FIG. 1.

trough is a good standard for the average camp, and the latrines should be placed so that the maximum distance from any house or tent to the nearest latrine does not exceed 100 ft. With easy accessibility of latrines, promiscuous defecation is more easily discouraged.

The latrines consist of three parts: the pit, the box, and the shelter. The pit should be 6 ft. or more in depth, and in section slightly smaller than the box. The box is shown by Fig. 2 (also by permission of Maj. Straub). It should be made of tongued-and-

grooved boards, as ordinary lumber tends to warp and shink, so that it is difficult to keep the box fly-tight, reliance being placed on the tightness of the box to prevent the access of flies to the contents of the latrine. The covers of the holes should drop back automatically into place over the holes when the seat is not occupied. In summer no roof is provided for the shelter which, for privacy, is built around the latrine, as the direct action of sunlight and air is desirable as a disinfectant and deodorant. During the winter a roof may be provided, and during rains, at other seasons of the year, a tarpaulin should be used.

CAMP LATRINE

FIG. 2.

A metal urinal trough may be attached to the side of the latrine shelter, discharging into the pit through the box *via* a trap. The pit should be disinfected daily by being burned out with oil or oil-soaked straw. The urinal trough should be flushed with water and limed, and the interior of the box and the pit should be limed after being burned, to deodorize the latrine. Cleanliness in the use of latrines must be strongly insisted on, especially if the laborers are of foreign nationality.

Stables.—The stable, especially the stalls, should be cleaned out thoroughly each day, and the manure removed to a point at least ½ mile from the camp and burned with oil. In a hot, dry climate, it will suffice to remove the manure to this distance and spread it out thinly on the ground; either method will prevent fly-breeding. Under average conditions, horse manures are the favorite breeding places of flies. From estimates based on actual counts of represen-

tative samples, it has been shown that a manure pile weighing 1 000 lb. may contain upward of 450 000 fly maggots at the end of 4 days' exposure. Therefore, unusual care should be taken of manures, and the stables kept clean. There is no substitute for cleanliness; treating the stalls and manure with oils, chemicals, and poisons is in general more expensive and less effective than cleanliness and the proper disposal of manure.

Water Supply.—An endeavor should be made to obtain a pure water supply. Where the water is known to be polluted, it can be sterilized by calcium hypochlorite (chloride of lime or bleaching powder), used at the rate of from 10 to 40 lb. per million gallons, depending on the intensity of pollution. When used in this amount no taste or odor of the chemical will be noticed, and the water will be potable and practically sterile. For more permanent camps with polluted water supplies, sand filters can be constructed cheaply of wood, and can be made to give a fairly good effluent. Wells should be protected from surface contamination, and should not be placed in the vicinity of latrines.

Where camps are located on the water-shed of a city water supply, it will be necessary to take precautions to prevent the pollution of the supply by the camp. All such necessary precautions are usually covered by the laws of the State in which the camp is located.

Baths and Laundry.—In many respects personal cleanliness is one of the most important factors in health preservation, for the reason that disease is largely transmitted by contact, from person to person. It is advisable, therefore, that facilities for keeping personally clean be provided, and the men encouraged to make use of them. Shower baths can be easily and cheaply constructed. A simple and effective shower can be made from a 2-ft. length of 1-in. pipe, capped; along the lower side of the pipe are bored three parallel rows of $\frac{1}{16}$-in. holes set $\frac{3}{8}$ in. apart. The pipe projects horizontally from a tee in the vertical supply pipe, at about 8 ft. above the floor. The latter should be of wood with open joints. The bath should be provided with a shelter, and be without a roof in summer.

Laundry equipment and supplies, such as tubs, washboards, and soap, should be furnished gratis.

Rubbish.—Unless cared for, considerable rubbish tends to accumulate in any camp. It should be collected daily by the janitor, removed

to a specified place, and burned. Everything which tends toward neatness and cleanliness should be encouraged.

Flies.—The principal breeding places of flies, namely, manure piles, garbage heaps, and latrine pits, have been mentioned. They may also breed in any collection of decomposing organic matter, no matter how small. The fundamental theorem of fly control is cleanliness combined with proper destruction of waste products. Where destruction is not feasible, the rendering of such wastes unsuitable to fly-breeding, or inaccessible to flies, may be substituted.

Under midsummer conditions, flies will develop from egg to adult in from 10 to 14 days. The adult female lays from 75 to 125 eggs on the surface of the breeding material, and there may be several such layings during the average life of the insect. The eggs hatch in from 12 to 24 hours; the larvæ or maggots feed from 4 to 7 days, crawl away to the lower part of the breeding material, or into the adjacent earth, and pupate; in the pupal stage they remain quiet 4 days or more, and emerge full-grown flies. Fig. 3, given by courtesy of William B. Herms, Assistant Professor of Applied Parasitology, University of California, shows the four stages in the development of the common house-fly.

The rapidity of development is dependent on temperature, being accelerated by warmth and retarded by cold. Owing to the fairly constant warmth of decaying organic matter (for example, manure), the larval period is very nearly constant. The pupal period, being spent away from the decaying material, shows the greatest variation, and, in winter, may be lengthened to several months.

Owing to the fact that the fly maggot is very resistant to poisons and insecticides, it will be found cheaper and more effective, as previously stated, to destroy or remove the breeding material, than attempt to treat accumulations with poisons.

It has been proven conclusively that under conditions such as are usual in camps, flies may be gross transmitters of such diseases as typhoid, dysentery, and various intestinal disorders. During the Spanish-American War, when more soldiers were killed by disease than by bullets, large numbers of flies were often observed on the food in the mess-tents, the bodies and feet of many of them being whitened by the lime in the latrines which they had recently visited.

It may be stated almost as an axiom that the sanitary condition of a camp varies inversely as the numbers of flies present.

Malaria and Mosquitoes.—It is now conclusively proven that mosquitoes of a certain type are the sole transmitters of malaria. This disease is most prevalent during the warm months of the year, when the largest amount of construction work is carried on. In malarial regions the lost efficiency of the labor force from this disease is often 25% and more. Even where malaria-bearing mosquitoes are not present, and those of the common type are numerous, it is advisable to take measures for their destruction, as a night disturbed by these insects does not put a man in the best condition for a hard day's work. As previously mentioned, the doors and windows of wooden houses should be screened and, in mosquito districts, if tents are used, bed-nets supported by frames should be supplied.

The two types of mosquitoes, the *Anophelines,* or malaria transmitters, and the *Culicines,* or common mosquitoes, are shown in various stages of their life history on Fig. 5. The differences in the two types are easily recognized in three of the four stages. The *Culicines* lay their eggs on the water surface in boat-shaped masses of from 250 to 750 eggs; the *Anophelines* lay their eggs singly or in irregular clumps. In the larval or wriggler stage, passed in water, the *Culicines* project a posterior breathing tube to the surface, the remainder of the body hanging head downward at an angle with the surface; the *Anophelines* breathe while lying parallel to, and with every segment touching, the surface. The differences in the pupal or tumbler stage are not sufficiently well marked to be easily distinguished by the unaided eye. In the adult stage, two methods may be used to distinguish the types: The resting attitudes are different; an *Anopheline* resting on a plane surface holds the posterior part of the body away from the surface, the line of the body thus making a distinct angle of from 25 to 55° with the surface, whereas the *Culicine* adult rests with the line of the body parallel to the surface, or in a humpbacked position. The best method of distinction in the adult stage is based on the mouth parts, which can be seen with the unaided eye, but can be observed better with a low-power magnifying lens. In the *Anopheline* females, the palpi (the two appendages immediately on each side of the central proboscis or beak) are approxi-

(*e''*) HEAD AND APPENDAGES OF CULICINE FEMALE.

mately as long as the proboscis, while in the *Culicines* the palpi are shorter than half the length of the proboscis. The males, which do not suck blood, can be distinguished, if found, by the feathered or plumose antennæ or feelers.

Mosquitoes breed in stagnant or quiet water, the *Anophelines* preferring clear, fresh water standing but a few inches on grassy land. The *Culicines* are not as fastidious in their choice of breeding places, often thriving in the foulest water. The first principle of mosquito control, therefore, is the removal of all stagnant water. This may be effected by drainage, by filling in small low spots which cannot be readily drained, by emptying vessels which contain useless water, and by screening all others. Where drainage or filling in is not practicable, as will usually be the case in construction camps, oil or chemicals may be used to destroy the mosquito larvæ.

Oil sprayed on the surface of water which is breeding mosquitoes will kill them effectively by shutting off the air supply, the larvæ and pupæ dying by suffocation. The oil should have a specific gravity of about 30° Baumé, and may be applied conveniently and economically by a knapsack spray-pump, as shown in Fig. 4. Small ponds may be treated by throwing in several handfuls of cotton waste soaked in oil, which will gradually feed a film of oil on the surface for some time, and may be renewed at intervals.

Under midsummer conditions, the development of the mosquito requires from 10 to 14 days; in the spring and autumn, this period is somewhat longer. To prevent breeding, therefore, it is necessary to apply the oil by spraying once every 2 weeks in summer, and about once every 3 weeks in the spring and fall.

Where the water is full of vegetation, it is advisable to treat it first with copper sulphate (1 to 50 000) and then with oil. A preliminary copper sulphate treatment will be found an advantage where poisons or larvacides are used. Several poisons, such as nicotine sulphate, phinotas oil, and emulsions of a modified crude carbolic acid, have been used for mosquito destruction with varying success, but on the scale of operations which would be usually attempted for the protection of a construction camp, oil will be found to be cheaper and more effective.

It will seldom be necessary to carry on anti-mosquito operations beyond a distance of 400 yd. from the camp, and not all the water

in this territory will be found to be breeding mosquitoes. Only water which is actually breeding them need be treated.

Medical Treatment.—While the subject of medical treatment of the sick does not properly come under the provisions of camp sanitation, it is advisable to consider it briefly here, on account of its relation to the control of disease. The character of such treatment will depend on the size of the camp and the country in which the work is carried on. For small camps, in sparsely inhabited regions, a medicine chest of standard remedies, with bandages, liniment, and first aid to the injured materials, should be provided, to be administered gratis as needed. In malarial regions, in addition to screening and mosquito destruction, a daily prophylactic dose of quinine should be urged on the employees. Where small camps are within easy reach of a town, arrangements should be made with a physician to call at regular times, and as needed in emergencies, and, in addition, the medical and first aid equipment should be provided for minor complaints.

Where several camps are working a large number of men, directed from a central field office, it is advisable, and usually practicable, to install a field hospital with a resident physician, who, in addition to his hospital duties, makes periodic inspections of the camps. The expense of the hospital is usually provided for by nominal deductions from the pay of each employee, which entitles him to free medical attendance if sick or injured. This is often done on works of magnitude, an example with which the writer is familiar being the Los Angeles Aqueduct.

In any case, an employee suffering from any form of communicable disease should at once be laid off and isolated from the others, to prevent as far as possible the further spread of the disease.

The Value of Good Sanitation.—In its broadest sense, sanitation includes all methods and procedures necessary for the prevention of the spread of diseases. In its practical workings, it is limited to certain fields, which are not very well defined, owing to the interrelations of various factors in disease prevention. The procedure in disease prevention may be arranged roughly in three main divisions: First, the control of the source of infection, practically always a person sick with the disease; second, the control of the carrier or

means of distribution of the disease from one person to another; and third, the protection of the well persons individually.

The first division falls largely in the domain of the physician, though the engineer, by installing works for the prompt removal and purification of the infected discharges of the patient, plays his part here. The control of the carrier of infection, such as food, water, sewage, insects, etc., comprises the field of sanitation as usually defined, and in this field the engineer, chemist, bacteriologist, entomologist, and others, play the chief part. Personal hygiene largely covers the third division. All three divisions are links in a chain which is no stronger than its weakest link. Under camp conditions, however, it is not practicable to take the measures which are essential in an urban community, and it is not possible to pay much attention to personal hygiene. The bulk of disease prevention, therefore, must fall in the second division.

There are few engineers who are not familiar with the usual conditions in camps. Foul-smelling, open latrines swarming with flies, dirty and poorly ventilated quarters for the men, vile food, filthy mess-tent, and swarms of flies on and in everything, are the average conditions. Such being the case, it is well-nigh impossible for any man to remain in good physical condition, and it is the laborer's physical condition which largely determines the amount and character of his output. If a part of the labor force is weakened by ill-health, just that much less than the maximum possible work can be obtained. The contractor expects the maximum for his greatest profits; if he gets less than the maximum, he sustains a loss. A reduction of 25% in the efficiency of the labor force is not unusual. If we consider a camp of 100 men at an average daily wage of $2, this daily loss amounts to $50, and in a 30-day month would reach a total of $1 500. The additional cost of good sanitation above the amount spent for the poor sanitation which is at the bottom of this loss, would probably not exceed $250 per month, leaving a net profit, chargeable to good sanitation, of $1 250. The average saving would undoubtedly be less than this amount, but the writer does not believe that he has based this estimate on an extreme case. However, be the saving much or little, good sanitation in a camp is emphatically an economy, not an expense. Aside from ignorance, perhaps the chief

reason that camp conditions are usually so bad is that the contractor can actually see in dollars and cents the money expended for good sanitation, while the saving cannot be expressed so accurately or in such tangible form. Nevertheless, the economy can be shown at least approximately in every case, and in extreme cases may represent the difference between a profit and a loss on the contract.

DISCUSSION

R. C. HARDMAN, ASSOC. M. AM. SOC. C. E. (by letter).—This paper is one of very timely interest, its only fault being its brevity. The writer has had occasion to witness the good effects of camp sanitation, as well as to install certain sanitary appliances in a camp of 4 100 men, under unfavorable climatic and drainage conditions. The subject is one which deserves to be expanded, and should receive the careful attention of the Profession. Mr. Hardman.

In some camps which the writer has seen, the conditions approach those which must have existed in the Middle Ages, and now exist in the less enlightened portions of the world. In the provincial districts of the Philippines, for instance, Americans are horrified to see practically all human waste consumed by hogs kept in the back yards of nearly all the native shacks; yet they view with apparent equanimity the promiscuous deposition of fecal matter around a camp wherein the services of our porcine friends are not available.

The writer once met an American in Hong Kong who solemnly swore total abstinence from fish because he had seen in Canton, China, a fish pond wherein the fish were fed, in part, from a privy built over the edge of the pond. Yet we, at home, empty our raw, untreated sewage into our rivers from which fish are taken for the table, and in thousands of instances privies are built over streams and ponds, as in the case of the Buddhist monastery in Canton; and yet "the pot called the kettle black." The Cantonese did not use the pond for a water supply; we do use our rivers for that purpose.

To carry the comparison still farther: The writer has seen in Chinese cities huge tubs along the streets in use as "public comfort stations." In a great many cases, these "stations" overflow into the streets; yet this is not much worse than conditions in some construction camps where latrine trenches are dug, left open to the light and air, and flies, and allowed to fill up without destructive or disinfective treatment of any kind.

We think of the Chinese race and nation as a very filthy one, but the filth is only a matter of comparison. The Chinese have yet to be educated up to a high sanitary standard, while we have to be educated to the pre-eminence of health over dollars.

The writer has brought this subject to the attention of the Profession in a short article* containing rules for the use of the various appliances described and illustrated. They differ slightly in form from Mr. Gray's, but cover the same ground. The method, however, is of minor import.

Perhaps the greatest arguments for camp sanitation are found in the records made in the Canal Zone, in Cuba after the Spanish-

* *Engineering News*, October 17th, 1912.

Mr. Hardman. American War, in the various maneuver camps of the United States army in recent years, and, notably, in the work of the Japanese Medical Corps in the war with Russia. One has but to compare these with the history of the French Company at Panama and the disgraceful record of the U. S. Medical Corps during the Spanish-American War, at Chickamauga, Jacksonville, and elsewhere.

Mr. Gray dwells only on the baser financial side of "the value of sanitation." Of course, this is the only thing which will appeal to the average camp executive, but should we not, as engineers, also be moved by the more altruistic motive of helping the ignorant foreigner, who makes up the bulk of our camp population, to attain, by example and precept, the standard of living of the Americans with whom he is to become assimilated? Do we not owe it as a debt to the human race?

Mr. Miller. SPENCER MILLER, M. AM. SOC. C. E.—Mr. Gray's paper is interesting and valuable.

A Government contractor, building a lock and dam on one of the Western rivers, recently informed the speaker that an outbreak of malaria in his camp had nearly cost him the profit on his contract. Malaria and malarial fever disorganized his camp so completely that he found it practically impossible to keep a full force of men at work. New men arriving to take the places of sick ones would shortly succumb to the disease; others fled from the camp. It was only after this had continued for a considerable time that the contractor sought relief from a sanitary expert. The outbreak of malaria was attributed directly to the presence of the malarial mosquito. The camps were thoroughly fumigated and screened. The sick were properly guarded against the mosquitoes. The immediate vicinity of the camp was cleared up. The rank growth was mown down. Ditches were dug and drainage operations were carried out thoroughly. Every receptacle for holding water was either emptied, destroyed, or oiled regularly. Shortly the trouble disappeared. The camp became a healthy and a profitable one. All of which illustrates that it pays to be sanitary.

Mr. Winsor. FRANK E. WINSOR, M. AM. SOC. C. E.—This paper is a timely contribution on an important subject relative to which very little has appeared heretofore in the publications of the Society.

The construction and sanitation of camps for the temporary housing of men have, generally speaking, received little scientific consideration among those responsible for their creation, and the author's suggestions are so materially in advance of common practice as to be considered by many, perhaps, revolutionary.

The proper sanitation of construction camps depends on a variety of considerations, and involves many diverse problems. The character of camp construction should depend on seasonal variations of climatic

conditions, the length of time which the camp will be occupied, the nationality and intelligence of the occupants, the character of the country in which the camp is located—particularly whether in a populated or non-populated district—and other less important considerations. Mr. Winsor.

The following discussion is mainly from the viewpoint of camps located in more or less populous districts, the occupancy of which extends over more than one working season. The methods of camp construction and sanitation described have been used successfully along large portions of the Catskill Aqueduct, a structure some 90 miles in length, extending from the Catskill Mountains to New York City, and now nearing completion. The work and methods outlined are both practical and reasonable, and are believed by the speaker to be adaptable, with suitable modifications in detail, to substantially all conditions. The subject may be conveniently treated under the following headings:

1.—Location of Camp.—Generally speaking, camps should be located on high, dry ground, preferably sandy; and, where located on a drainage area tributary to a domestic water supply, a site remote from watercourses should be selected.

2.—Water Supply.—A water supply of suitable quality and quantity for drinking, bathing, and washing must be provided, and, if the camp is to be used for any considerable period, the supply should be properly piped under pressure to the various buildings. A ground-water supply from deep wells, protected from surface pollution, is generally the most satisfactory, although under some conditions it may be allowable to use surface springs or surface streams, if their purity can be properly and continuously safeguarded. Dug wells, open at the top, are almost always polluted, and it is seldom safe to use water from streams and lakes, particularly in a territory at all populated, without proper purification. It is important, especially with sources other than ground-water, to make frequent analyses in order to secure a continuous suitable quality of the supply.

3.—Food Supply.—An intelligent selection and inspection of all food products, particularly milk and such articles as are used without cooking, is important.

4.—Waste Disposal.—The most efficient method of disposal of human excreta, including urine, is by incineration, and it has been found entirely practicable to collect and incinerate such wastes from camps of both large and small size. Various types of incinerators have been used, including several small, portable ones with seats and urinals attached; but, generally speaking, with camps of considerable population, with several years occupancy in prospect, it has been found more economical and practical to build special incinerating furnaces, properly housed, and to collect all the fecal matter in tight cans, which are placed under the seats in the closets and changed daily. Suitable closets for housing the cans, protected from flies by

Mr. Winsor.

thorough screening, should be provided throughout the camp and along the line of the work. The speaker is of the opinion that, under all conditions, incineration is much to be preferred to the latrines suggested by the author.

With the fecal matter disposed of, the problem of the other camp wastes is materially simplified. Garbage should be collected and burned daily. Stable manure should be disposed of daily, preferably by incineration, although it may be allowable, in agricultural districts, to permit its use on land, if it is hauled a sufficient distance from the camp to make sure that any flies which might breed in it cannot reach the camp area. Liquid wastes from the camp, other than those previously mentioned, may be taken care of in a variety of ways, depending on local conditions. If the camp is located in a drainage area tributary to a public water supply, particularly if the drainage from the camp enters such water supply near an intake, extreme precautions are necessary. In the case of camps located on the drainage area of Croton Lake (the main source of supply of that portion of New York City which includes the Boroughs of Manhattan and the Bronx), the following precautions were taken: The camp was surrounded by intercepting ditches, and the rainfall on the area inside these ditches was collected in a settling basin of sufficient capacity to hold the rainfall from substantially all storms. From this settling basin the water was run through sand filters. These sand filters also filtered the wash-water from the camp, this water being collected by a proper sewerage system. The effluent from these filters was afterward dosed with chlorinated lime, so that a substantially sterile effluent was finally obtained—generally much better than the natural flow of the stream into which it emptied. In case of camps located in polluted drainage areas not used for domestic water supply, the omission of filtration for surface run-off from the camp and the substitution of septic tanks or broad irrigation for wash-water, etc., may be permitted.

5.—Character of Construction of Buildings.—Ample provision for air space and ventilation should be made in the buildings, and a minimum allowance of 400 cu. ft. of air space per occupant is believed by the speaker to be none too much. Proper heating in the winter season and suitable lighting should be insisted on. The mess-house should be detached from the other buildings. Hospitals of proper size and suitable equipment should be provided, and a building which may be used as an isolation hospital should be in readiness in case of contagious diseases.

6.—Medication.—A physical and medical examination of applicants for employment is very desirable, and may avoid much subsequent trouble. The continuous attendance of a properly qualified physician, to take charge of the sanitation of the camp and the health of the

occupants, is very important, particularly in camps housing a considerable number of men. Mr. Winsor.

7.—Protection from Flies.—One of the most important problems in sanitation is to prevent, as far as possible, the breeding of flies, which are believed by the speaker to be one of the greatest pests in existence. The daily collection and disposal of all camp wastes, in most of which flies may breed, should be rigidly insisted on, and all quarters for the men, and, in fact, all buildings in the camp, should be properly screened.

8.—Fences and Lighting.—As extreme precautions, high fences of a man-proof type entirely surrounding the camp, with one or more openings which can, when desirable, be placed under proper guard, and illumination of the camp area at night, have been found very effective as aids in securing compliance with sanitary rules.

9.—Police.—An efficient police force, while not essential, is a valuable adjunct in connection with securing the best results.

There is no doubt in the speaker's mind as to the economy of proper camp sanitation. It has been demonstrated as both possible and practicable to eliminate substantially the scourge of typhoid fever and other contagious diseases, and to secure sanitary conditions in temporary camps in advance of those found in most established communities. There is, no doubt, a great increase in the individual efficiency of men employed under proper sanitary conditions, and a large gain also due to non-interruption of the work on account of sickness among the force. The restriction as to time is very important in nearly all construction work, and expenditures for adequate camp sanitation, which should never exceed a small percentage of the cost of the work, will almost invariably be returned several-fold in economy resulting from increased efficiency of the force, earlier completion of the work, and other indirect and less tangible benefits. The safeguarding of the health of the surrounding country is also a most important factor in work located in populous districts.

The efficient enforcement of sanitary rules is a very difficult matter with the class of labor ordinarily employed on construction work, and the immediate discharge of employees who are discovered violating these rules has been found to be the most effective means of securing their enforcement. A continuous campaign of education is also of great value as an aid to securing the best results.*

W. E. Britton, Esq.† (by letter).—The importance of camp sanitation has long been overlooked by both engineers and contractors, doubt- Mr. Britton.

* A very complete and able paper by Andrew J. Provost, Jr., Sanitary Expert, entitled "Sanitary Problems of the Board of Water Supply," outlining the methods and results of sanitation along the line of the Catskill Water-works, the new water supply for New York City, was presented before the Municipal Engineers of the City of New York, and is published in the *Proceedings* of that Society for 1911.

† State Entomologist, New Haven, Conn.

Mr. Britton. less for the reasons given in Mr. Gray's admirable paper. Recent discoveries, which show how many communicable diseases are transmitted by insects, render strict rules and regulations imperative, and sanitary precautions and appliances essential. As regards the laborers, ignorance is their chief excuse, but this is not so with the engineer, who should also be a sanitarian, for prevention is better than cure.

The construction of the Panama Canal was primarily a problem of sanitation, and could not have been solved from other standpoints. The average contractor is probably more easily moved by a desire to further the progress and profits of his work than by humanitarian and philanthropic motives. For this reason, an appeal for sanitation on the grounds of increased efficiency of his men and to prevent economic loss seems to be wise. A few damage suits for criminal negligence in extreme cases might have a salutary effect. Of course, there are many construction, lumber, and mining camps located far from other human habitations, and, in such cases, a neglect of sanitation affects only those connected with the camps. On the other hand, there are construction camps located on the outskirts of many cities and villages, and here a neglect of sanitary measures imperils the lives and health of thousands, though, in most cases, such camps would be within the jurisdiction of the health officer.

After the resident physician, the engineer is probably the most important officer concerned with the establishment of construction camps, and it is to him that we must look in the future for a large degree of improvement in camp sanitation. If he has a knowledge of the dangers and will assume the responsibility of avoiding and remedying them, we are making real progress. It is gratifying that papers of this nature are presented before the Society.

Mr. Austin. F. W. Austin, Assoc. M. Am. Soc. C. E. (by letter).—Mr. Gray is to be congratulated for the manner in which he has presented this subject. The proper sanitation of camps should appeal to many construction engineers and contractors, and it is to be hoped that better sanitary conditions may be obtained. Any method or system, however, to appeal to the contractor, should consist of appliances which are easily and economically obtained. For example, Mr. Gray stipulates that copper or bronze screens should be used to protect the various openings, such as windows, doors, etc. The contractor is usually situated where copper or bronze cloth is not readily or economically obtained, and it is not quite clear to the writer why common iron screens will not answer the purpose quite as well, as they are for temporary use and all temporary buildings are abandoned by the contractor or sold for a nominal sum when the work is completed.

Mr. Austin.

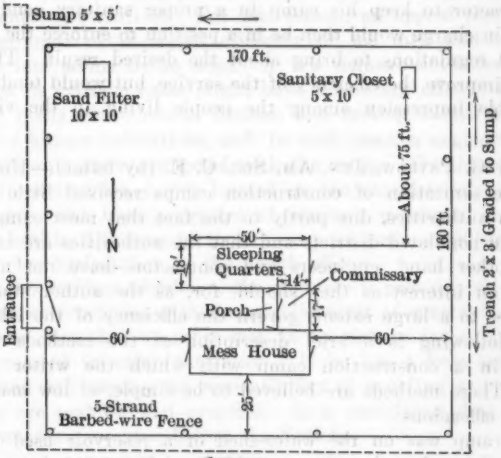
Perhaps the greatest obstacle to be overcome will be the lack of discipline. In the average contractor's camp, a large percentage of the laborers employed remain for a short time only, in some camps from 5 to 15 days is a fair average, and many of them are not enthusiastic about shaving and taking baths. They are also not much given to worrying about disciplinary measures, such as being suspended from the payroll or discharged from service. It is evident, however, that much improvement can be made. It will be necessary to arouse more interest on the part of contractors, for, as a rule, they do not take much interest in the sanitary condition of their camps.

If the company letting the contract would insert a clause requiring the contractor to keep his camp in a proper sanitary condition, the engineer in charge would then be in a position to enforce the necessary rules and regulations to bring about the desired result. This would not only improve the efficiency of the service, but would tend to create a favorable impression among the people living in the vicinity of the camp.

Mr. Payrow.

HARRY G. PAYROW, JUN. AM. SOC. C. E. (by letter).—Until recent years, the sanitation of construction camps received little attention by health authorities, due partly to the fact that most camps are remote from populated districts and that the authorities are indifferent. On the other hand, engineers and contractors have not manifested as great an interest as they should, for, as the author states, camp conditions, to a large extent, govern the efficiency of the labor.

The following is a brief description of the methods in actual practice in a construction camp with which the writer was connected. These methods are believed to be simple, of low maintenance cost, and efficacious.



This camp was on the water-shed of a reservoir used as a city water supply, and at that time an additional $1 000 000 dam was under construction. For convenience, the camp was near the work and on slightly sloping ground. An enclosure was formed, with a man-proof fence of 5 strands of barbed wire, and only one gate was provided. Outside of this fence a 2 by 3-ft. trench was excavated all around the enclosure to catch the storm-water, thus preventing it from reaching the reservoir. The trench was graded to carry the water to a sump where it filtered away.

The sleeping quarters consisted of a well-built, one-story wooden building, covered with weather paper. Instead of the old-style bunks, there were comfortable iron beds, a few being on a balcony along one side of the room. A large coal stove was used for heating. The mess-room was a separate, one-story building, and contained long tables with benches and two or three cook-stoves. Connecting the two buildings there was a commissary, where supplies of good quality were

Mr. Payrow.

sold at reasonable prices. All windows and doors were effectively screened.

The sanitary closets were within the camp enclosure, so that the men would not be tempted to go elsewhere. These were ordinary closets, except that galvanized-iron ash-barrels were used as receptacles. These barrels were taken away regularly every day to a farm situated far from the water-shed, and there emptied, washed, sprinkled with lime, and returned the next day. All garbage was also disposed of in this manner, barrels being placed in convenient places for the disposal of waste matter. At the height of fly-time all

SUGGESTED PLAN
OF A
CONTRACTOR'S CAMP FOR 30 TO 40 MEN

FIG. 6.

sanitaries were sprayed with a formaldehyde solution, which prevented to a large extent the accumulation of flies. For washing purposes, a small sand filter was constructed within the enclosure, and all wash-water was thrown on the filter.

There was a caretaker for the camp, and it was his duty to see that beds were aired daily, floors swept, disinfectant sprinkled about (especially in the sanitary closets), and that the men did not throw refuse carelessly about the enclosure. The patrolman of the water-shed, employed by the city, visited the camp at least once a day and forcibly reminded the caretaker of his responsibility.

Mr. Payrow.

The sanitaries on the work were provided with ash-cans which were collected daily and cleaned, as before stated. Any man on the work who was so forgetful as to fail to use the sanitary closet was either laid off or discharged, according to the seriousness of the offense.

Fig. 6, a plan of a contractor's camp, is submitted merely as a suggestion for a layout. Additional sleeping quarters can easily be provided if a larger number of men are to be employed. It is quite essential that there be plenty of yard room surrounding the building, for this tends to keep the men, while idle, within the enclosure.

After the men understood what was required of them, they gladly conformed to the regulations, and very few breaches occurred. They enjoyed the camp, very few of them left the contractor, and there was no trouble in getting men to come on the work. This was in marked contrast to another camp, of the old bunk variety, on the same work. This was conducted by another contractor, and the men were continually disgruntled and constantly leaving.

Mr. Gray.

HAROLD FARNSWORTH GRAY, JUN. AM. SOC. C. E. (by letter).—The writer is pleased with the kindly reception of this paper by members of the Society. It was his purpose to engage the interest of engineers in the importance of this subject, rather than to write a treatise on camp sanitation. For this reason, brevity was considered essential, and the subject matter was confined to a statement of underlying principles, with illustrations of simple methods of applying these principles to practice. The gentlemen who have kindly contributed to the discussion of this paper have described methods and equipment which, if adapted to local conditions, will work as well as, if not better than, those described by the writer, which were given as illustrations simply because they had been tried out under difficult conditions and had proved effective.

An oversight which the writer regrets is that due credit was not given for Figs. 4 and 5. These photographs were kindly furnished by W. B. Herms, Assistant Professor of Applied Parasitology, University of California, in advance of publication of his recent book, "Malaria—Cause and Control."

Mr. Winsor's discussion brings out several important points. His statement, "under all conditions, incineration [of excreta and urine] is much to be preferred to the latrines suggested by the writer," needs qualification. Restating the fundamental principles of waste disposal, the method is in general satisfactory if (1) during collection the wastes are inaccessible to external agencies (*e. g.*, flies), (2) during collection they do not constitute a nuisance, and (3) they are finally disposed of in such a manner as neither to create a nuisance nor to permit infection. Given two or more satisfactory methods of dis-

Mr. Gray. posal, the decision must rest with the most economical method as regards cost of installation and maintenance.

The minimum limitation of air space in sleeping quarters at 400 cu. ft. per occupant has no real practical significance, in the light of recent investigations. The amount of change of atmosphere is a better criterion for the efficiency of ventilation. For example, a space of 100 cu. ft. per occupant completely displaced four times an hour will in general give better results than a space of 400 cu. ft. changed only once. Small ventilator openings near the ceilings of rooms are cheap and effective. In addition, the men should be encouraged to sleep with windows open.

The writer cannot agree with Mr. Winsor that the enforcement of sanitary regulations is a very difficult matter, unless it is difficult to combine tact with firmness in handling men. He has lived in camps for long periods, in close personal contact with laborers of various types, and has reason to believe that they appreciate a square deal, and that a disposition on the part of the contractor to have some regard for their comfort and health will be met more than half way by the majority. Pride in the cleanliness of the camp can be easily obtained. The illustration given by Mr. Payrow's last paragraph is significant.

Mr. Britton has indicated certain legal phases of the subject. In view of some recent decisions, it is now possible for an employee successfully to sue for damages on account of sickness incurred in camp, if negligence on the part of the contractor can be proved. The imperiling of the health of communities adjacent to camps by reason of unsanitary conditions prevailing therein is a matter within the jurisdiction of local and State health officers, and failure to secure proper conditions in this respect is primarily the neglect of duty by public officials, though the contractor can by no means be excused because of a lax enforcement of the law.

In reply to Mr. Austin's query as to screens, it may be stated that bronze and copper screens do not deteriorate as rapidly as iron, especially in moist climates; they are therefore more economical in the long run, and are to be recommended for all except temporary camps. A rusted and broken screen is worse than useless. Mr. Austin's suggestion as to a clause in contracts requiring the contractor to maintain proper sanitation in camps is excellent, and will work to the benefit of contractor and owner alike.

Mr. Payrow's camp layout, though in general excellent, has one defect. It will invariably be better to separate completely the commissary and mess-house from the sleeping quarters by at least 40 ft.; in winter, a closed passage between the two may be permitted. The use of formaldehyde as described was undoubtedly an extravagance, as it has

no effect on flies, either adults or larvæ, as a contact poison, except in high concentrations and at a prohibitive cost. In warm weather, a few dishes of sweetened 3% formaldehyde exposed where the flies tend to congregate will kill large numbers (the flies drink it eagerly). Pyroligneous acid sprayed about places where flies tend to congregate will be found useful as a deterrent; but, if proper attention is paid to the disposal of wastes (excreta, garbage, manure, etc.), flies, as a rule, will be so few that the use of poisons and deterrents is unnecessary. Mr. Gray.

Mr. Payrow mentions the use of disinfectants. The distinction between disinfectants, insecticides, and deodorants should be borne in mind, and an article suited to the intended purpose purchased. In buying disinfectants proper, the manufacturer should be required to give (especially if a proprietary compound) a guaranty as to the potency of the product in terms of the U. S. Hygienic Laboratory phenol coefficient, as determined by an analysis of samples by a reputable laboratory. The disinfectant should be purchased on the basis of unit cost (price per gallon divided by the phenol coefficient), selecting, of course, the cheapest in unit cost thus determined. Such disinfectants should be diluted to be equivalent in strength to about a 3% solution of carbolic acid. If proper cleanliness is observed, however, disinfectants will seldom be necessary.

The writer thanks Mr. Miller for his illustration by a concrete example of the value of proper sanitation in camps. He regrets that more such illustrations were not presented, and considers this an indication that proper camp conditions are the exception.

The spirit of Mr. Hardman's criticism is especially fine. The writer freely admits that he is far more interested, as a citizen, in the altruistic phase of the question; but his endeavor was to make this a paper of engineering interest. He intentionally addressed his argument to the pocketbooks of engineers and contractors. He sincerely hopes, however, that, for the honor of the Profession, the members of this Society will be moved in this matter as much by their obligations as citizens as by any economic benefits to be derived.

Paper No. 1254

TUFA CEMENT, AS MANUFACTURED AND USED ON THE LOS ANGELES AQUEDUCT.*

By J. B. Lippincott, M. Am. Soc. C. E.

With Discussion by Messrs. J. M. O'Hara, L. J. Le Conte, Ralph J. Reed, Clifford Richardson, Luther Wagoner, E. D. Knap, O. E. Mogensen, Rapier R. Coghlan, Charles H. Paul, O. W. Peterson, Luigi Luiggi, and J. B. Lippincott.

Los Angeles is situated in a region where the annual rainfall is only 15 in., and where a water supply is requisite, not only for domestic necessities, but also for the beautification of grounds and for all forms of intensive agriculture. The Federal census shows that the population of the city increased from 102 479 in 1900 to 319 198 in 1910, or 211%, which is the greatest growth in any of the larger cities of the United States during this period.

General Description of the Line.—The city relies on the Los Angeles River for its local water supply. This stream rises from the gravel beds of the San Fernando Valley, and is uniform in its flow. It has been completely diverted, and encroachments have begun on the underground waters of the neighborhood. What is known as a miner's inch in Southern California is equivalent to 13 000 gal. per day, or $\frac{1}{50}$ cu. ft. per sec. The right to a miner's inch of water of continuous flow in this locality varies in value from $1 000 to $2 000, and is a measure of the scarcity of local water supplies.

Instead of exercising its right of eminent domain, and attempting to condemn other streams in Southern California, which would result in the depletion of commercially tributary areas, the Board of Water

* Presented at the meeting of December 4th, 1912.

Commissioners adopted the broad policy of going to some distant source for its new supply, where the minimum damage would be done to others, and where the maximum quantity of water would be obtained. As the value of water is increasing very rapidly throughout California, it was decided to construct as large an aqueduct as the city could afford. It was found that the most available supply could be obtained from the Owens River, which, for a distance of 120 miles, drains the eastern face of the Sierra Nevada. There are 40 peaks in this crest, the elevation of which rises above 13 000 ft., Mt. Whitney being the culmination of the range, with an elevation of 14 500 ft. This is the source of the water supply. To the east are the Inyo Mountains, a lower range, blanketed by the high Sierra intervening between the Inyos and the Pacific Ocean, and barren of water crop.

Owens River discharges into Owens Lake, having an area of 64 000 acres, from which the annual evaporation loss is about 6.8 ft. The lake has no outlet and consequently is saline. The aqueduct is being built to deliver a continuous flow of 20 000 miners' inches, or 400 cu. ft. per sec., which is two-thirds of the evaporation loss from the lake. The diversion is made 35 miles above the lake, and the city has purchased 105 000 acres of land in Owens Valley, including both banks of the river from the diversion point to the lake.

The precipitation on the crest of the Sierra Range varies from 40 to 60 in., and is mostly in the form of snow occurring during the winter, the drifts accumulating in the high mountain gorges and melting with the approach of summer. These snowbanks, however, are of such extent that they last over from year to year and some of them have compacted into banks of ice. The high-water period occurs in June and July, low water extending from September through the fall and winter. The annual rainfall in the valley floor is only 5 in.

For the first 60 miles, the capacity of the aqueduct as designed is equal to the mean June flood of the river at the intake, or 900 cu. ft. per sec. This portion of the conduit discharges into the Haiwee Reservoir, which has a capacity of 63 000 acre-ft., with a maximum center height of dam of 91 ft. This Haiwee Reservoir will act as a regulator, from which a continuous flow of 420 cu. ft. per sec. will be drawn. In addition to the surface streams, a large Artesian basin

has been discovered in Owens Valley, from which ground-waters can be drawn extensively during years of drought. In case this supply is insufficient, in the driest years and when the consumption of water approaches the full capacity of the aqueduct, the city can build the Long Valley Reservoir, which site it controls. This will have a capacity of 341 000 acre-ft., with a dam having a maximum height of 160 ft.

For the first 20 miles in Owens Valley the conduit is a dredged earthen canal. This part of the line is in the moist bottom lands of Owens Valley, which are saturated with water, and where the aqueduct will gain water. All other portions of the aqueduct are being lined with concrete. The 40 miles of the aqueduct immediately north of the Haiwee Reservoir, because of its large size, is an uncovered, but lined, canal. With the exception of the first 60 miles previously described, all portions of the aqueduct are lined and covered.

From the diversion point in Owens Valley, the line skirts the eastern base of the Sierra Nevada as far south as the Town of Mojave. It then crosses the western edge of the Mojave Desert, passes under the Coast Range, in a tunnel 26 860 ft. long, and then has three drops aggregating 1 842 ft., where power plants are being installed. Immediately above and below the first two power sites, with drops of 1 516 ft., reservoirs are being constructed.

The capacity of the aqueduct between these two power sites has been increased to 1 000 cu. ft. per sec., in order to provide for the variable power load. With these two reservoirs, it will be possible to increase the flow through the power plants during certain hours of the day to 1 000 cu. ft. per sec., and to regulate it back, below the power plants, to a continuous flow of 400 cu. ft. per sec. In other words, the power factor is taken at 40 per cent. Other large storage reservoirs are being built at the extreme southern end of the line.

The total quantity of cement required for the construction of the aqueduct is estimated at 1 500 000 bbl. Table 1 is a summary of the different classifications of work.

The conduit will deliver water at a point 25 miles north of the city, where the distribution system starts. On March 1st, 1912, 83% of the work was finished, and it is being completed within the estimated time and well within the estimated cost.

Classification.	Length, in miles.	Capacity, in second-feet.
Unlined canal	21	900
Open, lined canal	40	900
Haiwee by-pass	2	420
Covered conduit	98	420
Lined tunnels	43	420
Concrete flumes	0.2	420
Concrete pipe, 10 ft. diameter	2.8	420
Steel pipe	9.4	420
Power tunnels	8.8	1 000
Reservoirs	8.5	.....
Total length	233.7	.....

City Cement Plant.—The city has built a standard Portland cement plant on the Southern Pacific Railroad, near the center of the aqueduct line, at a place named Monolith, which is the brand name given to the cement. The mill has a capacity of 1 200 bbl. per day. The operation of the mill is successful, and the cost of producing the cement is reasonably low.

There are six other Portland cement works in California, the products of which are reliable and satisfactory. Apparently, however, there is a definite agreement among these manufacturers as to the selling price. It was not contended that the city could manufacture cement either cheaper or better than some of these larger plants; but the location of the city's cement plant on the line of the aqueduct eliminates 25 or 30 cents per bbl. in freight charges, and it was believed that the city could manufacture its cement on the line of the work at a price which probably would be lower than that for which manufacturers would sell their delivered product. Moreover, by having its own mill, the city is assured of deliveries at the rate required.

The Monolith cement mill is 14 miles from Mojave. A railroad has been built under contract with the city by the Southern Pacific Company, 140 miles long, northward from Mojave, along the line of the aqueduct; because of this special contract, however, freight rates on this new line are high, and amount to nearly 1 cent per barrel-mile.

Three tufa cement-grinding plants have been established on the line of the aqueduct, namely, Haiwee, Fairmont, and Monolith, extensive deposits existing at each of these points. Haiwee, where the northern tufa-grinding plant has been built, is 120 miles by rail

from Monolith, and 106 miles north from Mojave. The southern tufa-grinding plant, at Fairmont, is about 20 miles from the railroad and southwest from Mojave. Transportation charges from Monolith to both Haiwee and Fairmont amount to 90 cents per bbl. As the tufa cement process converts 1 bbl. of standard cement into 2 bbl. of tufa cement, there is saved in transportation charges alone about 45 cents per bbl. on the tufa cement product.

Tuff or tufa is a volcanic, pumiceous rock composed of minute particles bearing indications of having been laid down in water and partly consolidated. Sometimes tufa is a calcareous deposit, but that used for the manufacture of the cement described herein is of volcanic origin. It is of a grayish or creamy color and has a low specific gravity when in rock form; when pulverized, the powder has a specific gravity of 2.2.

According to Dana's "Manual of Geology," puzzuolana is a light-colored tufa found near Rome and elsewhere in Italy, and is used for making hydraulic cement. Puzzuolana is a local name, and tufa or tuff is the geological term. Samples obtained from Italy through the Consular Service in Rome show the puzzuolana to be a light purple-colored fragmental material having somewhat the appearance of volcanic ashes, and unconsolidated. Its analysis is given in Table 2. The tufa used on the Los Angeles aqueduct resembles the German trass, used in the manufacture of the German trass cements.

* $R_2O_3 = Fe_2O_3 + Al_2O_3$.

All the tufa along the aqueduct occurs in beds 100 ft. or more in thickness, and shows distinct lines of stratification, indicating that

it was laid down in water. The beds near Haiwee are in the immediate neighborhood of ancient volcanoes and lava flows. Ancient craters exist in the desert between Fairmont and Monolith. The Fairmont tufa is the purest of the three deposits. It is fine-grained or comminuted, and portions of the bed are entirely free from pebbles or other foreign matter. The Haiwee tufa is quite free from pebbles, but it contains some mica, which makes the grinding slower. The tufa rock at Monolith is more compact, and has a specific gravity of 1.97. It contains a good many pebbles of a flinty character, and occasionally granitic, which makes the grinding slower, but does not affect the quality of the product. The three tufas used on the aqueduct, when blended with cement, are much the same in strength, the average monthly tests showing greater strength first at one mill and then at another.

Silica cement is a term applied to mixtures of cement and silica, usually in the form of sand, ground together in a dry state to a greater fineness than the Portland cement. This mixture is then used with sand and gravel, as in the ordinary method of preparing concrete. The proportion of pure cement is reduced without a corresponding reduction in the strength of the concrete. The voids in the sand are filled with the ground sand, the gradation of the concrete aggregates being thus carried one step farther. This silica is not soluble with lime, and the cement is improved by the regrinding. In 1899 the United States Geological Survey made investigations of sand cement along the upper portion of the Gila River, in Arizona. The tests were made by laboratory grinds and are shown in Table 3. The silica used was a rock known as pearlite, which is a form of rhyolite, from the Butte dam site, and also a quartzite from the San Carlos dam site.

All the tests were made with the same sample of cement. The mixtures were made by weight. It will be noted in Table 3 that, in the case of the silica cements Nos. 1 and 2, all the cement used was passed through a 200-mesh screen. This was unfortunate, because it gave an abnormal fineness, and consequently an undue strength is shown; but, in the case of Nos. 5 and 6, the straight cement was treated in a similar manner, so that comparisons are possible. The sands used were standard in size, but were not standard testing sands.

Comparisons of Test No. 3 with Test No. 5 show the effect of fine grinding on standard cements.

* Some left on 200-mesh screen.

Since 1903, the writer, from time to time, has investigated the possibility of blending tufas with cement. He identified the Haiwee deposit of tufa, and shipped some of it to the laboratory at the Monolith cement mill. This led to the identification of the ledge of tufa in the immediate neighborhood of the mill and also to the discovery of the Fairmont deposit. The tufa was first ground with cement experimentally in the laboratory, and showed satisfactory tests. The experiment of mixing the ground tufa with slacked lime, without any cement, was also made, and it was found that this would set under water and slowly become hard, but it checked in drying in the pats. This hydraulic property indicated the solubility of the tufa in hydrated lime and its power to combine with the excess lime in the cement. This does not occur with silica cement.

A mill run was then made at Monolith, and a length of several hundred feet of canal was lined with tufa cement concrete, in order to observe its working conditions in the field. As this proved satisfactory, it was decided to build tufa regrinding mills at both Fairmont and Haiwee.

The Fairmont mill consists of a Climax jaw crusher which breaks the tufa to about a 1½-in. size. It is then carried to a No. 8 Krupp ball mill, where it is ground to pass through a 20-mesh screen, or

finer. This ground tufa is then blended in equal parts by volume with the standard cement. This blend is then conveyed to a Gates tube mill, 6 by 16 ft. in size, and the tufa and cement are ground together to a fineness of 90% or more passing through a 200-mesh sieve. The cost of the plant was $27 000. The grinding is much freer during the dry summer months in California than during the wet winter weather. A little moisture in the tufa seriously reduces the product, as it coats the pebbles, thus lowering their grinding efficiency. At the Fairmont mill it was found that, under natural conditions, from 1 200 to 1 500 sacks of tufa cement could be ground per 24 hours. By arranging crude drying devices and driving off the moisture in the tufa with a slow wood fire, this output was increased to from 1 800 to 2 000 sacks per day. In both the Haiwee and Fairmont quarries, the capacity of the ball mill is 40% in excess of the capacity of the tube mill.

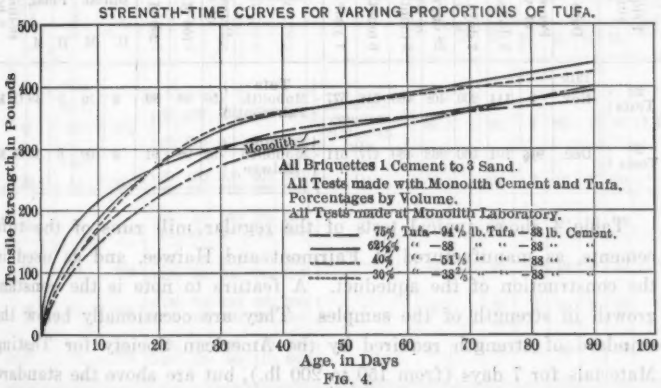

FIG. 4.

Table 2 shows the analysis of various tufas, including the Italian samples and Hawaiian lavas. Tests were made in the laboratory by mixing 4 lb. of tufa, 4 lb. of cement, and 1 lb. of slacked lime. This gave a result from 50 to 75 lb. per sq. in. stronger than when only tufa and cement were used. Subsequently, some mill runs were made with lime added in this manner, but they did not confirm the laboratory tests with lime, and the practice of adding the latter has not been continued. Mill runs were made with varying proportions of tufa at the Fairmont plant, and the results, with different percentages of tufa, are given in Fig. 4. These tests are not fully sustained by later mill and

laboratory tests, in that the higher percentages of tufa at first shown were relatively too strong. Possibly the mill run was not long enough to establish thoroughly the various ratios in the output. Finely ground Monolith tufa mixed with thoroughly hydrated lime in the ratio of 75% of lime to 25% of tufa was made into briquettes with sand in the ratio of 3 to 1. The briquettes were left in a damp closet for 28 days and then immersed in water, and gave the following strengths:

7 days.	28 days.	3 months.	6 months.
40 lb.	80 lb.	70 lb.	225 lb.

The briquettes were softened on the surface by the action of the water.

Table 4 shows typical tests of the regular mill runs of the tufa cements, as manufactured at Fairmont and Haiwee, and as used in the construction of the aqueduct. A feature to note is the constant growth in strength of the samples. They are occasionally below the standard of strength required by the American Society for Testing Materials for 7 days (from 150 to 200 lb.), but are above the standard for 28 days (from 200 to 300 lb.). As far as tested, the tufa cements manufactured on the aqueduct uniformly show this growth in strength with age, and in this respect are superior to the tests for strength in straight cement, which often show a loss after 28 days. Tests made by the Santa Fé Railway indicate that this loss in strength of straight cement continues, as far as observed, through a 5-year period, in four out of five brands tested.*

As tufa cements are high in silica, and as the silicates of lime are the more enduring but slower portion in the cements, this growing

* *Engineering News*, March 14th, 1912.

strength in tufa cement is quite rational. Straight cements which are slow in hardening show the greatest ultimate strengths, and a high 7-day test is regarded with suspicion.

Briquettes made of pure tufa cement without sand do not show as great strength as neat cement, but as cement is not used in practice in this form, it is relatively unimportant. The leaner the mixture in sand briquettes, the greater the superiority of the tufa cements is shown to be. Broadly speaking, sand briquettes containing 50% of tufa cement show marked superiority in ultimate strength over straight cement sand briquettes.

Table 5 shows a series of tufa cement laboratory tests with varying proportions of Monolith tufa with Monolith cement. This table is not in harmony with the mill-run tests shown in Fig. 4, but it appears to be the more rational. It will be noted that there is far less difference in the strengths at the end of 3 months than at the end of 7 days. Unfortunately, the results of the 1-year tests are not yet available.

Table 6 shows the tests of a mill run of 75% Haiwee tufa. It will be noted that the 6-month tests show a fine increase in strength over the 28-day tests.

15 Tests	1911 Nov.	....	52.8	86	201.6	365	Monolith Haiwee tufa	75	99	91	2	00	5	35	O. K.

Fig. 5 shows graphically the average of all breaks of three tufa cements manufactured by the City of Los Angeles during September, 1911. The standard Monolith cement is blended with 50% of tufa by volume. This is the standard practice on the aqueduct work. In making the test briquettes, the straight cement and tufa cement are mixed with standard sand in the ratio of 3 to 1 by weight, except in the one case shown, where the mix is 3 to 1 by volume. The tufa cement weighs 83 lb. per cu. ft., and the straight cement 95 lb. Standard sand weighs 110 lb. per cu. ft. A mixture by weight, as compared with volume, between tufa cement and straight cement, therefore, gives the former an advantage of 14% in the quantity of cement used. However, in mixing the tufa cement with sand by volume, and straight cement with sand by weight, and making the comparison, this is reversed, as the sand weighs 16% more than straight cement. In making concrete the field practice is to mix by volume, which, in the briquette, gives an idea of the strengths obtained in field practice with the tufa cements. Fig. 5 shows that the tufa cements are slower in getting their strength, usually attaining equal strength with the standard cement in from 6 to 10 days, but continuing to grow in strength, as far as observed, as shown in Fig. 6. All tests made in the aqueduct laboratories indicate this continued growth in strength of tufa cements. The standard cement, however, shows a loss in strength between 1 and 4 months, and then a slow recovery. Other California cement tested in the aqueduct laboratories shows similar loss.

In addition to the laboratory tests of the strength of the tufa, the sands and gravels which are used along the line of the aqueduct, were made into concrete with the tufa cements, and cast into test

slabs, 6 ft. wide and 12 ft. 5½ in. long, and loaded to destruction. These slabs were similar to those used in covering the aqueduct. Table 7 shows the details of these tests. The slabs were reinforced as indicated, and in a manner similar to the reinforcement used in the construction of the aqueduct. The wire mesh used is manufactured by

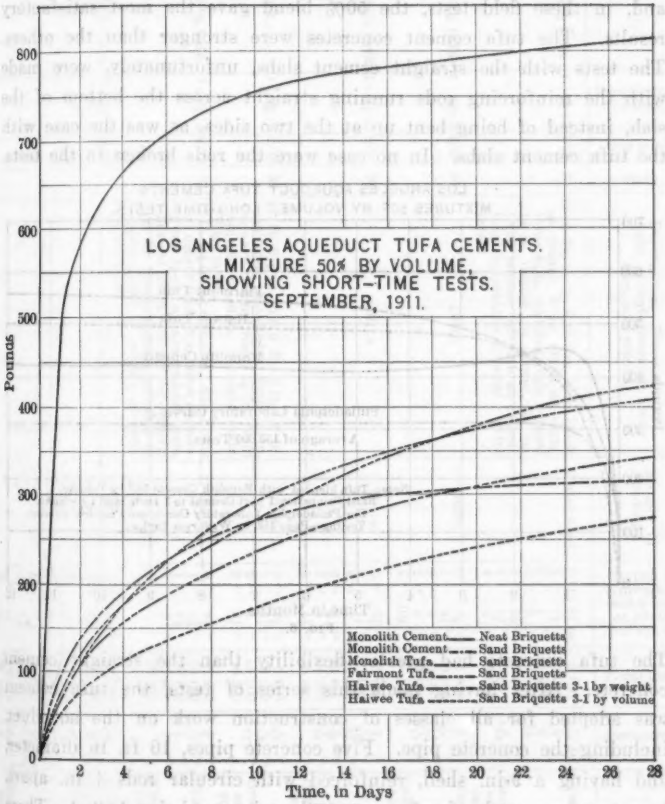

FIG. 5.

the American Steel and Wire Company, being from 58 to 42 in. wide. The practice was to roll these bundles longitudinally along the roof of the aqueduct. The mesh is triangular, 4 in. on a side, with No. 12 longitudinal and No. 14 diagonal wires. The concrete was made by hand, covered with a layer of earth, and kept wet for 20 days, after

which the slabs were dried until they were tested. The slabs were put over piers with a clear span of 11 ft. 5⅝ in. A water load was used, a large canvas bag being put inside of a wooden frame. Tests were first made with earth loads, but the arching effect of the earth destroyed their value. Tufa cements of varying proportions were used, and, in these field tests, the 50% blend gave the most satisfactory results. The tufa cement concretes were stronger than the others. The tests with the straight cement slabs, unfortunately, were made with the reinforcing rods running straight across the bottom of the slab, instead of being bent up at the two sides, as was the case with the tufa cement slabs. In no case were the rods broken in the tests.

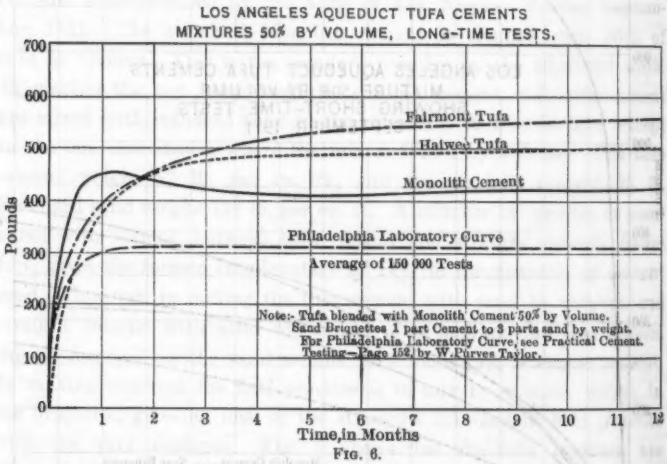

FIG. 6.

The tufa concrete had greater flexibility than the straight cement concrete. After having made this series of tests, the tufa cement was adopted for all classes of construction work on the aqueduct, including the concrete pipe. Five concrete pipes, 10 ft. in diameter, and having a 9-in. shell, reinforced with circular rods 4 in. apart, have now been made of tufa cement, the mixtures being 1:2:4. These pipes have been made for heads up to 75 ft. They have all been filled with water but one, which is necessarily empty until certain other connecting work is completed. Where they have been tested, the pipes are tight, with one exception where a slight circular crack developed. When this pipe was filled with water and soaked up, the crack closed

							5 " 6½ "	40 000	1 1/16 "	
							5 " 10½ "	42 500	2 1/16 "	

and became tight. In no case have any longitudinal cracks developed, and it is believed that the entire water load is carried by the concrete alone. When concrete takes its set, it shrinks slightly and throws the circular reinforcing steel under compression. Before the steel can carry the load, it must come under tension, and experience with concrete pipe elsewhere indicates that there is enough movement between these two conditions of tension and compression of the steel to cause a longitudinal crack in the concrete unless it carries the entire load. As a practical working test, therefore, this pipe of tufa concrete demonstrates the quality of the material.

The tufa concrete has also been used successfully in the lining of some tunnels in which the ground is exceedingly heavy, and where the sets in the tunnel, made of 10 by 10-in. timbers, spaced from 2 to 3 ft. apart, were repeatedly crushed. The tunnel lining, which has a theoretical thickness of 14 in. between posts, has not shown any failure. In the heaviest ground, however, 6-in. steel I-beams were placed and wedged up against the lagging, the wooden sets then being taken out. This was done because in some instances the timbers were so close together that they reduced seriously the thickness of the concrete tunnel walls. The steel I-beams are left embedded in the concrete as a reinforcement.

Laboratory tests of the tufa product are made continuously at all the tufa mills, and samples are also sent to the main laboratory at the Monolith cement plant. Figs. 5 and 6 represent an average of a month's breaks of briquettes made with equal parts by volume of straight cement and tufa mixed with three parts of standard sand. These are fairly typical of the average monthly mill runs, the tufa cements showing better results than the straight cements and also showing a continued hardening. In the case of the German trass cements, this hardening is known to continue for a period of five years. The lower line on Fig. 6 shows the average of a great number of breaks of various Portland cements at the Philadelphia Testing Laboratories.

A striking feature of the tufa cement is that, in all the four years in which it has been tested, there has never been a pat which failed under the boiling test. This indicates, further, that any free lime which may occur in the cement combines with the silicas in the tufa. Microscopic slides were made of some of the tufa cement and

sand briquettes. They were examined, but no satisfactory conclusion could be reached.

Samples of tufa cement were sent to the Bureau of Standards of the United States Department of Commerce and Labor, and were tested in the Pittsburgh Laboratory. The following quotation is from a letter from this Bureau under date of March 29th, 1911:

"* * * You desired particularly to know whether there was any chemical reaction between the tufa and the cement. The enclosed report shows that such has undoubtedly been the case.

"The addition of tufa or puzzuolana to Portland cement undoubtedly does not reduce the strength of the latter when in the form of a mortar or concrete, but there has always been a question as to whether this is due to purely chemical or chemical and physical phenomena. There has not been any doubt that there is a reaction between the cement and the tufa, but there always has been a doubt as to whether this reaction was sufficient to account for the usual strengths developed by such mixtures.

"The tests were conducted as follows: Mixtures of two parts Riverside cement with one part of tufa, and two parts Riverside cement with one part Ottawa Standard sand, ground 90% through a 200-mesh sieve, were made into briquettes and broken at the end of one-week, four-week, and thirteen-week periods. At the same time, a similar series, using Atlas cement, was carried on, and also the same mixtures used in connection with 1:3 sand briquettes. After breaking the thirteen-week period briquettes, they were dried, the outside surface completely removed, and the interior ground to pass 200 mesh, and used for determinations. By determining the amount of insoluble silica in the cements and in the tufa and quartz, it is possible to calculate the amount of insoluble silica which should be in the dry briquettes (by dry, meaning the complete expulsion of water and CO_2 at 1 000 degrees C.). From the analyses of these residues, there was also obtained the insoluble silica actually present. The difference between these two gives the amount of silica rendered soluble during this period of thirteen weeks. The figures are given in the following table:*

"The following results were obtained in breaking the briquettes:

Riverside.	2 Riverside, 1 tufa.	2 Riverside, 1 quartz.	
0.53	30.97	34.02	SiO_2 insoluble, calculated.

The neat briquettes made with tufa cement by the Bureau do not show as much strength as those made with straight cement. This is in harmony with tests made in the aqueduct laboratories. However, when cement is used in concrete, it is always blended with sand, and the sand briquettes tested correspond to practice in construction work. The tests made with the sand briquettes show that the tufa cements have as good strength as the straight cements, or better, and that the blend made of equal parts of tufa and cement is stronger than that made with but 33% of tufa. They also show clearly that the tufa cement, when mixed with sand, gives much better strength than the silica cement, indicating that the tufa combines in a different manner from the silica. In the neat briquettes, however, the silica cements develop the greater strength. The characteristic of the tufa cement continuing to harden substantially with age is indicated in these sand briquette tests. At the time the samples were sent to Pittsburgh, the Fairmont tufa was being blended with Riverside Portland cement. All other tests given of Los Angeles aqueduct tufas were made with the city's cement known as Monolith.

A review of an elaborate series of tests of the German trass cement, is given in a recent engineering periodical.* These are the best available laboratory tests of tufa cements. The investigations were carried on especially to determine the effect of sea water on cements of this class. They were made under the direction of the Prussian Minister of Public Works, and a committee consisting of representatives of the Royal Testing Laboratories, of the cement and trass industries, and Dr. Michaelis, cement specialist. The Royal Testing Laboratories were placed in their charge. Cements of two classes were used, those rich in lime and those poor in lime, and also mortars to which had been added trass and finely ground quartz sand, in order to determine whether trass only acts mechanically by increasing the density of the mortar, or chemically also. The tufas blend slightly better with the cements which are richer in lime. The results of these tests show that the addition of certain puzzuolana (tufa) materials to lean cement mortar is valuable in sea water. The detailed table (Table 9) is given because of the variety in the record,

* *Engineering Record*, August 27th, 1910.

the long period of the tests, and the excellence of the authority. The tests run over a period of five years.*

This cement (Table 9) contained 65.80% of lime, and 23.74% of silica. The cements which have been blended with trass give as much tensile strength as the straight cement when made in sand briquettes, and the samples put in sea water show results of slightly less strength than when they are put in fresh water. The compressive strength of the concrete is less with the trass cements than with the straight cements.

An additional table† shows the strength of mortars and concrete made with a mixture of three parts of trass, two parts of hydrated lime, and one part of sand, giving tensile strengths of 216 lb. in 28 days, 356 lb. in 1 year, and 400 lb. in 5 years. A mixture made of 1½ of trass, 1 of hydrated lime, and 1 of sand gave a strength of 244 lb. in 28 days, 383 lb. in 1 year, and 360 lb. in 5 years.

It is noteworthy in Table 9 that the straight cement sand briquettes, in three out of four instances, show marked loss in tensile strength between 1 and 5 years, the first test alone showing constant strength, while the tufa (trass) combinations show gains in six out of eight cases during the same periods. The two tests showing loss are of samples in sea water.

Dr. W. Michaelis‡ has written an interesting paper on "Portland Cement Reground with Oregon Puzzuolana," in which he enters into a discussion of the chemistry of the problem, and makes a demonstration of the solubility of the tufa with the excess lime of the cement. He shows that puzzuolana (or tufa) will combine with hydrated lime. The series of tests given show the same general results as the tests with German trass cements (Table 9)—that, especially with the leaner mixtures, the tufa blends of equal parts are fully as strong in tension as the straight cement mortars, or superior to them, and markedly better than the "silica cement." In the tests for compression in the leaner concretes (1:3:6), his tufas are as strong; but, with a richer mixture (1:2:4), they are about 20% less strong than concrete made of straight cement with the same aggregates.

* The results have appeared in a report of the Royal Testing Laboratory under the title, "Mittellungen aus dem Kgl. Materialprüfungsamt."

Dr. Michaelis gives the following explanation of the chemical reactions that occur when the tufa combines with the cement:

"These desired hydrates of silica, alumina and iron oxide are found in nature in the form of puzzuolanas, or tufas, volcanic products created by the action of water or steam upon basaltic or granitelike molten formations. They can be artificially obtained by running molten blast furnace slag into water. In both cases the original compounds of the basalt, granite or slag are completely decomposed into their constituents and, furthermore, transformed into comparatively loose material which can easily be crushed. The most valuable part of the various chemical ingredients to be found in a natural or artificial puzzuolana is the silica hydrate, so-called 'soluble' silica which, in distinction from quartz silica, powdered quartz, is soluble in a 10 per cent. solution of sodium carbonate. Such silica combines readily with calcium hydrate and forms an excellent hydraulic cement. To what extent the alumina hydrate and iron hydrate combine with calcium hydrate has not been definitely ascertained. However, from recent researches it appears that especially the alumina hydrate is able to combine with a very large percentage of hydrated lime."

Cost to Manufacture.—The average cost of blending 1 bbl. of straight cement so as to produce 2 bbl. of tufa cement with the small mills installed on the Los Angeles aqueduct is about 74 cents, distributed as follows:

	Cost per barrel of blend.
General expense—labor, live stock, etc.	$0.04
Electric power, at 1.85 cents per kw-hr.	0.105
Quarrying	0.025
Mill operations	0.20
Net milling cost	$0.37

The process of blending 1 bbl. of straight cement with an equal part by volume of tufa gives a resulting product of approximately 10% in volume in excess of 2 bbl. of tufa cement. For this reason, a little more than 1 cu. ft. of tufa cement is put in a sack. A sack of tufa cement weighs 83 lb. The cost of milling tufa cement will vary with the density of the rock. This cost of 37 cents per bbl. of tufa cement applies to all three of the tufa-grinding plants. The tufa at Monolith is denser and slower to grind; but, as this tufa mill is a part of a larger plant, the milling costs are no greater than at the other two places.

Action of Tufa Cement in Field Work.—Tufa cement is more sensitive, and requires greater care in curing, than straight cement, because it is slower in reaching its final hardness. As a rule, Los Angeles aqueduct tufa cements will show as great strength in 7 days as the straight cements, and after that period the tufa cement gains in strength faster than the straight cement. (See Fig. 5.) The tufa cement has to be kept wet longer in hot weather to attain full strength, and is subject to frost longer in cold weather. In slab work, where it is supported by forms, the forms should be left in two or three days longer with tufa cement than with straight cement. When the aqueduct roof slab (which has a span of 11 ft. 5 in.) is made of tufa cement, the forms are stripped in 6 days, in moderate weather. The particular places for which tufa cement is adapted are in massive work, in foundations, and in wet places. It is not claimed that it is suitable for high, thin walls exposed to the dry air of arid regions. It may be, but this has not yet been demonstrated on this work.

Gaugings made in arid America show that the greater portion of irrigation water diverted in earthen canals is lost by seepage before it reaches the fields. A lean tufa cement containing 75% of tufa could be used for earthen canal linings, and would be fully as dense as concrete made with straight cement. It would have sufficient strength to stand up on 1:1 slopes, and it can be given as smooth a surface as ordinary concrete. A length of several hundred feet of open canal lining of this kind has been put in the open flood section of the Los Angeles aqueduct, with 75% tufa. The concrete does not show up as hard in the field as the 50% tufa concrete, but it is satisfactory. Tufa cement, in being more finely ground, adheres somewhat more to the forms than concrete made with straight cement, which is a slight disadvantage. In places along the aqueduct where 50% tufa concrete joins concrete made with straight cement, both being a year old or more, no difference can be detected in the quality of the concrete by picking into it. Plaster made of tufa cement is smoother, and the laborers, after they get used to it, prefer it to straight cement plaster.

Prejudice Against New Cement.—Some cement manufacturers take a stand against tufa cement for two reasons: because it is a cheaper product, with which they would have to compete; and because,

having established a business for a standard Portland cement, anything which might be considered an adulteration would possibly mitigate against the reputation of all cements. This active opposition has already been encountered among the cement manufacturers in Southern California, who opposed the proposed building ordinance of Los Angeles containing a provision permitting the use of tufa cements. If, however, a product can be furnished which is cheaper in cost and as good in quality, the consumer should have the benefit of it, and undoubtedly will ultimately derive this benefit.

Some foremen and superintendents are also prejudiced against the use of a new product. This is true generally in various branches of industry, and it applies to tufa cement. On the Los Angeles aqueduct, it was found that some of the foremen at first endeavored to avoid the use of tufa cement, but now, after the lapse of two or three years, and having had some practical experience with it, they are willing to accept either that or straight cement from the city mills without any hesitation for all classes of work.

Other Combinations.—Diatomaceous earths are found at various places along the Pacific Coast. Their analysis is similar to the tufas, which they resemble somewhat in appearance and in physical characteristics. A test made with a diatomaceous earth found near Santa Barbara gave the following results:

	Monolith cement. 1 to 3 sand.	Half Monolith and half diatomaceous earth.
3 days	100	210
7 days	200	300
28 days	310	370
3 months	330	620

The briquettes were made as provided for in specifications for testing cements. Only one set of tests was made, and this table is not given as conclusive evidence.

In the Hawaiian Islands, the volcanic rocks prevail. As far as the writer's knowledge of that country extends, there are no lime deposits suitable for the manufacture of cement. The black basaltic lava has been analyzed by the branch of the Department of Agriculture located on the islands, and the following contents determined:

SiO_2	TiO_2	Fe_2O_3	Mn_3O_4	K_2O	Na_2O	CaO	MgO	FeO	Al_2O_3
51.98	1.50	2.90	0.92	0.97	2.70	9.57	5.61	6.84	15.85

It is difficult to grind this lava in the mills. There is another form of volcanic material, locally called red clinker, which resembles somewhat in appearance a cement clinker. Experiments were made in grinding with Santa Cruz cement both the basaltic lava and the red clinker in a local tube mill. The results are given in Table 10. After making the first three tests, 1½% of gypsum was added, which improved the strength of the material. All these tests were made with mixtures of one part of the cement indicated to three parts of standard sand. While the results did not seem to be as satisfactory as those obtained with the Southern California tufas, nevertheless, enough strength was developed to indicate the possibility of blending these lavas with cement in such a way as to result in an economy.

It will be noted that the chemical analysis of the lava quite closely resembles the analysis of tufa, and it is this resemblance of chemical properties which suggested the experiments with the lavas. There is a marked difference in their physical characteristics as compared with the tufas. They have not been comminuted by contact with water as the tufas have, a process which is considered important, if not essential.

Conclusions.—The following conclusions are drawn for tufa or puzzuolana cements:

1st.—The tufa, when finely ground with cement and used in concrete, combines both chemically and mechanically. Blends of 50%, when mixed with sand, give greater tensile strength after 10 days than straight cement mixed with the same proportion of sand. The leaner the mixture, the greater the relative superiority of the tufa cement. In compression, the tufa cement concrete is less strong (20%) in rich mixtures (1:2:4), and as strong in leaner mixtures (1:3:6).

2d.—Tufa cements, in tension, of blends from 30 to 80% show a continued growth in strength with age, as far as tested, up to 5 years, and in this respect are superior to straight cements, which usually show declining strengths.

3d.—The tufa concretes must be handled with greater care with reference to both cold and drying, and forms should be left in place about one-third longer. In massive work this feature is negligible.

4th.—From the fact that the tufa cement is more finely ground and, in part, combines mechanically with other aggregates, carrying

the gradation of fineness one step farther, it makes a denser and more impervious concrete.

5th.—Where cements are high priced, a substantial economy may be effected if deposits of tufa are available. These conditions occur in portions of Western America. The milling cost of producing the extra barrel of tufa cement in small plants should not exceed 75 cents.

The development of the tufa cement on the aqueduct, as is usually the case with affairs of this kind, is the result of the co-operation of a number of different parties. Mr. E. Duryee, Cement Chemist for

the aqueduct at that time, conducted the preliminary experiments. Mr. G. M. Andrus, who succeeded Mr. Duryee as Cement Chemist, has done a great deal in investigating these cements. Mr. Andrus has been of much assistance to the writer in the preparation of this paper. The cement plant is under the direction of Mr. Roderick MacKay, Mechanical Constructor, and William Mulholland, M. Am. Soc. C. E., is Chief Engineer in general charge of the work on the aqueduct. The writer has been Assistant Chief Engineer since the beginning of the work.

DISCUSSION

Mr. O'Hara. J. M. O'HARA, ASSOC. M. AM. SOC. C. E. (by letter).—According to Professor Eakle, of the University of California, the rock ground with the cement used on the Los Angeles Aqueduct, is a rhyolite-tuff and a trachyte-tuff, which, when finely ground, will possess the same characteristics as finely ground clay.

The cement produced by the method used at Monolith and Haiwee, Cal., is similar to cement adulterated with clay. Rhyolite-tuff and trachyte-tuff are not to be confounded with the volcanic rocks known as puzzuolana and trass, which have been used for the manufacture of cement. Puzzuolana and trass are the hardened products of volcanic action in their original state, in which respect they are similar to blast-furnace slag. On the other hand, the volcanic tuff of the nature found at Monolith and Haiwee, is not comparable to blast-furnace slag, being more of the nature of altered volcanic rock.

In Professional Paper No. 28, issued by the United States Government, through the Corps of Engineers, it is stated:

"Puzzolan cement never becomes extremely hard like Portland, but Puzzolan mortars and concretes are tougher or less brittle than Portland. * * * It is unfit for use when subjected to mechanical wear, attrition, or blows. It should never be used where it may be exposed for long periods to dry air, even after it is well set. It will turn white and disintegrate, due to the oxidation of its sulphides at the surface under such exposure."

A series of tests made at the Ohio State University, under the direction of Professor C. E. Sherman, seems to prove that clay, up to 15% of the weight of the sand, adds strength to the mortar. One plausible explanation for this increased strength is that the addition of smaller particles of material aids in filling the voids in the sand. One detrimental result was definitely established, namely, that mortars made from sand carrying clay could not be placed under water safely, because the clay softened and warped under its influence.

Mr. Lippincott states:

"As tufa cements are high in silica, and as the silicates of lime are the more enduring but slower portion in the cements, this growing strength in tufa cement is quite rational. Straight cements which are slow in hardening show the greatest ultimate strengths, and a high 7-day test is regarded with suspicion."

Tufa and Portland cement, as used on the Los Angeles Aqueduct, is a mechanical mixture, the two materials being blended in equal parts by volume. Under these conditions, no silicates of lime are found, and the gradual increase in strength is not due to the same cause as the slow hardening of a high silica Portland cement.

In setting under water, especially sea water, the lime set free from cement by the action of the water combines with soluble silicates, and maintains the strength of the mass. The percentage of lime set free is small, however, and in the Aqueduct product would not combine with much of the silica. When the concrete sets in air, little or no combination with the tufa will take place, and it is only present as an adulterant. Mr. O'Hara.

In the manufacture of Portland cement to-day, the clinker is ground much finer than was the custom some years ago, and the lime factor is higher. Consequently, the calcium silicates hydrate more readily, and ultimate tensile strength is reached at an earlier period. Besides, the flash strength, due to the calcium aluminates or gypsum, should not be mistaken for the final strength, due to the calcium silicates.

A high 7-day strength is not of itself an indication of poor quality in a cement, all other things being normal; it may be an indication of early ultimate strength.

The writer is of the opinion that the trend of the paper, to show that the tufa cement, as made at the Los Angeles Aqueduct, is as good as a Portland cement, is dangerous and without precedent.

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—The natural property possessed by tufa of combining with the free lime in all Portland cements, is certainly a very great discovery, the full importance of which cannot be over-estimated. This interesting feature is further emphasized by the announcement of Dr. Michaelis that his tests, extending over five years, show conclusively that the addition of tufa to lean Portland cement mortar is valuable in sea water, this latter being especially important to harbor engineers. In view of the general experience that Portland cement concrete slowly disintegrates in sea water, Italian harbor engineers usually recommend a mixture of puzzuolana and Portland cement for all concretes exposed to its ravages. In many cases where unit strength and quick setting are uncalled for, they use a mixture of ordinary fat lime and puzzuolana. This shows a tendency to return to the old Roman practice, long before the time of Vitruvius, 14 B. C., and recalls the old adage: "Verily, the footprints of the old Roman engineers are eternal." Mr. Le Conte.

The writer's attention was first called to the fact of the falling off in strength of Portland cement briquettes after 1 year, while on the fortifications at and near Fort Point, San Francisco, Cal., in 1895 to 1897. At that time some 350 000 bbl. of European Portland cements had been used. The records showed a general falling off in strength after 1 year, a few samples extending to 10 years. The same feature was noticed in the reports of the Metropolitan Water Board, Boston, Mass., and seems to be the experience everywhere.

The author's experiments, indicating that sand briquettes con-

Mr. Le Conte. taining 50% of tufa cement showed marked superiority in ultimate strength over those with straight Portland cement after 6 months, are certainly most encouraging.

Years ago, the writer decided that the well-known "Dyckerhoff" brand of Portland cement was the best in the market, but its use was prohibited by its high cost due to transportation expenses from the works to the seaport. In private works under his charge, he overcame this difficulty with a 1:5:10 concrete, which gave highly satisfactory results. It would be exceedingly interesting to know how tufa cement in the same proportions would behave.

There seems to be a fad for demanding "sharp coarse sand" in specifications for concrete. This fad is based on the general craze for short-time high tests, and nothing else. Engineers often go to great expense to get good coarse sand to make a high-test record, when, in point of fact, after 3 months, briquettes made with fine beach sand show just as great strength as those made with coarse sand, if not greater; that is, after the expiration of 3 months, all the advantages of using coarse sands have entirely disappeared. The cost of manufacture given by the author is most encouraging, and puts new life into the industry.

The lining of irrigation canals in leaky ground is certainly a most serious question, and all sorts of expedients are being tried to overcome the practical difficulties. The proposed lining with lean concrete seems to be the best solution of the problem. The experiments with Kieselguber are very instructive, and broaden the entire field of investigation.

Mr. Reed. RALPH J. REED, JUN. AM. SOC. C. E. (by letter).—It is obvious that, on account of finer grinding and consequently better mechanical combinations with other aggregates, tufa cement must make a more dense and impervious concrete. It would have been interesting to have presented some experimental data showing comparisons between the permeability of straight Portland cement concretes and those made with tufa Portland cement. Doubtless experiments along these lines have been carried on in the Los Angeles aqueduct laboratories.

The writer wishes to bear witness to the excellent appearance in general of the concrete work on the aqueduct. A large portion of this work has been constructed with tufa cement concrete. By far the largest portion of the work has been completed under conditions which those at all familiar with Western deserts will recognize as far from ideal for the most successful concrete work. It has apparently been difficult at many points to obtain first-class aggregates. Water for sprinkling the finished work has been hard to supply, and, in fact, the many difficulties encountered are appreciated only by those connected most closely with the work. The writer has been especially impressed with the freedom from cracks shown by the finished tufa

cement concrete work in tunnels, open and covered conduits, and especially in the large reinforced concrete siphons referred to by Mr. Lippincott. Mr. Reed.

That the tufa cement must be handled with greater care during drying is apparent from the fact that in the vicinity of open manholes along the covered conduit in the Mohave Desert, where the concrete during the later stages of drying has been exposed to the sun, cracks are frequent. A little farther back, where the atmosphere has been humid on account of water left standing in the conduit, very few cracks are noticeable. In the tunnels, where the atmospheric conditions, and especially humidity, have been most completely in control, the tufa concrete lining is dense, hard, and tough, and rarely shows any cracks.

CLIFFORD RICHARDSON, M. AM. SOC. C. E. (by letter).—The title of this paper might well have been puzzolan cement, instead of tufa cement, in order to make it more intelligible to the cement expert. From a geological point of view, tufa is, no doubt, a more accurate designation of the material in use in California than puzzolan, but the latter is commonly used, as witnessed by the title of Part VII of Eckel's "Cements, Limes and Plasters," which is "Puzzolan Cements." Eckel includes among puzzolanic materials "all those natural or artificial materials which are capable of forming hydraulic cements on being simply mixed with lime, without the use of heat." It is stated by Mr. Lippincott that by mixing the ground California tufa with lime, without any cement, it would set under water and slowly become hard. The material, therefore, may be recognized as being puzzolanic. From the analyses of the tufa in use in California, it appears that those denominated Fairmont and Monolith contain a much higher percentage of silica than is found in the puzzolans from Italy and France, and in the trass from Germany, the percentage of silica in the Italian materials varying from 39 to a maximum of 63, in those of France from 31 to 48, and, in the case of the trass from Germany, 46 to 67.6, according to Eckel. The California material corresponds more closely in composition to santorin earth, which carries as much as 73%, and averages 66.4%, of silica. Unfortunately, no data are available showing what proportion of the silica in any of the materials occurring abroad, or in those in California, is soluble in acid, as it is hydrated silica of this description which possesses the greatest hydraulic value. There seems to be no question, however, but that the ground mixture of Portland cement and California tufa produces a true puzzolanic cement. Mr. Richardson.

It appears that the tufa in California is ground and then blended with the Portland cement. It is natural to suppose that the tufa cannot be economically ground unless it has been thoroughly dried, in view of the general experience in the cement industry with grinding

Mr. Richardson.

slags and other raw materials. To the writer it would seem that it would have been better practice to grind the tufa and the Portland cement clinker together at the same time, in the same mill, as a more intimate mixture of the materials would result.

One fails to find in the paper the results of any tests of the tufa cement with the local sands in use, either in tension or compression. Data of that description would be instructive, especially as it has been recognized, at least in Germany, that tensile strength tests of cement are of small importance as compared with those in compression, and, on this account, have been abandoned there.

Mr. Lippincott states that:

"A striking feature of the tufa cement is that, in all the four years in which it has been tested, there has never been a pat which failed under the boiling test. This indicates, further, that any free lime which may occur in the cement combines with the silicas in the tufa."

To the writer, this does not seem to be a conclusion which can be justified. It merely means that the cement has been ground finer by passing it through the Gates tube mill after the two materials have been blended, and, consequently, that it does not contain the coarse particles which cause pats to fail under the boiling test, a test which the best German authorities consider of very little value, and which seems to the writer to bear no relation to the conditions to which the cement is exposed in actual construction.

It appears that, in its Pittsburgh laboratory, the U. S. Bureau of Standards has determined the amount of insoluble silica in the cements and in the tufa, but, unfortunately, the percentages of soluble silica are not stated in the paper, although there is sufficient evidence that there is a considerable percentage of silica in the tufa in a hydrated condition which, in the cement in a set condition, is in the soluble form, although there is no evidence that it is combined with lime.

It would be interesting to determine in some manner the hardness of the puzzolan cement in concrete and its resistance to attrition and impact, as compared with Portland cement. It is frequently deficient in this respect, and is not always as satisfactory as concrete made with Portland cement. Mr. Lippincott is quite right in stating that a cement of this type is more satisfactory when used in moist places and in masses where it cannot dry out, than where the latter is possible, and, on this account, work done with it requires greater care in order to permit of satisfactory setting than that done with straight cement.

Based on the writer's experience with sand cement, it would seem that there was plenty of justification for using tufa cement in the California work, but it will be interesting to watch its behavior during a long period of years.

Mr. Wagoner.

LUTHER WAGONER, M. AM. SOC. C. E.—Influenced by the reports of the successful use of tufa by the Los Angeles Aqueduct Board, the speaker located several tufa claims for a contemplated work in Arizona, and until recently supposed that the successful use of tufa was definitely settled. In 1911, some parties desired to build a dam and other works near Prescott, Ariz., which would require large quantities of cement. The speaker furnished them with samples of his tufa and was informed that they had also used these and other near-by samples in combination with Portland cement from Iola, Kans., and Portland, Colo., and that all the samples thus tested gave poor or negative results.

On the speaker's return homeward, he compared samples of the Arizona tufa with those of California tufa, in the Aqueduct office at Los Angeles, the samples appearing to be nearly the same in physical characteristics. Both seemed to be rhyolite tufa.

In June, 1912, he received a copy of a "Report on Municipally Manufactured Cements, Los Angeles Aqueduct," signed "Gervaise Purcell, W. H. Sanders, F. C. Finkle, Chester B. Loomis, Consulting Engineers." This was a report made to Mr. Edward M. Hagar, President of the Association of American Portland Cement Manufacturers, Philadelphia, Pa., in which they attacked vigorously the results obtained by mixing tufa with the cement made by the Aqueduct engineers. They claim that the hydraulic index of the municipally manufactured cement is as low as 1.66 to 1.69, while average American Portland cement has an index averaging 1.91, and German brands 1.98; and they also claim that the tufa used is the physical equivalent of clay, hence the poor results found by them.

Thus far, the speaker has not heard of any public denial by the Aqueduct Board of the truth of the above quoted charges, and the whole matter is thus enveloped in doubt. It would certainly be a matter of considerable interest to the Profession to have careful tests made of the said California tufa, using a standard brand of cement, so that this element of uncertainty as to hydraulic index might be removed, and at the same time settle the question, whether the real benefit is not due so much to the character of the adulterant as to the fact that the regrinding with the tufa brings a larger percentage of the otherwise inert, non-setting grains of Portland cement into a finer state, whereby, when wetted, they "gel" or enter into a colloidal condition.

Concerning the incidental matter of fine grinding, the speaker at one time made tests on a certain fine-grained ore carrying silver chloride, the pan tailings assayed 12 oz. per ton, and 11% of the silver was soluble in "hypo"; 1 gramme of the tailings was ground for 1 hour in an agate mortar with "hypo", and every effort was used to crack and break up the grains of mineral, the result being that 50% of the silver was made soluble. On washing and separating the

Mr. Wagoner.

coarsest grains, the latter were found to have a maximum diameter of $\frac{1}{100}$ mm. This test shows that the finer grains probably have a cushioning effect which protects the larger ones from effective action, and this raises the question: Could not the present methods of grinding clinker be greatly improved by using a gradual reduction method in which the fine dust would be removed more promptly, and thus enable much finer grinding of the cement, and probably with greatly improved efficiency, by enabling a larger percentage to act as colloids?

With his present information on the matter, the speaker considers that there are still several points to be cleared up before venturing on the extensive use of tufa as an adulterant or adjunct to Portland cement.

Mr. Knap.

E. D. KNAP, ASSOC. M. AM. SOC. C. E.—The speaker has looked up some records relative to one phase of this tufa cement question, that is, of Portland cement ground with varying percentages of silica, which makes a compound not unlike that of tufa, in that the main ingredient of the latter seems to be a form of silica. These records show the results of tests up to 6 months for mixtures in which the Portland cement ranges from 100% down to 12½ per cent. The strength of the 100% mixture starts with 417 lb. at 7 days, and runs up to 650 lb. A Portland cement ground with an equal weight of white quartz, making a 50% cement, starts at 270 lb. at 7 days, and runs up to 653 lb. at 6 months, which is 201% of the strength of the neat cement, considering the cement content of the mixture.

There is another compound which consists of the second, that is, the 50% Portland cement, and 50% sand, one part each of sand and cement ground together, and another part of crushed quartz mixed with it mechanically. This compound started at 257 lb. and ran up to 614 lb. in 6 months, which is 283%, counting the Portland cement at 33⅓ per cent.

There was still another mixture which was one part each of cement and sand ground together, with two parts of quartz added, making a 25% mixture. This mixture started at 264 lb. and went to 585 lb., which is 360%, considering the quantity of cement it contained.

From these figures, it would seem that the chief thing to be gained by adding and grinding together silica of any kind and Portland cement, is first to provide a filler, and secondly to increase the impalpable portion of the Portland cement, because everybody knows that only a small part of the cement in the average Portland cement is of any use, and that is the impalpable powder. The remainder acts as a filling to hold it together, and by grinding quartz and cement together, the binding proportion is very much increased by the additional fine grinding, which cannot be obtained in any other way, at least, it cannot be obtained commercially in any other way.

Mr. Knap.

For instance, in addition to this 25% mixture, there is another 25% mixture of the same brand of Portland cement mixed with three parts of standard crushed quartz sand, as in ordinary mortar, and that starts at 134 lb., as against 264 lb., and only runs to 388 lb. at 6 months, which is very much less than 585 lb.; and it seems to the speaker that this "diluted" cement, this tufa, is beneficial chiefly in that, for a certain quantity of cement used, a very much greater strength is obtained because of this grinding, as the fine content fills the voids. For instance, the strength of the 25% mixture of sand and cement in the ordinary way as mortar, and the strength of the corresponding mixture partly ground together, is as 1 to 1½; that is, the mixture ground together is 151% of the strength of the ordinary mortar; therefore, it would seem that, aside from the possible combination of some of the free lime, or the extra lime, with the soluble silica of the tufa, as against the insoluble silica of the quartz, probably the greatest advantage is derived from the extra grinding.

The speaker has also the results obtained with a 12½% mixture, a mortar made with three parts of standard crushed quartz sand and one part of the 50% "ground together" mixture previously mentioned, which, at 6 months, shows a strength of 126%, considering the cement content. This mixture, however, starts at only 96 lb. at 7 days and takes 28 days to reach the minimum strength allowed for 7 days. Obviously, this would unfit it for use in any work requiring early strength, no matter how strong it might become later; and this same trouble, namely, the lengthening of the time required for work to "stand alone," seems to be one of the strongest arguments against "diluted" cements in general. They all seem to be good enough in the course of time, but time is often a governing factor. This is true, not only in the case of form work, where every day that the forms have to be left in place causes additional expense, but even more so in cases where frost or bad weather must be considered.

The time consideration applies somewhat to the remarks of others in reference to fine *versus* coarse sand. A sand which will give great ultimate strength may be unfit for use in many cases, because immediate strength also is required. The speaker's experience with different sands, however, leads to the conclusion that, to say that a fine sand is poor and a coarse sand is good is not in all cases accurate. He has found good fine sands and poor coarse ones. The measure of efficiency in any sand, it would seem, is in the difference in the relative sizes of the grains composing it, rather than in the actual maximum size of some of the grains; or, expressed differently, in the absence of voids, which are likely to be much less in a sand having grains with a great range of sizes than in one in which the sizes are more uniform.

Mr. Mogensen

O. E. MOGENSEN, M. AM. SOC. C. E.—During the past two years more or less comprehensive articles have appeared in the technical periodicals mentioning this half-and-half mixture of cement and tufa used on an extensive scale on the Pacific Coast. The subject is an important one, of interest to engineers throughout the United States, and the speaker, therefore, was pleased to see it described so thoroughly and comprehensively before this Society.

The high results in tensile strength and the generally good behavior of the laboratory tests, described so fully in this interesting paper, are obtained partly by the chemical reaction and partly by the process of re-grinding in the tube-mills the straight Portland cement mixed with tufa to a fineness greater than that generally required for Portland cement. By this process the two materials are mechanically and intimately mixed and pulverized, which, of course, could not be done on the mixing board. This applies to tufa, or puzzolan, or to slag.

The question as to why fine sand, which is generally known to produce an inferior mortar as compared with coarse sand, in this instance gives such high tensile strength, is readily explained, and is really the secret of the whole process; it is due to the re-grinding and intimate mixing process in the grinding mills.

The combination of Portland cement with a certain percentage of puzzolan is a subject which occupies many minds at the present day; and, whether it be as tufa cement, slag cement, sand cement, or cement mixed with diatomaceous earth, the speaker agrees with the author in his statement: That the consumer should derive the benefit, if a product can be furnished which is cheaper in cost and as good in quality. To this the speaker would add: and provides the same degree of safety to structures occupied by people, or to structures otherwise dangerous if insecure. It must be borne in mind that a large percentage of the cement manufactured, perhaps the largest, is used for concrete in bulk, and for work of lesser importance, and for this a puzzolan cement will meet all requirements, and in certain cases be more satisfactory than straight Portland.

It is natural that the cement manufacturers on the Pacific Coast should oppose such a radical step as this, but it is certainly a very short-sighted policy when the finished product, the concrete, as claimed in the paper, has been proved to be free from defects, and continues to give good results.

Table 1 is a summary of the different classifications of the work. It is not clear from this table that the tufa cement was used in the construction of the 91-ft. dam of the Haiwee Reservoir. The paper describes its application for the lining of canals, the covering of conduits, and for pipes, tunnels, and reservoirs. The speaker would like to know if the engineers of the Los Angeles Aqueduct made any

discrimination against the use of the tufa cement by excluding it from structures in which possible defects would have serious consequences, causing loss of life. Such discrimination would seem very natural, as no one can predict, even from the most elaborate and carefully conducted laboratory tests, how a new material, such as concrete made from this tufa cement, will stand in the course of years. Mr. Mogensen.

Mr. Wagoner's personal opinion and expressions of the views held by some of the engineers on the Pacific Coast are not very encouraging, although not convincing, as they reflect a doubt as to the stability of the work. It is to be hoped that several disinterested engineers who have given this work time and study will contribute liberally to the discussion of this paper. If the author's conclusions, which apparently agree with the results obtained in Europe with like materials, the so-called trass cement, are borne out by the test of time, the knowledge of this material and process cannot be spread too soon for the benefit of the Engineering Profession.

There are, of course, sections of the country and many cement plants where proper materials of this and of similar composition are not available or cannot be obtained at a reasonable price, where no benefit would be derived by deviating from the standard Portland cement practice. This fact, however, should not mitigate against those plants and those communities which would be in a position to benefit by the combination referred to.

Under the heading, "Other Combinations", the author mentions that diatomaceous earth resembles the tufas in their analyses and in physical characteristics, and he gives the result of a set of tensile tests of one-half Monolith cement mixed with one-half diatomaceous earth. At the Congress of the International Association for Testing Materials, New York, 1912, a paper on this subject entitled "Diatom-Earth as Puzzolan for Cement," was presented by Mr. A. Poulsen, Chief Engineer, to the Danish Government Maritime Works. In this paper Mr. Poulsen describes the favorable results he has obtained by mixing diatomaceous earth, in proportions determined by chemical analyses, with Portland cement clinker, the two substances being pulverized together in the mill. The cement thus made has shown remarkably good results by producing a concrete which has the property of resisting very effectively the action of sea water. Mr. Poulsen's theory agrees with the author's, in so far as the laboratory tests he has conducted show that a chemical reaction takes place between the cement and the diatomaceous earth. The free lime, which he estimates constitutes 30% of the weight of Portland cement, and which in sea water becomes the direct source of disintegrating the concrete by being transformed into calcium sulphate, combines

Mr. Mogensen.

with the silica hydrate and the alumina hydrate in the diatomaceous earth. The diatomaceous earth which he used contains:

Soluble silicic acid (SiO_2).....	51.6 per cent.
Soluble alumina (Al_2O_3).....	8.5 " "
Making a total of.....	60.1 per cent.

of active substance available for the absorption of the free lime in the concrete.

Mr. Poulsen's paper also contains the results of tests of the tensile strength, of the chemical relations, and the compressive strength of mortars with and without puzzolan. By these tests he wishes to point out the distinct advantage of using diatomaceous earth, as compared with the trass or tufa, and the results agree essentially with those of the author in respect to the advantage of the leaner sand mixture as compared with the richer mixtures.

Mr. Poulsen's statement that the cement when mixed with water contains free lime to the extent of 30% of the weight of Portland cement surprised the speaker, but, in discussing this matter with his associate, Mr. Pontoppidan, Chemical Engineer, the latter confirms the presence of a considerable amount of free lime in mortars made from Portland cement, and explains the chemical reaction which takes place in the following manner:

"This 'free' lime, which is Ca $(OH)_2$, calcium-hydrate, or what is ordinarily called slaked lime, crystallizes as such in long needles, and is important in giving the cohesive strength to the mortar. When Portland cement is mixed with tufa, trass, or 'Moler' (diatomaceous earth), and then made into a mortar with water, the alkali-soluble silica in the tufa, trass, or 'Moler' will enter into combination with the formed calcium hydrate, so that this, instead of crystallizing as such, crystallizes as mono-calcium silicate, after this formula:

$$Ca(OH)_2 + SiO_2 + H_2O = CaO, SiO_2, 2\,H_2O.$$

This is the same chemical process which gives the strength to the sand-lime brick, made of 98 parts of sand (silica) and two parts of slaked lime; only, in this case, the silica in the sand is not soluble, and a prolonged storage in superheated steam of 8 atmospheric pressure is required to effect the combination.

"The alkaline water of the desert countries contains, very often, potassium sulphate ($K_2\,SO_4$) and sodium sulphate ($Na_2\,SO_4$); these salts are undoubtedly destructive to Portland cement in the same manner as is the magnesium sulphate in the sea water, and it is therefore reasonable to assume that the admixture of trass, tufa, or 'Moler' to the straight Portland cement will be as beneficial for concrete work in these countries as it is for sea-water works."

The paper entitled "The Effects of Alkali on Cement," by George G. Anderson, M. Am. Soc. C. E.,* mentions this very condition, and

* *Transactions*, Am. Soc. C. E., Vol. LXVII, p. 572.

in the discussion, attention is directed to remedies which may be found by using puzzolan cement rather than straight cement. There is, therefore, good reason not to condemn offhand this adulteration, which for certain purposes may prove superior to straight Portland cement and for others equally well adapted. The speaker is fully aware of the danger and the difficulty opened up by the introduction of two or more standards for cement. These difficulties, however, will gradually be overcome if the combination can prove its right to existence, that is, its technical and economical advantages. Mr. Mogensen.

RAPIER R. COGHLAN, ESQ.* (by letter).—The blended cement manufactured by the City of Los Angeles for use in the Aqueduct would have been spared many criticisms if a more fortunate name had been applied to it. The officials of the Aqueduct Commission, in their various papers concerning the product, have used indiscriminately the terms, tufa-cement, tufa-Portland cement, puzzolan-cement, and puzzolan-Portland cement. Some engineers, not aware of the real composition of the cement, have claimed for it many of the bad qualities of the artificial puzzolans, such as are manufactured from blast-furnace slag and hydrated lime; while others have claimed that it is a simple adulteration of Portland cement with clay or clay-like material, and therefore harmful. These claims are widely at variance with what is actually the case. Mr. Coghlan.

The term sand-cement, while ordinarily meaning a blend of pure silicious sand and Portland cement, is not of necessity restricted to such a combination, but can be applied to a blend of Portland cement with granitic, basaltic, or many other sands that contain other elements and minerals than quartz. Even in the case of the Aqueduct cements, the tufa had to be reduced to a coarse sand before it was possible to blend it with the Portland cement. For this reason, it would seem that the best name to adopt for such a blended cement would be sand-cement. The nomenclature allows of the use of many materials, which have been experimented with and found to be as well adapted to the process as tufa.

Experiments have been conducted by the U. S. Reclamation Service on the blending of Portland cement with basalt, basaltic tufa, rhyolitic tufa, granite, andesite, trass, infusorial earth, and sandstone. In every instance it has been found that excellent grades of sand-cements can be produced from these materials, cements, which, up to the present time, have shown little or no decrease in strength. Researches on limestones and quartzites have shown, that, excepting those instances in which the amount of material added to the Portland cement was less than 40% by volume, these materials are not suited to the process.

It is a geological fact that the ultimate products of the decomposition of igneous or volcanic rocks are clays. Experiments by eminent

* Mfg. Cement Chemist, U. S. Reclamation Service, Elephant Butte, N. Mex.

Mr. Coghlan

men in the Engineering Profession have shown the deleterious effect of the addition of clay to Portland cement. Some concrete failures have been traced to the presence of too much clay in the sand or gravel, so that engineers have become accustomed to setting a maximum limit on the quantity of clay allowable in sand which is to be used for concrete. The results obtained with the so-called tufa-cement do not indicate that clay or clay-like substances have been blended with Portland cement. Tests made by the U. S. Reclamation Service laboratory, on material from the Aqueduct plants, corroborate fully the data set forth by Mr. Lippincott; in fact, by using a brand of cement (which was a recognized standard brand) other than that used at the Aqueduct plants, the results were greatly exceeded.

Careful chemical analyses of the raw materials suitable for sand-cement manufacture show that they are all dependent for their fitness on the quantity of colloidal or active silica; and many of the materials tested by the Reclamation Service experimentalists show a higher content of colloidal silica than the Los Angeles tufa. Most of these materials are harder to pulverize than tufa, but the resultant cement has proven to be as good in every particular. So fruitful have been the results of the researches that three sand-cement plants are being operated or erected by the Service: at Arrowrock, Idaho, Lahontan, Nev., and Elephant Butte, N. Mex. When all three of these plants are in operation, they will have a combined daily output of 2 300 bbl. of sand-cement. Such a wholesale manufacture and use of sand-cement would not be permitted by the engineers in charge of the work if the product was considered unreliable or apt to deteriorate with time. At those places where the cement is being used it is proving its worth. Little or no difference is apparent between sand-cement concrete and Portland cement concrete. It must be mixed a little dryer, and it sets and hardens more slowly than Portland cement concrete. The forms come away clean from the set concrete, and the water that comes to the surface brings little or no cement with it. Daily tests are made on all concrete placed in the dams, and the results of the compressive tests show that it is amply strong for the great stresses put upon it.

Sand-cement is of economic importance to the engineer in the West, as it allows him to use a cheaper cement at a price a little more than half of that of straight Portland. Before undertaking its manufacture or use, two things must be settled: The Portland cement must be of undoubted quality, a standard brand passing all tests; and the blending material must contain colloidal silica and be in an almost unaltered condition.

Mr. Paul.

CHARLES H. PAUL, M. AM. SOC. C. E. (by letter).—This paper opens up the subject of the use of blended cements, which is of great

interest to all engineers engaged in work in the West, where high freight rates and long wagon hauls usually combine to make the cost of Portland cement excessive. Mr. Paul.

In the construction of the Arrowrock Dam—which is being built by the U. S. Reclamation Service to store the flood waters of the Boise River—about 550 000 cu. yd. of concrete will be laid, and the cost of cement is, of necessity, a most important item. The dam is about 22 miles above the City of Boise and 17 miles above Barberton, the nearest point on the Oregon Short Line Railroad. A railroad from Barberton to Arrowrock has been built by the United States Government, over which the freight rate on cement charged against the work is 23 cents per bbl. The commercial freight rate on cement from Utah mills to Barberton is $1.14 per bbl., from California points $2 per bbl., and from Kansas points, $2.09 per bbl.; so that the total freight charges on cement to the Arrowrock work are from $1.37 to $2.32 per bbl.

Laboratory tests on sand-cement have been carried on by the Reclamation Service for 6 years or more, and, during the winter of 1910-11, when the investigations in connection with the storage works on the Boise River were nearly finished, a series of these tests was started, using for blending material the native rocks in the vicinity of Arrowrock, particularly granite from the spillway site, a large quantity of which would have to be wasted during the construction period.

TABLE 11.—AVERAGE OF THREE LONG-TIME TENSILE TESTS ON SAND-CEMENT MORTARS (1 TO 3, BY WEIGHT, STANDARD SAND), EACH TEST BEING AN AVERAGE OF 5 BRIQUETTES; AND COMPARISON WITH MORTARS MADE FROM PORTLAND CEMENT USED IN THE MANUFACTURE OF THE SAND-CEMENTS AND TESTED UNDER THE SAME CONDITIONS.

Kind of cement.	7 days.	28 days.	3 months.	6 months.	1 year.	2 years.	3 years.	5 years.
Sand-cement.....	219	333	397	423	457	423	449	444
Portland cement.....	266	400	425	482	460	496	428	404

Blending material for sand-cement was river sand, bank sand, or granite, blended in each case with equal parts by weight of Portland cement.

TABLE 12.—AVERAGE LONG-TIME TENSILE TESTS ON 13 BRANDS OF PORTLAND CEMENTS USED BY THE U. S. RECLAMATION SERVICE DURING THE LAST FIVE YEARS.

Mortar briquettes, 1 to 3 by weight, standard sand.	7 days.	28 days.	3 months.	6 months.	1 year.	2 years.	3 years.	5 years.
	260	373	448	447	432	411	379	398

Mr. Paul. It is noticeable that there is not the marked decrease in strength in the case of the sand-cement briquettes as is shown here, and is so common with Portland cements.

TABLE 13.—SAND-CEMENT TESTS ON MATERIAL FROM ARROWROCK DAM SITE, ARROWROCK, IDAHO.

Blending material, spillway granite. Mix, 1 to 3 by weight with standard sand. Strength, in pounds per square inch.

50	1 471	1 763	2 729	3 121	3 712
70	458	938	1 215	1 256	1 560

In Table 13 the first line in each case (0% blending material) represents the Portland cement from which the sand-cement is made, tested under the same conditions.

Investigations of the actual use of sand-cement in structures which had been in service for 10 or 15 years, further tests in the local laboratory, and estimates of cost of installation and operation of the necessary equipment, finally led to the decision to use sand-cement, in so far as practicable, in the construction of the Arrowrock Dam, and to use for blending material granite from the spillway excavation.

A sand-cement plant, with a capacity of 1 000 bbl. per 24 hours, consisting of a crusher and sand rolls, rotary dryer, ball mill, mixing machine, and three tube mills, all electrically operated, with the necessary bins, hoppers, and conveying machinery, has been erected and has been in operation for about 2 months. The cost of this mill, complete, was about $46 000, itemized as follows:

Excavation	$1 500
Foundations	3 750
Erection of building, chutes, etc.	8 150
Equipment, including freight	23 000
Installation of equipment	7 850
Electrical work	1 750
	$46 000

Mr. Paul.

The total output of the mill to date has been about 25 000 bbl., and about 20 000 cu. yd. of sand-cement concrete have been placed in the dam, up to the present time.

All incoming Portland cement is tested and accepted before shipment. All sand-cement is tested for fineness, blend, setting time, and tensile strength in 1:3 sand briquettes, and is subjected to the boiling test before being used in the work. Tests for fineness and blend are made every hour that the mill runs, or oftener if either needs correction, and the other tests are made on an average sample from each day's run. The blend now being used is 45% granite by weight, and the requirement for fineness is at least 90% passing a 200-mesh sieve. Standard Portland cement requirements are satisfied by the other tests, and no sand-cement is used until it has passed the 7-day tensile tests of 200 lb. per sq. in. The writer's experience with sand-cement confirms that of the author with tufa cements, that no sample tested has ever failed to pass the boiling test.

TABLE 14.—MILL-RUN TENSILE TESTS ON SAND-CEMENT MANUFACTURED AT ARROWROCK.

All tests on 1:3 standard sand briquettes. Strength, in pounds per square inch.

Average of all (52) 7-day tests	258	Average of all (29) 28-day tests	332
Average of 10 lowest 7-day breaks	221	Average of 10 lowest 28-day breaks	304
Average of 10 highest 7-day breaks	297	Average of 10 highest 28-day breaks	366

None of the sand-cement tested has failed to pass either the 7-day or the 28-day requirements. Occasionally, briquettes have been broken at the age of 4, 5, or 6 days, and in every case yet tested these briquettes have shown a strength exceeding 200 lb. per sq. in.

TABLE 15.—COST OF MANUFACTURING SAND-CEMENT.

Items	Unit cost of sand-cement, per barrel.
Granite delivered to crushers	$0.02
*Portland cement, including freight and storing	1.35
Handling and storing Portland cement	0.08
Labor, operating	0.10
Power and lights, including maintenance, etc	0.16
Installation, depreciation, supplies, repairs, etc	0.14
Total cost	$1.85

*Portland cement @ $2.36 per bbl., f.o.b., Arrowrock.

A representative cost of manufacturing 1 bbl. of 45% by weight blend of sand-cement at Arrowrock is given in Table 15, which includes depreciation, on the plant and installation, at a rate which

Mr. Paul. will wipe out the total cost at the time that a total output of 500 000 bbl. is reached. It does not include sacking, as most of the sand-cement will be used in bulk.

The use of sand-cement under actual working conditions brings out several characteristics that are different from those of Portland cement.

Comparing sand-cement concrete with Portland concrete, batch by batch, an experienced concrete man will note no difference, either in its appearance or in its behavior while being spread, but, after a run of an hour or two, in mass work, it will be noticed that an ordinary plastic or quaking mixture gives off water more readily than does Portland cement concrete, and that this water is clearer and apparently carries less cement than is the case with ordinary concrete.

A mushy or really wet mixture which is worked up continually shows, at the surface, an accumulation of sloppy material which is more marked than in Portland concrete and sets and hardens very slowly. In fact, it is the writer's opinion that, for this reason, extremely wet mixtures should be avoided, especially with sand-cement concrete.

Sand-cement concrete sets more slowly than ordinary Portland concrete, and its slowness in hardening is very marked. It is natural to assume that internal shrinkage stresses, due to setting and hardening, will be less on this account, but, at the present time, we have no other evidence on this point.

The writer has not noticed that sand-cement concrete adheres to the forms any more than Portland concrete, and as he has had no occasion to use sand-cement plaster, he has not had an opportunity to compare it with ordinary cement plaster.

The author states that tufa cement makes a denser and more impervious concrete than Portland concrete. The writer has heard this statement made before, both in connection with tufa cement and sand-cement, but has never found record of any experiments or definite evidence to that effect. It would be interesting if the author would discuss that point more fully, and give the members the benefit of any experiments along that line with which he is familiar.

It is natural for the ordinary construction man to look on a new product with prejudice, especially when it shows characteristics to which he is not accustomed; but, supposing, for the sake of making a comparison from another viewpoint, that sand-cement had been in general use for years and that Portland cement were the new product being introduced; would we look with favor on a cement which almost invariably showed a decrease in strength after a few months? Or one which not infrequently failed to pass the boiling test? Would we consider it a favorable sign that the excess water coming to the surface of concrete apparently brought with it an unusual quantity

of cement? Quick-setting cements are usually considered undesirable for use in mass work, and were we accustomed to the slow-setting and slow-hardening sand-cement, might we not look with suspicion on a quick-setting cement, especially if one of the quicker-setting Portlands happened to be the first of the new product to fall into our hands? Mr. Paul.

The use of sand-cement in mass work, where the requirements are enough to justify the installation of the necessary grinding machinery, where suitable blending material is available, and where the transportation charges on Portland cement amount to a considerable portion of its cost laid down, will result in a marked saving in construction costs, and will give a product which is at least the equal of the Portland cement from which it was made, in fact, one which, for ordinary requirements, is not open to the least suspicion.

O. W. PETERSON, ASSOC. M. AM. SOC. C. E. (by letter).—The use of Haiwee tufa cement in the lining of about 40 miles of ditch of 930 sec-ft. capacity, during the past 3 years on the Olancha Division of the Los Angeles Aqueduct, has given the writer considerable first-hand experience with this product. This cement has been used, not only for lining the ditch, but in building various structures, such as arched flume crossings of 33 ft. span, etc. In fact, tufa cement has been used in exactly the same manner as any other cement, except that account has been taken of its slow setting. Mr. Peterson.

This open ditch section is excavated with long-boom, power shovels to as neat a line as possible, but, necessarily, in trimming the ditch to a true surface behind the shovels, back-filling is generally required. In such a dry country as this, which has an annual rainfall of only 5 in., the use of a well-compacted back-fill was considered, and has proven sufficiently good construction.

Against this trimmed earth section the 6-in. concrete lining is placed, without the use of forms. The finished ditch is 11 ft. wide at the bottom, with a 1-ft. invert, and the side slopes are 1 to 1. The depth of the ditch is about 13 ft. The concrete side lining is placed in alternate sections, 12 ft. wide, only 2 by 6-in. board strips being used to support the edges of the first set of alternate panels put in. Necessarily, the placing of concrete on such a steep slope without forms, cannot, even with the best efforts, result in the greatest compactness. Thus the tufa cement concrete is subjected to a further test, but again experience has shown that the strength of the slabs is sufficient to carry the load even against a support partly or entirely of back-fill.

The usual mixes of concrete have been 1 to 5 and 1 to 6, depending on the aggregates used. Generally, an extremely clean gravel, ranging from 40 to 75% of stone on the ¼-in. screen, has been easily obtained, but at places it has been necessary to add crushed rock.

Mr. Peterson.

The ditch is plastered with an extremely thin coat of 1 to 3 plaster, and for this purpose tufa cement seems to be especially well adapted, due largely to its fineness.

The temperatures in this locality range from 110° in summer to 8° in winter. A slow-hardening cement must be carefully protected at either of these extreme conditions. In summer, fresh work is sprinkled constantly for 2 weeks and covered with boards or canvas. In winter, boilers are used to furnish hot water for mixing purposes, thus turning out a warm concrete. This precaution, together with a covering of 1-in. boards or several layers of canvas, is sufficient protection against frost. The plaster is also mixed with hot water in winter, but generally no plastering is done in mid-winter.

From this brief description of operations, one can realize how difficult is the test to which the concrete for this work is subjected; and yet the practical completion of this division and the actual test of a full ditch of water for the greater part of 20 miles of work for 2 years' time has proven that the canal is water-tight. As the side concrete is really made up of separate 12-ft. slabs, slight joint lines show when the ditch is empty, but the expansion of the concrete due to moisture closes these, as well as other cracks, as the ditch is filled. Horizontal cracks are very infrequent, and arise from numerous causes, chief of which is probably occasional carelessness in back-filling. As a proof of the imperviousness of the lining, the leakage of the 20-mile section referred to has been less than a miner's inch per mile. This new ditch has never had running or muddy water in it.

The concrete has no tendency to swell under the influence of moisture, except to such an extent as all concrete expands in passing from a dry to a wet condition. This is a most desirable property for ditch lining, as it insures water-tightness.

In order to determine the value of cement rich in tufa, a carload of 75% tufa cement was obtained from Haiwee, and 300 ft. of concrete lining was put in with the usual mix. The laboratory tests showed that this special tufa was very slow setting. Frequent comparative tests for hardness were made of the special 75% tufa concrete and the ordinary 50% tufa concrete, using a pick for the purpose. At first the special tufa was much the softer, but as weeks went by the two products approached the same degree of hardness. At the last visit, when the age of both concretes was 10 weeks, there was but little difference in hardness. In fact, two visiting engineers were unable to detect any difference. This test seems to be proof of the value of Haiwee tufa. There are no perceptible cracks or indications of disintegration in the 75% tufa cement concrete. It will be watched with a great deal of interest.

In the lining of open canals, where proper care can be taken of the fresh concrete, slowness of hardening is no inconvenience. A saving

of from 40 to 60% in the cost is sufficient consideration to warrant the extensive use of tufa cement. No doubt the use of long-boom, power shovels to excavate canals, and the lining of the section with tufa cement concrete could have wide application in the economical building of many large irrigation channels, resulting in a great saving of water now lost by seepage, and consequently a large extension of irrigated areas. Mr. Peterson.

About twenty-five cars of straight Monolith cement have been used at times when the Haiwee mill could not supply the demand. Concrete made with this cement sets faster, but, as far as has been observed, it shows no advantage in ultimate hardness and strength over that made with Haiwee tufa.

A comparative test was made with blocks of tufa cement concrete in the strongly alkaline waters of Owens Lake and in fresh water. On removal, the concrete block which had been in the lake water 6 months was sound and apparently unaffected by the alkalis. It was not different in appearance from the block which had been in fresh water. However, this is not considered conclusive, as only from careful and extended tests can a thoroughly reliable conclusion be reached.

Luigi Luiggi, M. Am. Soc. C. E. (by letter).—From time immemorial, pozzolana, which is a variety of tufa, has been used in Italy for preparing mortar capable of setting under water. Mr. Luiggi.

The usual proportion is one volume of slaked lime and two volumes of pozzolana, mixed very intimately. Generally, the mixing is done by hand, but, lately, it has been done by machinery, which grinds the pozzolana more finely and mixes it more intimately with the lime. In this latter case the mortar is far superior, and sets more quickly, than when the mixing is done by hand. This is because the machinery makes a much more intimate mixture of the ingredients, and the silica of the pozzolana can act more directly and quickly on the hydrated lime.

All the harbor works by the Romans, which have lasted until now, for instance, that at Porto Trejano, at Porto d'Anzio near Rome, and Porto Adriano near Bari, were built with mortar, either for masonry or for concrete, made as indicated; and even now all, or nearly all, sea works in Italy are made in the same way, and always with excellent results.

However, pozzolana has one drawback: it sets very slowly, from 10 to 15 days in summer—when the heat accelerates the chemical reaction of pozzolana on lime—to from 15 to 30 days in winter. As it never freezes in Italian harbors, construction work is carried on throughout the winter, but, during that season, the setting of the mortar is very slow.

For accelerating this setting, Portland cement, in the proportion of 100 to 200 kg. per cu. m. of pozzolana concrete, is often used. The

Mr. Luiggi.

setting then takes place in 24 hours, or even less, and thus the concrete stands better the washing of waves, when it is laid under water or is used for bag-work.

This concrete has always stood perfectly the chemical action of salt water, as the silica of the pozzolana neutralizes all the free lime, which is inevitable even in the best Portland cement. There is even an excess of silica, which makes the mortar rather acid—not basic—and thus the action of the sulphate of magnesia of the sea-water is better counteracted.

The necessity of having a mortar of greater resistance, and more rapid setting qualities, however, has induced Italian harbor engineers to adopt Portland cement mortar and concrete. The writer was perhaps the first to use it in 1882 in some parts of the Harbor of Genoa. In those days, as Portland cement was rather a novelty for Italian engineers, the mortar was made rather rich in cement, at least in the proportion of 1 cement to 2 of fairly graduated sand with from 30 to 35% of voids, and often even 1 to 1. These mortars, and the concretes made with them, have stood the action of salt water very well. On the other hand, with mortars made afterward, with a smaller proportion of cement, or with sand rather fine, that is, with more than 35% of voids, the results have been bad, and, in some cases, disastrous. This the writer attributes to the porosity of the mortar, which, under the shock of waves, or the action of tides, permits the salt water to penetrate and percolate through the mortar and decompose it. On the other hand, when the mortar is rich in cement, and as impermeable as it is possible to make it, the action of salt water is nil, or at least so much diminished as to cause no bad consequences.

Therefore, the writer always recommends his engineers to use at least 10% more Portland cement than the quantity necessary to fill all the voids of the sand, and the extra expenditure for cement is only a very small fraction of the cost of the mortar or of the concrete, and absolutely negligible in comparison with the damage that might result by the decomposition of the mortar.

There is always, however, the latent danger of the free lime, unavoidable in Portland cement, being acted on by the sulphate of magnesia, with the consequent decomposition of the mortar. It was for this reason that the writer, in 1888, used, and has recommended ever since,* the addition of some pozzolana in Portland cement mortars and concretes, in order to neutralize this free lime. In this he took advantage of experience on the Roman sea-works. If they lasted some eighteen centuries, certainly the addition of pozzolana to Portland cement will correct the dangers of the free lime.

*"La Pozzolana ed il Cemento Armato nelle Opere Marittime," *Giornale del Genio civile*, 1910.

Mr. Luiggi.

Experience in Italy since 1888 has been uniformly good, and now pozzolana is being used for improving the concrete for the construction of a very large graving dock in Venice, which will be 850 ft. long, 120 ft. wide at the entrance, with 40 ft. of water on the sill.

The composition of the concrete for this very important work is shown in Table 16.

TABLE 16.

Components for 1 cu. m. of concrete.	Concrete in contact with sea-water for a thickness of about 6 ft.	Concrete for the inner mass of the graving dock.
Portland cement, in kilogrammes....	400	250
Pozzolana, in liters.....	150	70
Sand, in liters.....	450	440
Broken stone, in liters.....	1 000	1 000

This really gives a little more than 1 cu. m. of concrete.

The practice of adding pozzolana, or its equivalent in trass, or tufa, to Portland cement for sea-works is becoming rather common. It is followed in Holland and Germany, and was adopted also by the Japanese in the construction of the Nagasaki Dry Dock, and, thus far, the results have been uniformly good.

Pozzolana, or trass, or tufa, are volcanic materials of very little cost, the transportation being the only real drawback to their more general use.

Besides neutralizing the free lime of Portland cement by the large quantity of silica in these materials, they tend also to make the concrete less permeable, by the colloidal action of the alumina they contain.

The usual proportion recommended by the writer is about $\frac{1}{2}$ to $\frac{1}{3}$ of pozzolana for 1 volume of cement, the higher proportion being for Roman pozzolana, containing from 51 to 53% of silica, and $\frac{1}{3}$ for Naples pozzolana, which contains from 62 to 65% of silica.

This addition of pozzolana, besides adding very little to the cost of Portland cement concrete, makes it less permeable and eliminates the danger of decomposition in sea-water. The experience on Roman works made with pozzolana concrete and exposed to salt water for more than eighteen centuries is a guaranty of the soundness of this practice.

Thus the use of tufa cement, or Portland cement reground with tufa, as practiced on the Los Angeles Aqueduct, is quite correct, both with regard to the cost and the durability of the work.

The mortar and the concrete will certainly be less permeable than if ordinary Portland cement had been used, and impermeability is an all-important condition in all aqueducts, especially in one of such magnitude as that of Los Angeles.

Mr. Lippincott.

J. B. LIPPINCOTT, M. AM. SOC. C. E. (by letter).—The writer is gratified at the generous number of contributions that have been presented in the discussion of this paper, especially as arguments have been given vigorously on both sides of the question. Before entering into a review of the discussion, it is desirable to add certain data which have become available since the paper was written.

On page 530 there is given a test (up to an age of 6 months) of a mortar made of 75% of hydrated lime and 25% of tufa. The 1-year break shows a strength of 252 lb., an increase of 27 lb. over the 6-months break. This briquette shows a continued hardening in water, and demonstrates the hydraulic properties of the tufa in combination with lime.

Table 4 gives the strengths of Haiwee and Fairmont tufa cements up to an age of 1 year. Unfortunately, briquettes for longer time tests were not kept during the early stages of the work on the Los Angeles Aqueduct. A series is now being held for this purpose, but the 2-year period has not yet been completed. For briquettes made of tufa cement consisting of 50% of tufa and 50% of Monolith cement, mixed with 3 parts of sand, four breaks, made at the Haiwee mill, indicate a growth in strength from 500 lb. at the end of 1 year to 595 lb. at the end of 1 year and 289 days. Breaks of the oldest briquettes have just been made at the Fairmont plant, with the following results, each figure representing an average of ten tests. The cement used was 50% of Monolith and 50% of Fairmont tufa mixed with 3 parts of standard sand:

3 days.	7 days.	28 days.	3 months.	6 months.	1 year.	1 year, 319 days.
153 lb.	240 lb.	388 lb.	467 lb.	492 lb.	555 lb.	565 lb.

More breaks were not made because it is desirable to preserve the series for testing at regular periods. They indicate the continued hardening of the tufa mortar with age, which is characteristic.

Table 5 shows tufa sand briquette tests with varying proportions of tufa for ages up to 6 months. Table 17 gives results in continuation of that table.

The cement used (in the tests in Tables 5 and 17) was Monolith, and the tufa was from the Monolith quarries. A good increase in strength is shown between the 6-months and the 1-year breaks. Especial attention is called to the strengths shown in the 1-year breaks of the 80 and 85% tufa cements.

On page 544 is recorded the results of tests with a blend of Monolith cement and diatomaceous earth in the proportions of 50% of each. It should have been stated that this blended cement was mixed with 3 parts of sand.

TABLE 17.—TUFA SAND BRIQUETTE TESTS, WITH VARYING PROPORTIONS OF TUFA: A CONTINUATION OF TABLE 5.

Briquette number.	Percentage of tufa.	Tensile Strength.					
		3 days.	7 days.	28 days.	3 months.	6 months.	1 year.

26	80	15 20	70 70	90 90	140 110	230 260	310 265

Table 10 states the results of tests made with a mixture of volcanic clinkers and lavas found on the Hawaiian Islands with Santa Cruz (California) cement in equal parts by volume. Few tests were available for longer periods than 28 days at the time of writing the paper. Table 18 contains the results of tests for periods up to 1 year.

TABLE 18.—SAND BRIQUETTE TESTS MADE WITH A MIXTURE OF HAWAIIAN LAVA AND SANTA CRUZ CEMENT: A CONTINUATION OF TABLE 10.

			3 days.	7 days.	28 days.	3 months.	6 months.	1 year.			100 M.	200 M.	Initial.		Final.		
													H.	M.	H.	M.	
2	1911. Nov.	10½	140	255	340	450	465	480	.....	0	93.8	....	2	15	6	30	O. K.
18	Dec.	10½	112	190	307	400	467	470	Red Clinker.	50	....	92	2	30	6	00	"
10	1912. Jan.	10½	168	148	230	295	388	391	Lava.	50	....	92	1	..	11	..	"

The tests in Table 18 show fair results, and indicate a cement suitable for ordinary hydraulic work. This cement is not as strong as the blends made with the tufas already described. The tests show a uniform growth in strength with age.

Some tufa cement was sent to Robert E. Ford, Professor of Mechanical Engineering of Throop Polytechnic Institute, at Pasadena, Cal.,

Mr. Lippincott.

with a request that it be tested for compression. Standard briquettes were made and first broken in tension and the two halves then crushed. Cubes, 2 in. square, were also crushed, and the ratio of tension to compression was obtained. An unusual quantity of water was used by Professor Ford to get normal consistency (28½% for neat cement), and this, possibly, may account for the fact that the values are lower than those usually obtained in the city laboratories. The cement was Monolith, and the tufa was from Fairmont. Standard sand was used. Table 19 is a summary of the tests. The results for compression compare favorably with tests given by Taylor* for Portland cements, but these cements are not as strong as the German trass cements (the tests of which are given in Table 9), nor are they as strong as those mentioned in Table 13, of materials tested at the Arrowrock Dam, as quoted by Mr. Paul, either for their blended material or for their straight cement mortars.

* "Practical Cement Testing," p. 215.

Mr. O'Hara states that Professor Eakle, of the University of California, considers that "the rock ground with the cement used on the Los Angeles Aqueduct, is a rhyolite-tuff and a trachyte-tuff, which, when finely ground, will possess the same characteristics as finely-ground clay." Mr. Lippincott.

Mr. O'Hara continues:

"The cement produced by the method used at Monolith and Haiwee, Cal., is similar to cement adulterated with clay. Rhyolite-tuff and trachyte-tuff are not to be confounded with the volcanic rocks known as puzzuolana and trass, which have been used for the manufacture of cement. Puzzuolana and trass are the hardened products of volcanic action in their original state, in which respect they are similar to blast-furnace slag. On the other hand, the volcanic tuff of the nature found at Monolith and Haiwee, is not comparable to blast-furnace slag, being more of the nature of altered volcanic rock."

Table 2 gives an exact chemical analysis of the tufas used on the Los Angeles Aqueduct, of Italian tufa, and also of Italian puzzuolana (as used in that country), as determined from samples furnished by the American Consul. A detailed analysis of the German trass is given in Table 20 where it is shown that it has a close resemblance to the California tufas. The local clays analyze much more closely to the Italian puzzuolanas than the California tufas. The percentage of silica in the local tufas, soluble in alkalies, is greater than that in the samples of Italian puzzuolanas, in the ratio of 4 to 1, according to determinations by the Monolith Laboratory, and this is believed to be a very important factor. Mr. O'Hara is mistaken when he refers to these tufas as an altered volcanic rock. If he had ever seen these quarries, he probably would not think so. The tufa used is an unaltered volcanic ash which has been thrown down in water and comminuted. It has been partly consolidated by pressure. Physically, it has no more resemblance to clay than unground cement clinker, which also contains chemically a high percentage of clay. It resembles somewhat the pumice stone which can be purchased at most drug stores. Many of the hardest rocks, such as granite, slate, and lava, on decomposition form clay, and it would be as misleading to say that a granite is a clay as to say that this tufa is a clay. The writer is familiar with tufa in its altered and clay-like condition. It is found near Haiwee.

The tufas are very low in sulphur, containing usually less than one-tenth of 1%, and it is difficult to see how there is any extra danger because of being blended with straight cements containing 1¾% of sulphur, on this account, as Mr. O'Hara states. Reference is made to the discussion by Mr. Luiggi as to the enduring quality of these cements in sea water.

Mr. Lippincott.

Mr. O'Hara also says:

"Tufa and Portland cement, as used on the Los Angeles Aqueduct, is a mechanical mixture, the two materials being blended in equal parts by volume. Under these conditions, no silicates of lime are found, and the gradual increase in strength is not due to the same cause as the slow hardening of a high silica Portland cement."

The chemical analyses of the Bureau of Standards, given on page 537, as well as the analyses at the laboratories of the Los Angeles Aqueduct, show that silicates of lime are formed between the tufa and cement. Mr. O'Hara's statement, as given, is only empirical, and should not outweigh these chemical determinations. The writer regrets that Mr. O'Hara considers the practice of blending tufa cements on the Los Angeles Aqueduct as "dangerous and without precedent." Many unprecedented things are done, especially by the Engineering Profession, which result in general benefit. There is comfort in the fact that the U. S. Reclamation Service is now building or operating three cement blending and re-grinding plants, after careful investigations, made by its engineers, as shown by the instructive discussions contributed by Messrs. Rapier R. Coghlan and Charles H. Paul.

Mr. Reed calls attention to the severe climatic conditions under which the concrete work on the Los Angeles Aqueduct is carried on. The relative humidity in the Mojave Desert during the summer is about 20%, and this, together with temperatures which are often greater than 100°, and the great scarcity of water, makes a most trying condition for concrete work. Except on the 40 miles of open canal described by Mr. Peterson, methods of work were devised which kept the green concrete shielded from the sun and wind. Standing water is usually maintained in the conduit with small dams, to give an artificial humidity. Doors or curtains were maintained at tunnel portals. The roof was cast on the outside conduit before the forms were taken from the sides, and it was covered with wet earth on top as soon as the concrete was poured. The bottom was placed last, and the manholes were kept closed. It was only by such methods that shrinkage cracks could be avoided, no matter what kind of cement was used. In this way, mile after mile of the outside conduit could be built without any expansion joints and without transverse cracks. Leaving a manhole open for a week or two would often cause a transverse crack to open within 10 ft. Where the conduit has been filled since, these cracks, in many instances have swelled shut.

Mr. Richardson states that:

"Unfortunately, no data are available showing what proportion of the silica in any of the materials occurring abroad, or in those in California, is soluble in acid, as it is hydrated silica of this description which possesses the greatest hydraulic value."

Mr. Lippincott.

It is the writer's understanding that it is solubility in an alkali solution which is desired. This laboratory determination is made with a dilute solution of sodium carbonate. On page 537 the U. S. Bureau of Standards is quoted as showing that 7.17 out of 30.97 parts of the silica in the briquettes made of Fairmont tufa cement, or 23%, were soluble in the mortar. A test of the pure pulverized Monolith tufa, in the Monolith Laboratory, showed 8.4% soluble.

Comparative analyses of the German cements and the Monolith tufa are given in Table 20. The information in reference to the German materials (referred to in Table 9) is from the report of the Royal Testing Laboratory.*

TABLE 20.—ANALYSES OF GERMAN TRASS AND MONOLITH TUFA.

	German trass.		Monolith tufa.
Loss on ignition	3.29	10.25	6.28
Water of crystallization	6.96		
Insoluble silica	41.58	68.49	69.48
" "	1.39		
Soluble silica	25.54		
Iron oxide	2.27		2.52
Aluminum	9.83		11.87
Lime	1.05		1.80
Magnesia	0.67		2.95
Potassium	3.04		Not determined.
Sodium	3.09		" "
Phosphorus	0.11		" "
Sulphuric acid	0.06		0.48
(Unable to translate)	0.10		....
	98.96		

These analyses show a striking similarity between the German trass and the Monolith tufa. The quantity of sulphur shown in Monolith tufa is unusually large in this sample, and the 69.48% is for total silica, no division having been made between soluble and insoluble.

The sample of Italian tufa available at the Monolith Laboratory shows only 2% of silica soluble in dilute sodium carbonate. This sample was furnished through the American Consulate, and possibly may not be typical. What was furnished as Italian puzzuolana shows practically the same.

Replying further to Mr. Richardson, the tufa is separately ground in the ball mill, so as to pass through a 20-mesh screen, but the final grinding of the blended tufa and cement is done in the tube mill. An effort was made to grind the cement clinker with the crushed tufa, but it ground very slowly in the tube mill. As it was also desirable to save transportation charges, the final grinding and blending were done mostly at distant points on the work, where tufa was available, thus saving half of the freight.

Mr. Wagoner quotes from a printed "Report on Municipally Manufactured Cements of the Los Angeles Aqueduct" made to the American

* Mitteilungen aus dem Königlichen Materialprüfungsamt, 27 Vol., 1909, p. 348.

Mr. Lippincott.

Portland Cement Manufacturers Association, by a party of five engineers. The circulation of the report has been suspended by the Association. As an example of its bias, an illustration is given of a test slab which was not a portion of the Aqueduct, and had been loaded to destruction by the city's engineers, in order to test the concrete materials, as used in construction. In the pamphlet this is labeled "Slabs of poor concrete, where cover on L. A. Aqueduct has already collapsed and been replaced, on desert west of Mojave." The writers of that report state that there are three kinds of concrete on the Aqueduct: good concrete made of purchased cement; fair concrete made of Monolith cement; and poor concrete made of tufa cements. They state the places where these concretes are found, and it is amusing to note that their "poor concretes" in most cases actually were made of purchased cements.

The Monolith mill has been run for four years. The product, with minor exceptions, has been standard. The hydraulic index which Mr. Wagoner has taken exception to, has usually been about 2.0. It is not claimed that the mill is infallible. Neither are other mills. It has been watched closely by cement manufacturers, and when it was in temporary trouble, due to a change in the limestone quarry, it was promptly investigated. The writer regrets that it is necessary to refer at all to this report. Much more could be said, but it would involve local politics and business foreign to this discussion. Table 21 contains an independent analysis of Monolith cement.

Mr. Wagoner suggests that tests with tufa and some standard cement be made for the Profession. Many barrels of tufa cement have been made with both Colton and Riverside cement, and they show the same results as those made with Monolith cement.

In reply to Mr. Mogensen, it may be stated that no discriminations have been made against tufa cements. Two reinforced concrete towers have been successfully built of tufa cement, as well as several flumes, and nine reinforced concrete pipes, 10 ft. in diameter, for heads up to 80 ft. Many miles of reinforced roof slab, 8 in. thick, with a span of 11 ft. 5½ in., have been successfully laid. The Haiwee Dam referred to is an earthen structure with a clay core; no concrete was used in its construction. Numerous prominent engineers have examined the work, and, although most of it is in a remote and unoccupied region, every effort has been made to aid investigations by the Profession.

Approximately, the following quantities of cement of various classes have been used to date on the Los Angeles Aqueduct:

Monolith standard cement	900 000 bbl.
Tufa cements	636 000 "
Purchased standard cements	260 000 "

The ratio of the weight of the aluminum silicate to that of the lime is called the Hydraulic Index, and should be as high as 1.91, the German cements showing 1.98. This analysis indicates for Monolith cement 2.08. (Note by J. B. LIPPINCOTT.)

Mr. Lippincott.

The contributions to the discussion by Messrs. Coghlan and Paul are of particular interest and value. Little may be added to these discussions; they are commended to those interested in this subject. The writer agrees with Mr. Coghlan's statement, referring to materials suitable for blending, "that they are all dependent for their fitness on the quantity of colloidal or active silica"; and that they should "be in an almost unaltered condition." Mr. Paul's tests, showing the results of blending the granites at the Arrowrock Dam of the U. S. Reclamation Service, are especially interesting, as they broaden the opportunity for this economy. The writer's experience with the lavas from the Hawaiian Islands, though very limited, is in accord with that of Mr. Coghlan.

It must be constantly borne in mind by Eastern engineers, in considering this subject, that the prevailing price of cement at central points in the Far West, is about $2 per bbl., and that transportation charges are high. Engineers in this region are anxious to build the necessary works with the available funds. The saving on the Los Angeles Aqueduct, due to the use of tufa cement, will amount to about $700 000.

Mr. Peterson's discussion gives the experience of an engineer who has used tufa cement for three years, and, for this reason, it is of value.

Mr. Luiggi, who is Inspector General of the Royal Civil Engineers (of Italy) and Professor of Maritime Construction at the Royal School of Civil Engineers, gives a most interesting discussion of the subject, referring both to the old Roman cements, made of lime and puzzuolana (tufa), and the blending of Portland cement with puzzuolana. He has practiced this latter blending since 1888. He approves the practice, and states that it is "quite correct, both with regard to the cost and the durability of the work."

Mr. O'Hara quotes Professor Eakle, of the University of California, as stating:

"The rock ground with the cement used on the Los Angeles Aqueduct, is a rhyolite-tuff and a trachyte-tuff, which, when finely ground, will possess the same characteristics as finely ground clay."

Mr. O'Hara then makes the deduction that "the cement produced by the method used at Monolith and Haiwee, Cal., is similar to cement adulterated with clay." Presumably, he gets this information from the pamphlet issued by the Association of American Portland Cement Manufacturers. The writer, having communicated with Professor Eakle and called his attention to the paper and to Mr. O'Hara's discussion, received, under date of February 27th, 1913, the following:

"Your letter of February 26th, informing me that I had been quoted by cement manufacturers was news to me, and so I have looked up the

quotation to which you refer. I am rather in the dark regarding the matter, as both the gentlemen using my name and the rock in question are unknown to me. However, I constantly receive samples of rock for identification, and always try to accommodate the sender with whatever information I can give, and as to the persons sending me material seldom give me the localities or state what they wish to do with my report, I only hear of it later by some roundabout way as this." Mr. Lippincott.

After receiving this communication, the writer forwarded samples of the tufa from the Fairmont quarries to Professor Eakle for indentification and for an expression of opinion. He was requested to put this in such form as to permit of publication. The following letter has been received in compliance with this request:

"The samples of tuff you sent me cannot be classed as strictly fresh rocks, as the original more or less glassy base has become devitrified, a portion of the alkalies leached out, and the tuff is considerably hydrated. The alteration has, however, been more in the nature of an incipient kaolinization and silification producing a hardened stony base, as shown by the gritty powder, so the value of the rock for the use you make of it has not materially suffered by the slight change. The amount of alumina in the tuffs is rather high and there is no doubt that an extra amount of clay-like material is added to the cement, but your experiments and those of German cement users seem to prove conclusively that such rocks do not act as adulterants, but, on the other hand, produce a better and stronger cement, if properly used. Much of the free silica and alumina silicate of these tuffs is in a more soluble state than it is in ordinary clay and quartz sand, and it is presumably due to this fact that the tuffs have their value. Their solubility is shown by treatment with HCl and with alkali carbonates, and is also shown in the field where many of them have become silicified and often impregnated with opal, deposited from the colloidal silica formed. When these tuffs are ground so intimately with cement, every portion of this soluble silica and silicate comes into contact with the lime, and during the gradual drying out of the moist mass, a chemical action is taking place to form lime silicate. The longer you can keep the interior mass moist, the more complete should be the crystallization and the stronger the mass. In quick setting we would expect the tuffs to act more as an adulterant. It would be interesting and of value to know if thin sections of the cement at different periods of solidification would not show what is taking place. The tuffs you sent are rhyolite tuffs. Your article states you use equal parts of cement and tuffs, but the analysis of the Monolith tuff cement shows a proportion of about one part tuff to three parts cement. There is a discrepancy in these analyses. The tuff cement has more water than the tuff and the amount of alumina is not larger than some Portland cements contain, and the total allows nothing for alkalies which must be present.

"I would like to offer a suggestion about the name 'Tufa Cement' which you use. It has become the custom with petrologists and

Mr Lippincott

geologists, at least in this country, to use the word 'tufa' for calcareous deposits, and 'tuff' for volcanic ash rocks; so it might be better to call the cement a 'tuff-cement.'

"You are perfectly welcome to make use of anything in this letter you may find of assistance."

With reference to Professor Eakle's comment on a discrepancy in the analyses, it should be remembered that the pulverized tufa is blended with the cement at the mills in equal parts by volume. The ratios are: 60% by weight of cement to 40% by weight of tufa, approximately. The mixture for this sample, the analysis of which is given in Table 2, was of equal parts by volume. The analyses, of course, show percentages by weight. According to the writer's computations, there is the following relation between the analyses given and the theoretical quantities which should occur:

	Silica.	Iron and alumina.	Lime.
Theoretical quantities....	41.1	10.87	38.19
Analysis	35.34	11.89	41.05

The percentages shown in these different analyses, either for the cement or for the tufas, will vary from time to time, and cannot be expected to check absolutely. The quantity of silica in the tufa used in this blend is unusually high.

Mr. O'Hara also quotes from the U. S. Corps of Engineers,* as follows:

"Puzzolan cement never becomes extremely hard like Portland, but puzzolan mortars and concretes are tougher or less brittle than Portland. * * * It is unfit for use when subjected to mechanical wear, attrition, or blows."

In order to test the tufa cements for attrition, twenty pieces of briquettes of tufa cement (50% by volume being tufa and 50% by volume Monolith cement, mixed with 3 parts of standard sand) which had attained an age of one year, were revolved in the small laboratory ball mill with flint pebbles; and twenty pieces of broken straight cement briquettes which had been tested for tension, which were a year old, and had been mixed with 3 parts of standard sand, were treated in a similar manner. The tensile strength of the briquettes of tufa cement was about the same as those of straight cement, each set having averaged more than 400 lb. The briquettes were weighed separately before being subjected to the rattler test, and were weighed at equal intervals of time as the test proceeded. The briquettes of tufa cement were run separately from those of straight cement, because it was difficult to distinguish between them after the grinding had proceeded for some time. The results are given in Table 22.

* Professional Paper No. 28, p. 1779.

Mr. Lippincott.

TABLE 22.—ATTRITION TESTS OF TUFA CEMENT AND STRAIGHT CEMENT BRIQUETTES MADE WITH 3 PARTS OF STANDARD SAND.

Time	5 minutes.	20 minutes.	50 minutes.	2 hours.	5 hours.
Straight	5.26%	10.85%	14.23%	28.007%	48.13%
Tufa	3.13%	7.66%	13.93%	28.9%	63.41%

The percentages represent the loss in weight.

This test indicates that, for periods up to 50 min., the tufa briquettes stood abrasion better than those of straight cement; that, for the 2-hour run, they were practically the same; and that on the 5-hour run the straight cement showed a superiority of about 30 per cent. It has been established in the tensile strength tests, that the tufa is slower in hardening than the straight cement, and it would appear that the outer portion of the tufa briquettes had attained a greater hardness than those of straight cement, but that the interior was not yet as hard.

INSTITUTED 1852

TRANSACTIONS

Paper No. 1255

THE SEWICKLEY CANTILEVER BRIDGE OVER THE OHIO RIVER.*

By A. W. Buel, M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, Charles Worthington, Theodore A. Straub, C. W. Hudson, V. R. Covell, Henry H. Quimby, and A. W. Buel.

Introduction.

The titles of half a score of papers presented to this Society bear the familiar names of great cantilever bridges. Of such bridges in the United States, five exceed the Sewickley Bridge in weight of steel per linear foot, and four exceed it in length of channel span; but some details and erection methods used in this bridge are thought to have sufficient merit and novelty, at least in their application, to justify the hope that a description largely confined to such features may prove interesting.

The Sewickley Bridge has a channel span of 750 ft. from center to center of towers. This is exceeded in the United States by the Blackwells Island Bridge, 1 182 ft.; the Wabash Bridge over the Monongahela at Pittsburgh, 812 ft.; the Memphis Bridge, 790 ft., and the Beaver Bridge, 769 ft. The Mingo Bridge and the Thebes Bridge both have shorter channel spans, 700 ft. and 671 ft., respectively.

The weight of steel, including the buckle-plates under the roadway floor, is 3.48 tons per linear foot of bridge. This is about 70% of the weight per foot of the Thebes Bridge; 77% of that of the Wabash Bridge at Pittsburgh, and more than 99% of that of the Memphis

* Presented at the meeting of November 20th, 1912.

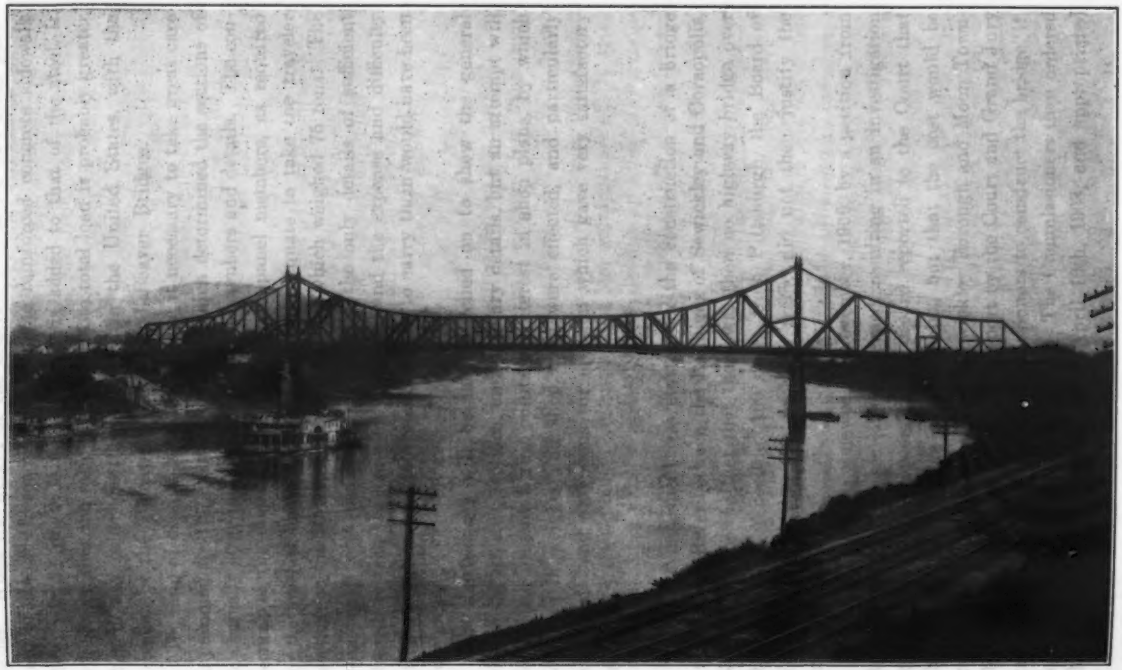

FIG. 1.—THE SEWICKLEY BRIDGE OVER THE OHIO RIVER. DISTANT VIEW.

Bridge. When the weight of the concrete foundation and block pavement of the 28-ft. roadway and of the reinforced concrete sidewalk slabs, 5 ft. 7¾ in. wide on each side, is added to that of the steel, it will be seen that the ratio of dead load to total load is probably greater than in any other cantilever bridge in the United States, with the exception of the Blackwells Island and Beaver Bridges.

The ratio of dead to total loads made it necessary to take great care in providing for the erection stresses, which determined the sections of an unusually large number of both truss members and details. The connections of the floor system and the sub-panel members, as required for the finished bridge, were entirely inadequate to take the traveler reactions or the 30-ton locomotive crane, which weighed 75 tons. The main panel point pins were practically the only details of sufficient strength to take the traveler reactions, and the expense and difficulty of increasing other members and details to carry them would have been very great.

The illustrations will be largely relied on to show the general dimensions, stresses, sections, and ordinary details, but an attempt will be made to present a few points of interest in shop plans, by which economies in weights and shop costs were effected, and particularly some details and provisions for erection which gave very satisfactory results.

Historical.

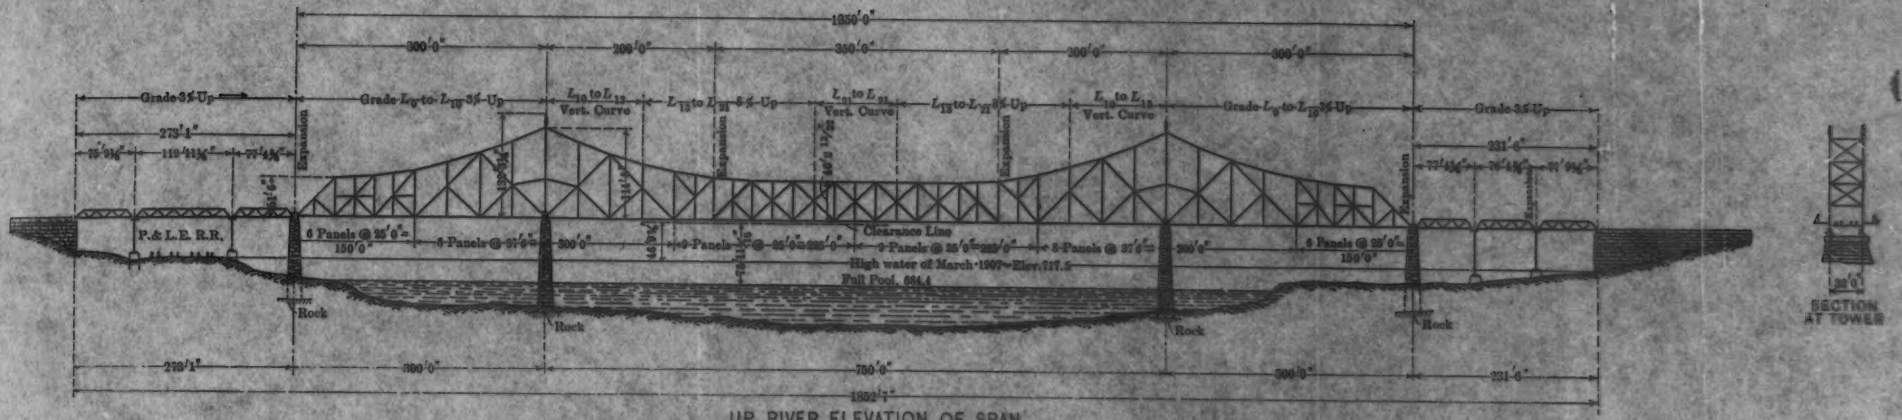
In 1894 a movement was started for the construction of a bridge over the Ohio River between the Boroughs of Sewickley and Coraopolis. Notwithstanding the fact that there was then no highway bridge over the river above Wheeling, 100 miles from Pittsburgh, the Board of Viewers reported that the probable traffic did not then justify the expenditure.

The movement was renewed in November, 1906, by a petition from the inhabitants of the sections concerned, resulting in an investigation by a new Board of Viewers. This Board reported to the Court that there should be a bridge at this point, but that the cost would be greater than it was reasonable for Sewickley Borough and Moon Township to bear. The approval of this report by the Court and Grand Jury gave authority to the County Commissioners to construct the bridge, if, in their opinion, it seemed expedient. The Commissioners then ordered the construction of the bridge, on April 10th, 1908, and appropriated

funds for the work during the following year. The principal considerations which resulted in this action were:

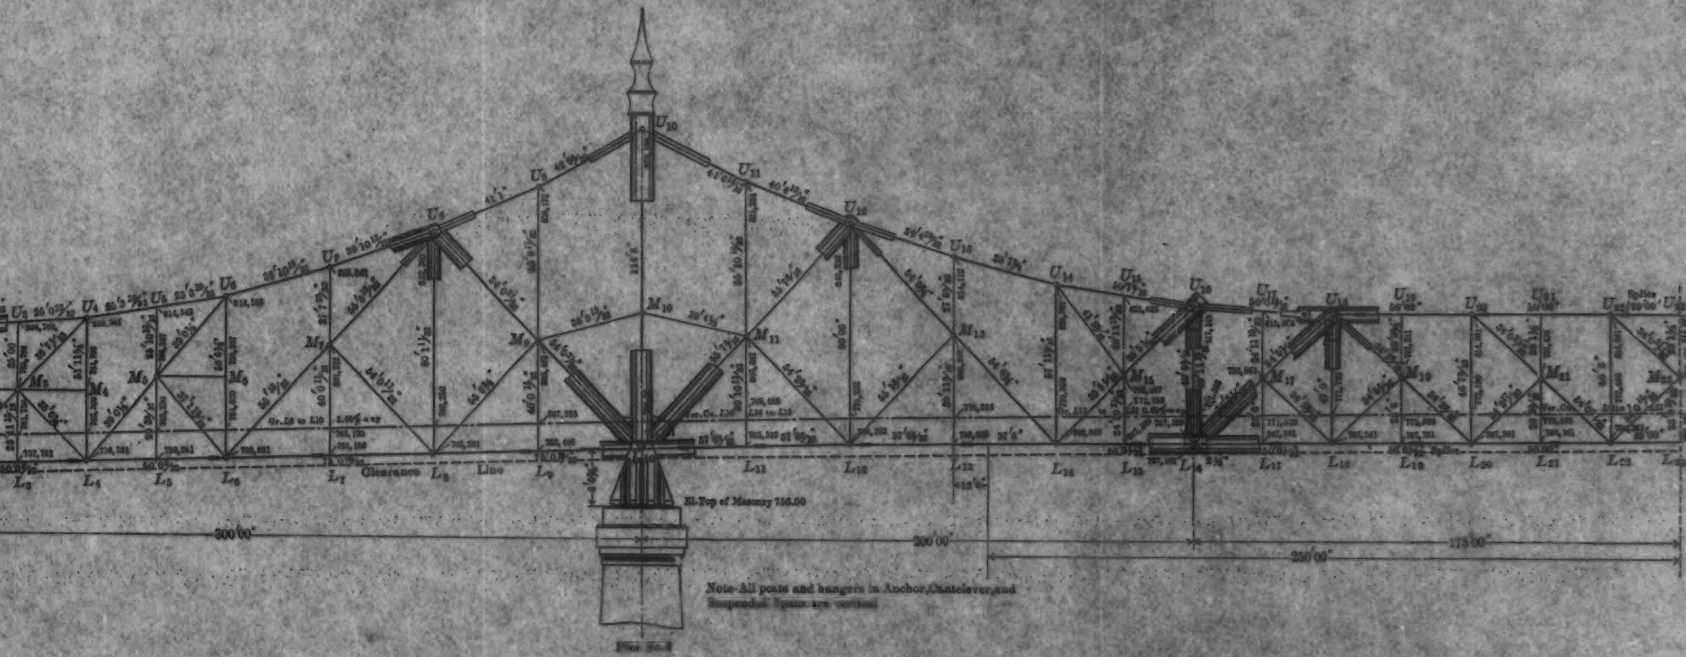
First.—That there was no highway bridge over the Ohio River above Rochester, which is 25 miles below Pittsburgh.

Second.—That Sewickley is approximately midway between Rochester and "The Point" (at the junction of the Allegheny and Monongahela Rivers) where both streams are spanned by bridges.



Third.—That Sewickley and Coraopolis are the largest towns on the Ohio River in Allegheny County.

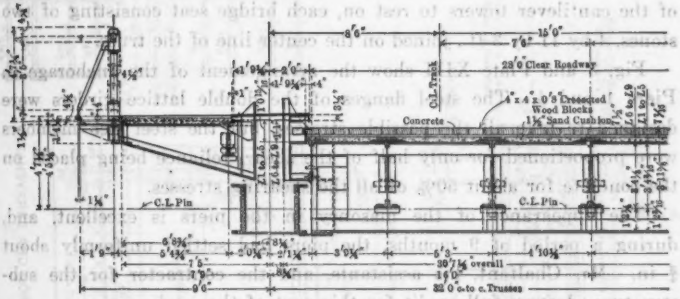
Fourth.—That the bridge would be a connecting link between road systems on each side of the river, comprising many miles of improved roads. At the present time there are 30 miles of improved country roads on the north side of the river and 40 miles of such roads on the south side, tributary to this bridge.



Following the authorization by the County Commissioners, surveys were made and contract plans and specifications prepared under the direction of Mr. J. G. Chalfant, County Engineer. The contract plans comprise 27 sheets, showing general details and arrangements of all parts of the substructure and superstructure. The sheets showing the substructure were, practically, final details. The sheets showing the general details of the superstructure were generally to a scale of $\frac{1}{2}$ in. to the foot.

Surveys.

The preliminary surveys were made during the spring and summer of 1906, and were sufficient to fix accurately the length of the spans and locate the piers and abutments, together with the grades on the approaches and over the bridge. The center line was monumented on both sides of the river during June, 1909, and a triangulation system was laid out. That this part of the work was done with a high degree of skill and accuracy was proven by the satisfactory way in which all parts of the work came together in the field; and it reflects great credit on the County Engineer and his assistants. The triangles closed with errors of one part in 77 000 to one part in 192 000, and to within one or two seconds of arc. The Bridge Company checked the channel span by direct measurement before erecting the south half of the suspended span, and found it to be correct.



UP RIVER ELEVATION OF SPAN

SECTION AT TOWER

Contract Plans.

Outline.—Plate XII is a skeleton elevation of the structure, with dimensions and elevations, prepared in the County Engineer's office. These dimensions were strictly adhered to in the construction. The length of the channel span, the direction of the axis of the bridge in relation to the current at low stage, and the clearance above high water, were practically fixed by the regulations of the Federal Government. The outline and many of the general details of the trusses, shown on the contract plans, were similar to those of the Wabash Bridge, mentioned previously; but, in the latter, the main towers on the cantilever piers are made up with two columns in each truss, connected by horizontal bracing in the plane of the truss, without diagonals; whereas, in the Sewickley Bridge, these towers have only one column in each truss.

HALF CROSS-SECTION THROUGH FLOOR AT PANEL POINT L_6
THIS SECTION IS TYPICAL, EXCEPT FOR SIDEWALK FASCIAS AND STRINGERS

Fig. 2.

Floor System.—The floor system of the Sewickley Bridge was necessarily very different from that of the Wabash Bridge, as the latter is a double-track railroad structure, whereas the Sewickley Bridge is a highway structure, carrying a 28-ft. roadway with two electric car tracks and two 6-ft. sidewalks on brackets outside of the trusses. The trusses are 32 ft. from center to center. The roadway floor consists of a 4-in. wood block pavement on 1½ in. of sand, with concrete filling, averaging about 3 in. thick, over the ⅜-in. buckle-plates, which were placed with buckles down, and supported by stringers. The sidewalks are reinforced concrete slabs, with an average thickness of about 5 in., supported on two lines of stringers. Fig. 2 is a cross-section of half of the roadway and sidewalk.

Substructure.

The substructure comprises two abutments with wing-walls, four pairs of pedestals, two on each side, supporting the approach spans, the two anchor piers, and two cantilever piers. The foundations of the South Anchor Pier, No. 1, and of the two Cantilever Piers, Nos. 2 and 3, were carried to rock, which was found at elevations of from 30 to 35 ft. below "Full-Pool" water level. The work was done with coffer-dams, without unusual difficulties. The North Anchor Pier, No. 4, was founded on a very dense clay and gravel formation at Elevation 706.4 (about 20 ft. below "Full-Pool" level).

All piers were faced with sandstone and backed with 1:3:5 gravel concrete. The stone for Piers Nos. 1, 2, and 4 came from Wampum, Pa., and for the others from Morgantown, W. Va.

Granite bridge seats, 8 by 11 by 3 ft., were provided for the shoes of the cantilever towers to rest on, each bridge seat consisting of two stones, 4 by 11 by 3 ft., joined on the center line of the truss.

Fig. 3 and Plate XIII show the arrangement of the anchorage in Piers 1 and 4. The steel flanges of the double lattice girders were designed to take all the possible stresses, but the steel web members were proportioned for only half of the shear, reliance being placed on the concrete for about 50% of all the shearing stresses.

The appearance of the masonry in the piers is excellent, and, during a period of 9 months, the piers had settled uniformly about ¾ in. Mr. Chalfant, his assistants, and the contractor for the substructure, deserve full credit for this part of the work.

Loading.

Dead Loads.—The dead loads consist of the weight of the structure itself, including that of the floor system, of any special features peculiar to the structure, and of the street-car rails.

For the contract plans, the dead load was assumed to be concentrated with two-thirds on the loaded chord and one-third on the unloaded chord. In the final computations, made by the Bridge Company, the actual concentrations were computed and used.

Live Loads.—

(b) A 15-ton road roller arranged as follows: 6 tons on the forward axle and 9 tons on the rear axle; axles 11 ft. apart, rollers 20 in. wide, the two on the forward axle being placed 2½ ft. from center to center, and the two on the rear axle, 6 ft. from center to center.

(c) A wagon load of 10 000 lb. on two axles, 8 ft. apart, wheels 5-ft. gauge.

(d) Two 50-ton street cars, as in Fig. 4.

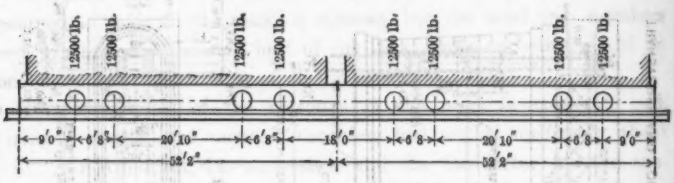
(B) Trusses.

Suspended, cantilever, and anchor spans, 1 600 lb. per lin. ft. of truss.

Approach spans, 2 000 lb. per lin. ft. of truss.

A wind pressure of 35 lb. per sq. ft. of exposed vertical surface on both trusses, the structure being considered as unloaded.

The maximum stress due to wind added to the maximum stress due to live and dead loads was not permitted to exceed 20 000 lb. per sq. in., reduced by compression formulas for struts.



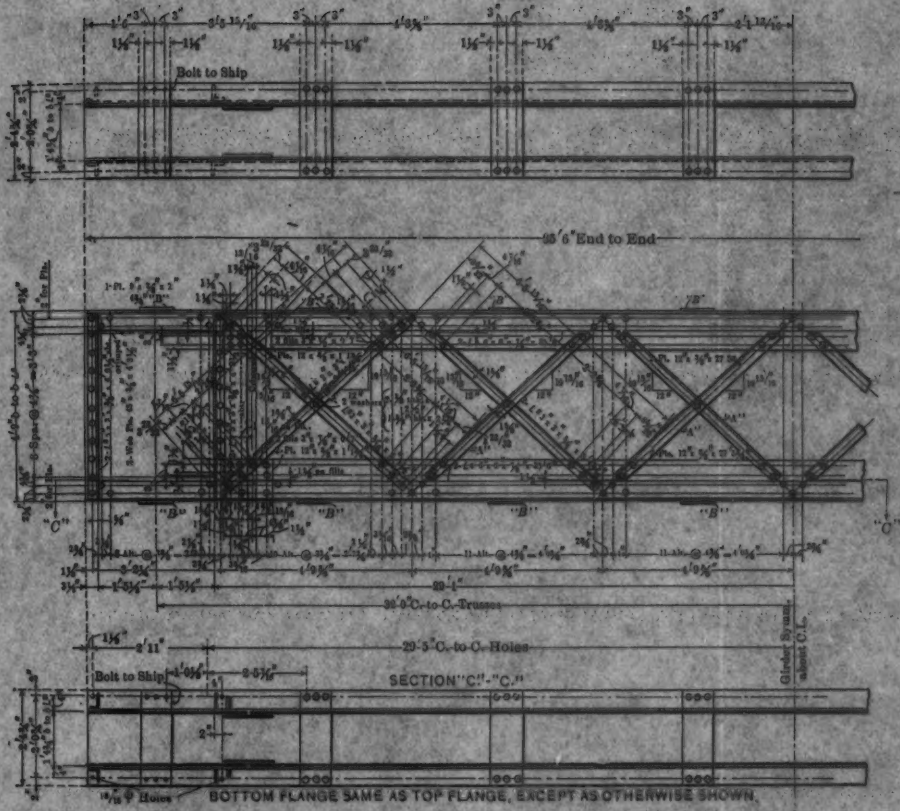


FIG. 4.

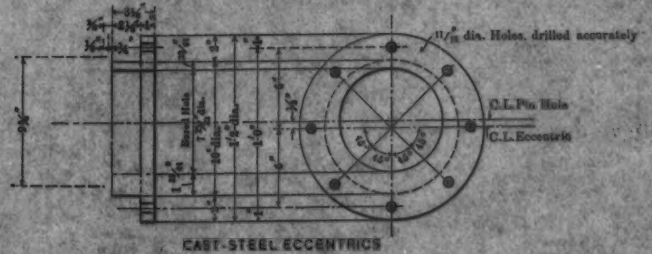
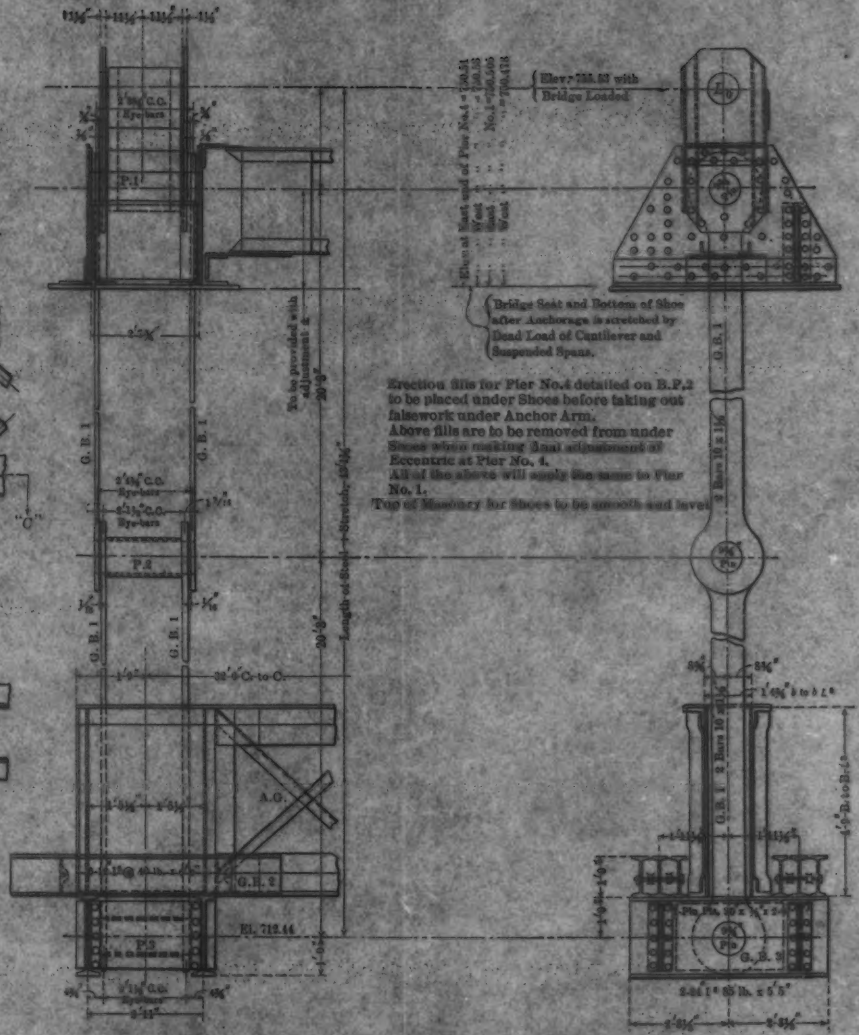
UNIT STRESSES.



(Medium Steel.)

The different parts of the structure were proportioned so that the maximum stress, in pounds per square inch of section, did not, in any case, exceed the following:



Tension.—	Dead loads.	Live loads.
Net sections of shapes in bottom chords, main diagonals, and other parts not enumerated, forged eye-bars, main diagonals, and counters.....	24 000	12 000
Extreme fibers of rolled sections used as stringers and floor-beams, or flanges of plate girders when used as such..	12 000	12 000

ANCHORAGE GIRDERS

CAST-STEEL ECCENTRICS

ANCHORAGE DETAILS FOR PIERS 1 AND 4

	Dead load.	Live load.
Net sections of shapes or eye-bars in suspenders, hip verticals, hanger yokes, or other members subject to sudden loading	20 000	8 000

Compression.—

	Dead loads.	Live loads.
Chord members	$24\,000 - 80\frac{l}{r}$	$12\,000 - 40\frac{l}{r}$
Intermediate and end posts of through and deck trusses, and columns in trestle bents	$20\,000 - 90\frac{l}{r}$	$10\,000 - 45\frac{l}{r}$
Laterals and rigid bracing	$13\,000 - 60\frac{l}{r}$	

l = length of the member, in inches.

r = least radius of gyration of the section, in inches.

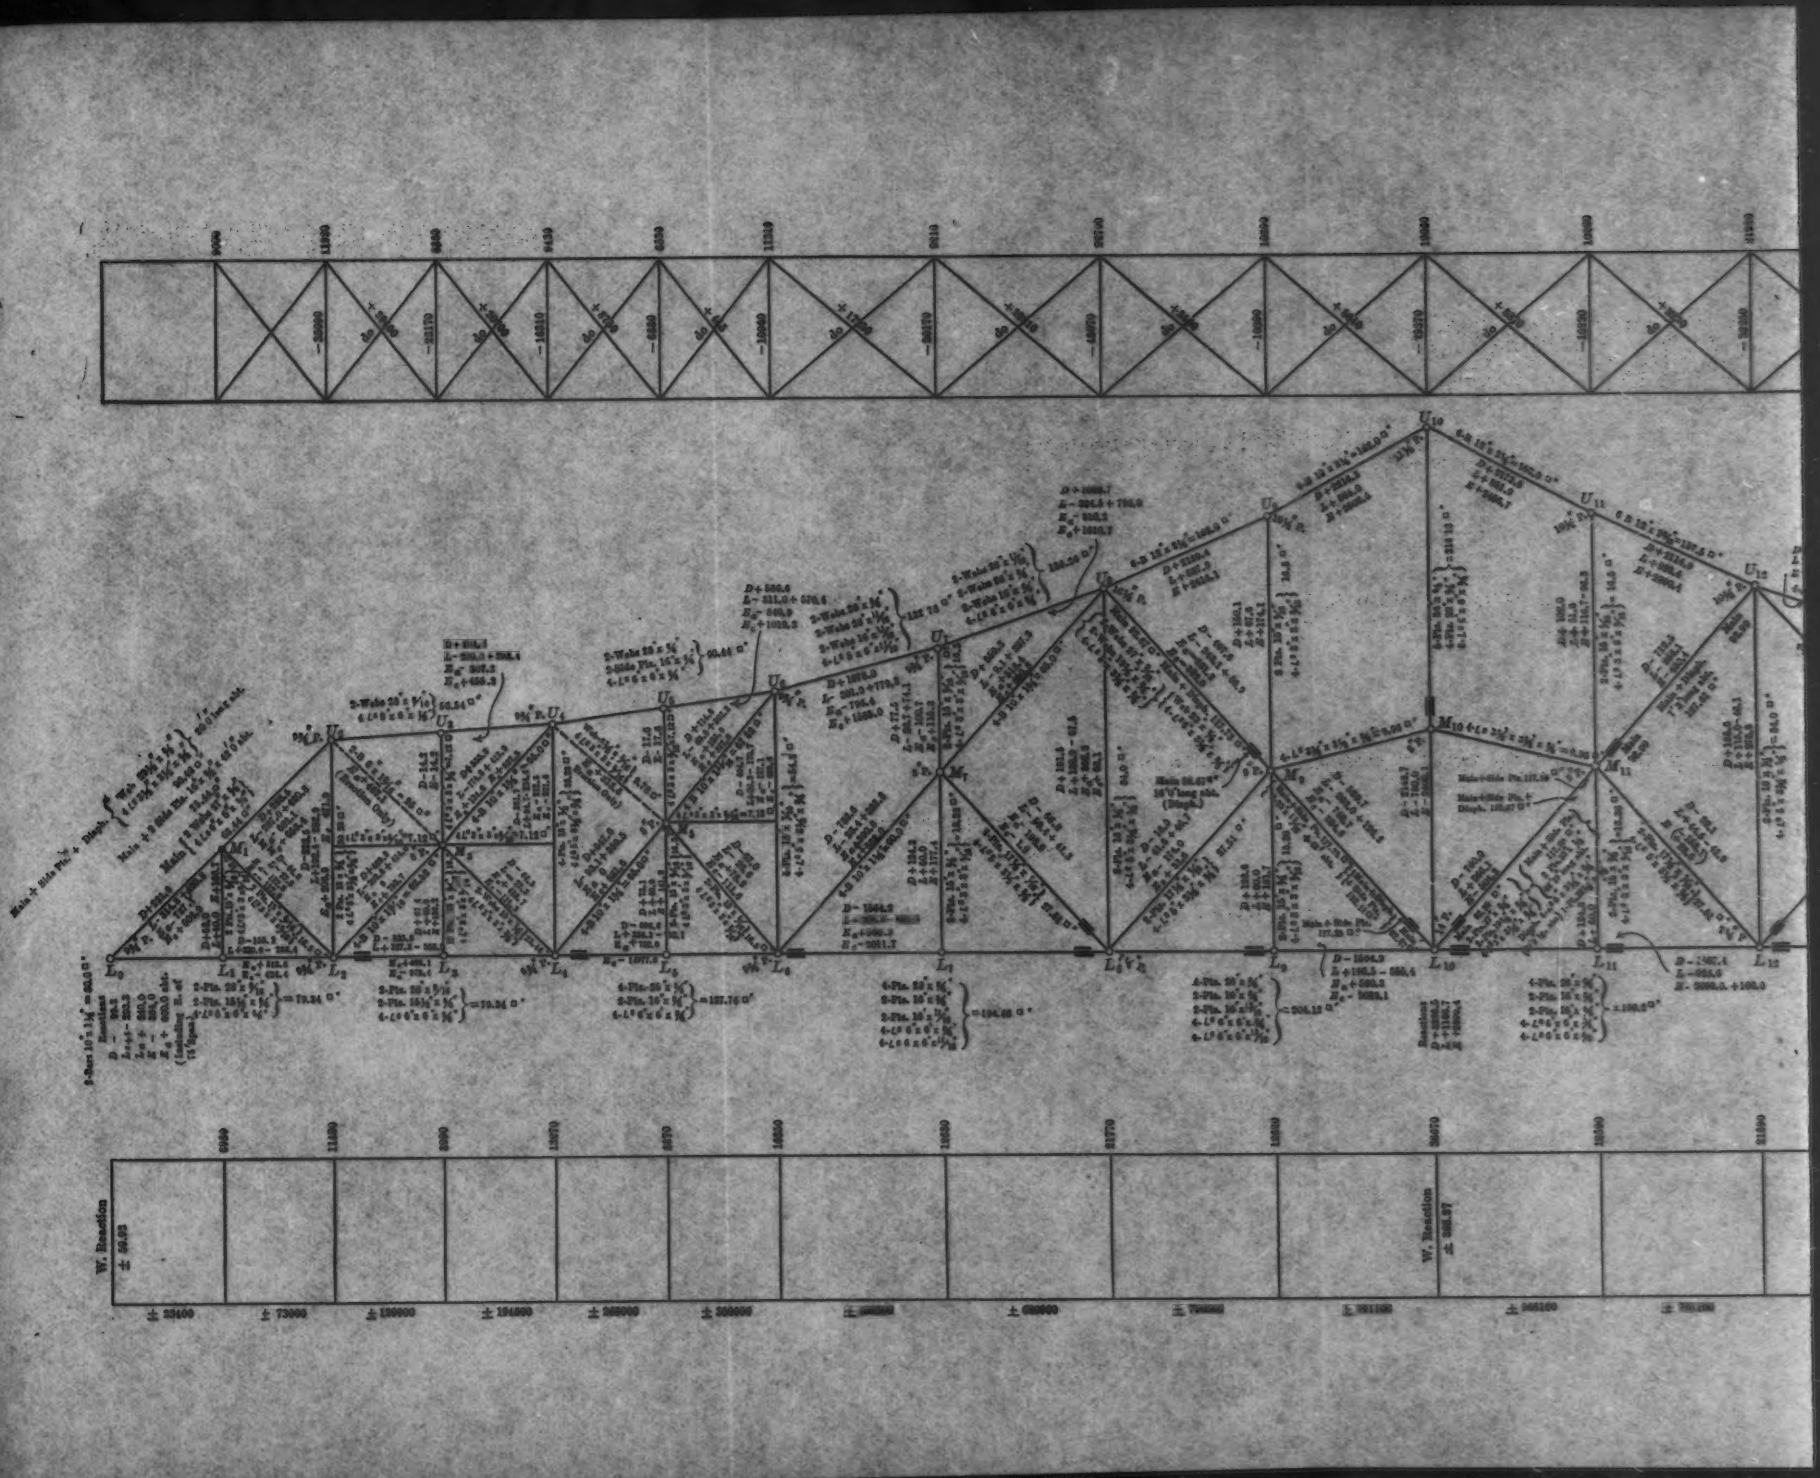
No compression members have a length greater than 120 times their least radius of gyration in the direction of possible flexure, except for the struts in the wind-bracing systems, which were limited to 150 times their least radius of gyration in the direction of possible flexure.

Bending.—	
On extreme fibers of pins closely packed	25 000
Bearing.—	
On pins	22 000
On shop rivets	20 000
On expansion rollers, per linear inch (where D = diameter of roller, in inches)	$500D$
On bridge-seat masonry—sandstone	500
On bridge-seat masonry—granite	1 000
Shearing.—	
On pins and shop rivets	10 000
On webs of plate girders used as stringers and floor-beams	5 000

The unit stresses on the shop rivets of the floor system and their connections did not exceed 80% of the foregoing for all kinds of stress. This applies also to the field rivets in the main girders and trusses. The unit stresses on all the field rivets of the floor system and bolts did not exceed two-thirds of the foregoing for all kinds of stress. The unit

stresses on the rivets in the lateral and sway-bracing were increased by 40% of the foregoing for all kinds of stress.

The other sections of the specifications conformed to the best practice for steel bridgework, requiring sub-punching and reaming, and all details of workmanship were of the highest grade.



The contracts were awarded about July 1st, 1909, to the Fort Pitt Bridge Works, of Pittsburgh, Pa., for the superstructure, and to Adam Laidlaw and Company, for the substructure. The contractor for the superstructure will hereinafter be referred to as the "Bridge Company." Ground was broken on July 21st, and actual work was started on the following day.

Preliminary Work of the Bridge Company.

The Bridge Company concluded to have the engineering work, including the most important of the detailed plans, executed by a specially selected squad of their own engineers and draftsmen, who would devote their entire attention to this particular job, under the supervision of the writer, who was specially employed for this work, and afterward retained as Consulting Engineer during erection. Before this squad could be gotten together, some progress was made by the regular engineering force of the Bridge Company, which took up the work immediately. They first proceeded with a careful revision of the estimated weights and dead loads, and then made graphical check analyses of the stresses. At this point the special squad took charge.

Checking and Revising Computations and Sections.

From the results of the graphical check analyses and other considerations it seemed that the weight of that part of the anchor piers directly over the anchorage might possibly not have a sufficient margin of safety, and, if the greater part of the mass of masonry above the elevation of the anchorage could be made absolutely effective, there would be a considerable excess. As some progress had already been made on one of the anchor piers, any change in the anchorage had to be decided on immediately, or serious delay would result. It was suggested, therefore, that heavy lattice girders, extending nearly the entire length of the pier, should be embedded in the concrete so as to bring practically the entire weight of the superimposed masonry into positive action to resist the uplift. This suggestion was adopted, with the

incidental advantage of reinforcing the piers so that no danger of cracks need be apprehended.

The next step was to check and review thoroughly the dead-load determinations and compute the actual concentrations at each main and sub-panel point (at each point of intersection).

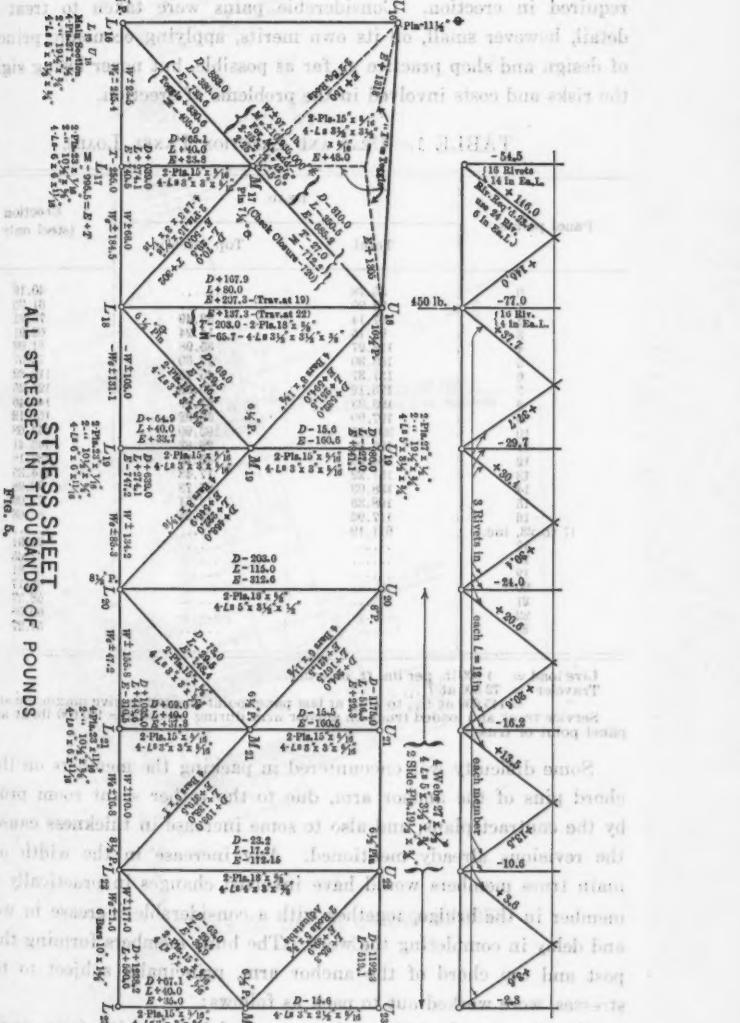
Then tables of stress coefficients, giving the stress in each member for a unit load at each and every point, were prepared and carefully checked. With the tables of stress coefficients and the revised dead-load concentrations, the stresses in each member for the loads at each point were computed and tabulated. These tables were arranged so that the maximum stresses were readily determined by taking summations between limits, which the tables indicated clearly by the plus and minus signs.

The stresses due to wind were then computed and tabulated, the wind load at each panel being based on an accurate estimate of the exposed areas. The wind shear from the top chord was assumed to go down to the lower chord in the planes, U_{18} to L_{16}, U_{16} to L_{14}, U_{12} and U_8 to L_{10}, and U_2 to L_0, only two panels of wind load being considered as going down the tower, U_{10}-L_{10}.

The final results of this work proved the accuracy of the stress computations on which the contract plans were based, but indicated the advisability of making a few changes, and these were authorized subsequently by the County Engineer.

Top Chord of the Anchor Arm.—The sections and make-up of the end posts and top chords of the anchor arm called for by the contract plans, from L_0 to U_8, consisted of eye-bars (proportioned for the principal tensile stresses), packed inside and outside of a very light riveted member which latter consisted of two 28-in. built channels, latticed top and bottom. These riveted members, while probably sufficient for the slight compression to which they might be subjected in the end post, L_0-U_2, under certain conditions of loading in the finished bridge, were entirely inadequate for the erection loads, should it become desirable or necessary to swing the anchor arm before the cantilever arm was erected. The Bridge Company considered it very important to provide for swinging the anchor arm at this stage of the work. It is also difficult to pack eye-bars in the same member with a riveted chord so that all will work in unison. On presentation of these considerations, the County Engineer approved the change submitted by the Bridge Company,

whereby the end posts and top chords of the anchor arms, from L_0 as far as U_8, were made entirely of riveted tension members designed to carry compression during erection and, in the finished bridge, where the stresses reverse toward the end of the anchor arm. Some details of these members will be described later.



Lower Chord Sections.—Some increase in the lower chord sections between L_6 and L_{14} being indicated as advisable, in the light of the revised computations of stresses due to dead, wind, and erection loads, and as an increase in depth of the 28-in. webs would have involved considerable difficulty and delay at that time, these members were changed from two built channels (with four 6 by 6-in. angles) to two built I-sections (with eight 6 by 6-in. angles). This reduced the unsupported length of the top and bottom lattice bars, so that flats could be used instead of channels or angles.

The foregoing changes, together with some in minor members and details, required an entire revision of the dead-load concentrations. This work was expedited and facilitated greatly by the tables of stress coefficients. It was possible for two men to make and check an entire set of revised dead-load stresses for the anchor and cantilever arms in two or three days. As this had to be done several times, these tables saved more than their cost, in the work of computing stresses alone, even if their great value in calculating deflections be neglected. They not only saved time, but made it possible to utilize junior and clerical assistants for a considerable part of the work, which was almost entirely reduced to the simple mechanical operations of slide-rule multiplications and summations by adding machines.

The final stresses and sections are shown on Plate XIV, for the anchor and cantilever arms, and by Fig. 5, for the suspended span. The latter are practically identical with those shown on the contract plans, no material changes having been made, except in the diagonals, U_{22}, M_{23}, and L_{22}. The dead and erection loading for each panel is shown in Table 1.

Shop Details.

The revised stresses and sections having been approved by the County Engineer, the preparation of shop details and mill order bills was commenced. Each member and each main and sub-panel point was laid out to a scale of 1½ in. to the foot, beginning with the chords of the anchor arm and following with all the other members throughout

Live load = 1 600 lb. per lin. ft. of truss.
Traveler = 72 500 at U_{11}.
" = 145 000 at U_{13} to U_{23}, at last panel point erected to give maximum stress.
Service track and loaded truck on anchor arm during erection = 100 000 lb. at any one panel point of truss.

Some difficulty was encountered in packing the members on the top chord pins of the anchor arm, due to the rather scant room provided by the contract plans, and also to some increase in thickness caused by the revisions already mentioned. Any increase in the width of the main truss members would have involved changes in practically every member in the bridge, together with a considerable increase in weight, and delay in completing the work. The built members forming the end post and top chord of the anchor arm, principally subject to tensile stresses, were worked out to pack as follows:

The lower end of the end post was designed with forks engaging the pin, L_0, between the webs of the lower chord and the rocker, the in-

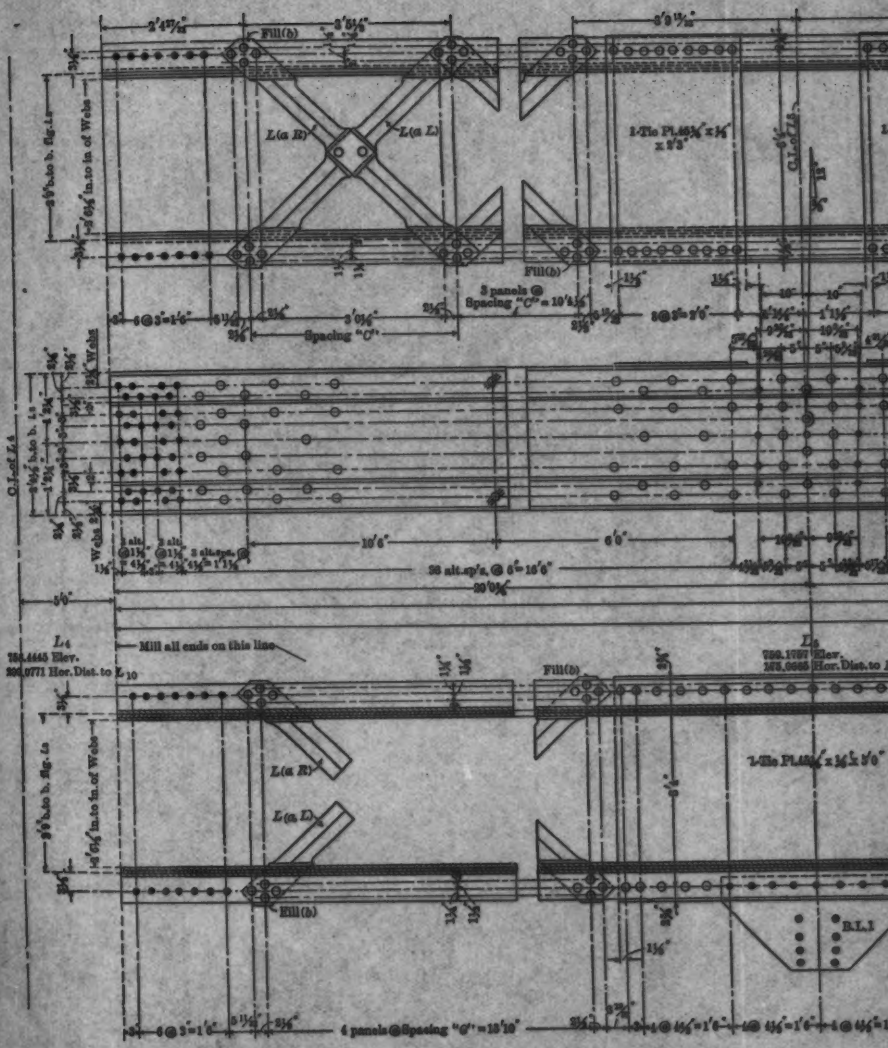
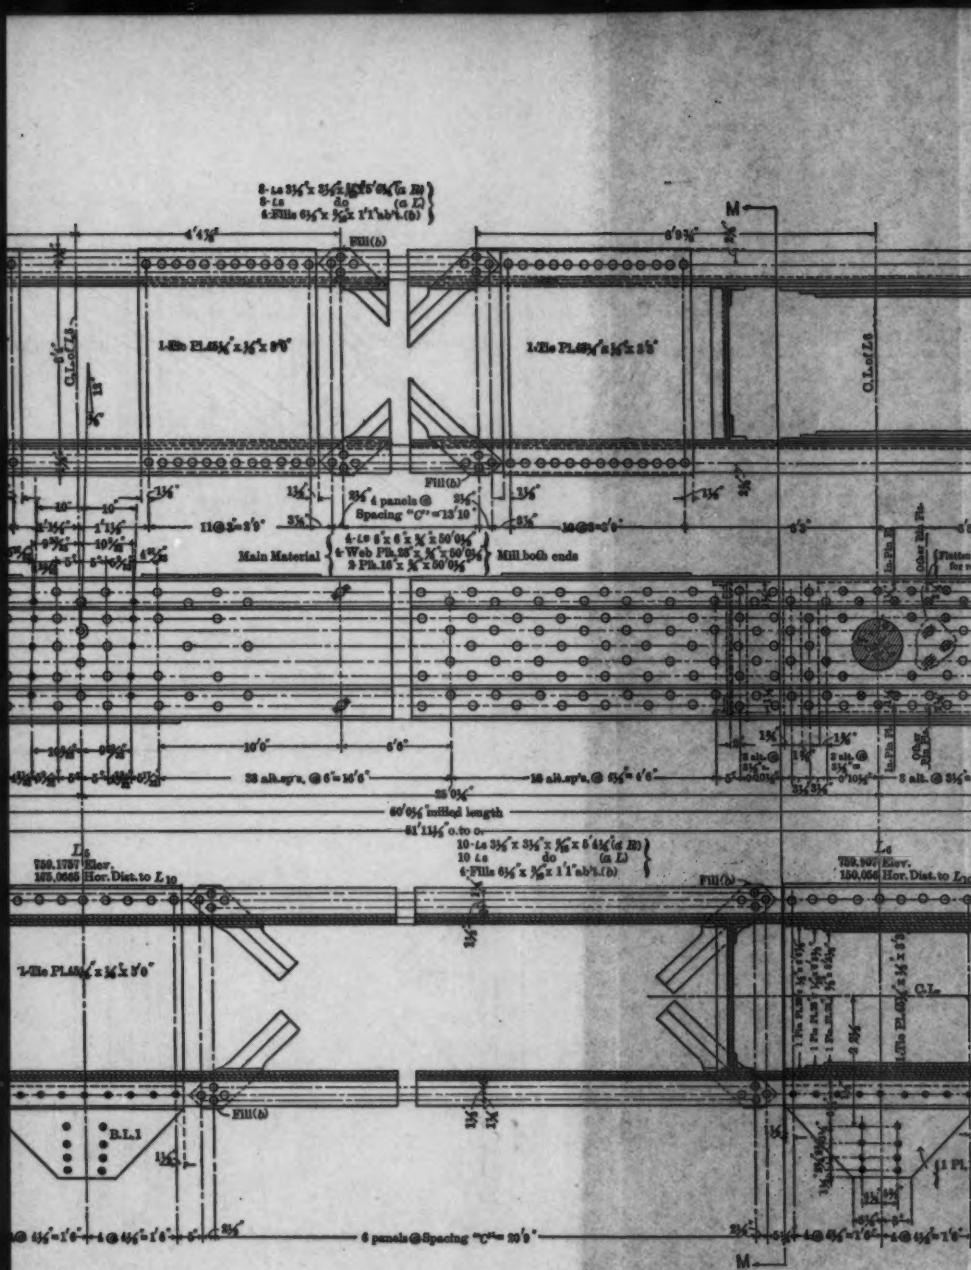
to-in and out-to-out dimensions of the chord and rocker, respectively, being retained as shown on the contract plans. This fixed the dimension, in to in, of webs of the end post, and determined the dimension, in to in, of pin-plates for this member at U_2. This figure was adopted for the dimension, in to in, of pin-plates, for both ends of the top chord sections, U_4-U_6 and U_7-U_8. The dimensions, out to out, of pin-plates at both ends of U_2-U_4 and U_6-U_7, were then fixed at $\frac{1}{2}$ in. less than the in-to-in dimensions of pin-plates on the adjoining members, thus giving $\frac{1}{2}$ in. total clearance for packing. It will be seen that this arrangement resulted in the end post and two top chord members being wide and the other two intermediate top chord members being narrow; also, the dimension, back to back of webs, was variable, due to the variation in the thickness of the pin-plates required. In order to minimize the appearance of this difference in the width of the top chord members, those that packed outside were built up with 6 by 6-in. angles, whereas those that packed inside, and were consequently narrow, were built up with 6 by 8-in. angles, the 6-in. leg being always against the web.

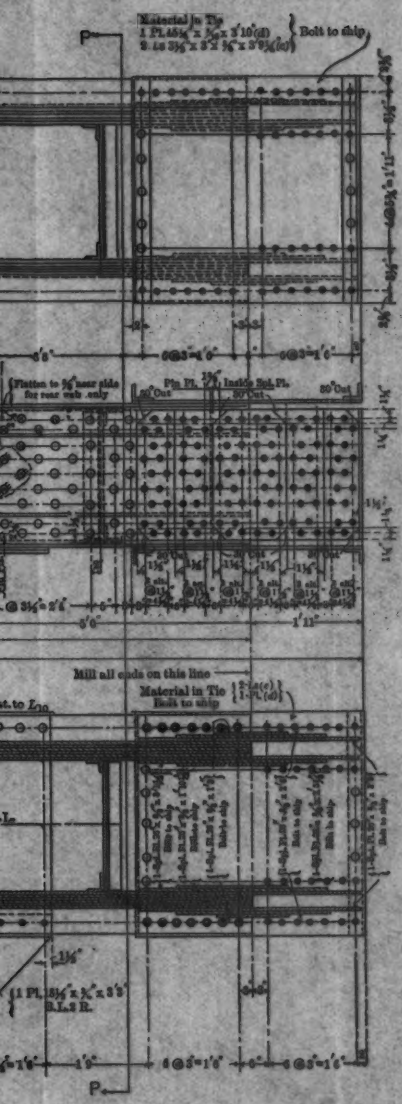
The rivet spacing in the webs and pin-plates of these five members was worked out so as to keep the net section, through and back of the pin-holes, as large as possible and to give similar spacing in all pin-plates. The spacing through the body of the members is 6 in., alternating with a fractional space between the 6-in. spacing and the closer pin-plate spacing. Plate XV shows the upper chord, U_6-U_7, which is typical.



All the lattice bars, top and bottom, were made in two lengths, without any special bars. This result was obtained by varying the pitch slightly to compensate for the difference in dimensions between gauge lines, and by varying the length of the end tie-plates. This plan was followed throughout the work, an effort being made to keep the lattice bars of the same length for all similar members, and to avoid special bars. Tables showing the items of the lattice bars were then made, with sufficient data for the shop to prepare all the bars, ready for assembling. This was an appreciable advantage, not only in preparing the bars, but in assembling, as the shop plans designated the lattice bars for each member by their item numbers as given in the tables.

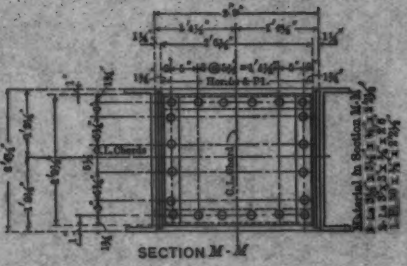


Camber and Finished Lengths of Truss Members.—It was desired to camber the bridge so that, under full dead and live loads, it would come to the exact position and elevations shown by the contract dia-



gram, Plate XII, which gives the "geometric lengths" of all members. The geometric lengths were corrected by an amount equal to the change of length of the member under full load, increasing the geometric length of compression members and shortening that of tension members. The changes of length due to full load were computed for each member with the table of stress coefficients, which are the values of the ratio, u, in the formula, $\frac{p u l}{E}$. A table was then prepared showing the geometric lengths, the increase or decrease for camber, and the finished length of each member, both in feet and decimals and in feet and inches, and the finished lengths for the stringers, which, being shorter than the finished lengths of the lower chord members, were not riveted to the floor-beams until after the lower chords were under a considerable compressive stress. For erection purposes, and to carry the locomotive crane in setting the falsework bents and floor members, the stringers were supported on shelf-angles with stiffeners proportioned for the erection loads. This table, having been made and checked carefully, assisted materially in avoiding errors in the preparation of the detailed plans.

Provision for Adjustment at the Anchorage.—The lower anchor-bars, up to the first pin below the top of the masonry, were embedded in the concrete, but above this pin an open well was left to permit of some lateral movement and adjustment. After the erection was completed, it was planned to fill the well with concrete through a hole left for the purpose in the top of the pier, completely embedding the anchor-bars. The rocker links connecting the pin, L_0, in the bottom chord with the pin in the upper end of the anchor-bars were not bored until after the anchor-bars were in place. Elevations were then carefully taken on the upper pin-holes in the bars, and the rockers were bored to such lengths as were required to compensate for errors in setting the anchorages. The actual variations were small fractions of an inch.



The 9¾-in. pin, engaging the upper end of the anchor-bars and the lower end of the rocker, was made with a reduced diameter of 7¾ in. at each end where it passed through the webs of the shoe. The pin-hole in the shoe was bored to a diameter of $10\frac{1}{32}$ in. There was then inserted at each end of the pin, and engaging the webs of the shoe, flanged bushings, bored with ½ in. of eccentricity. As the maximum erection uplift, with the traveler near the center of the suspended span, was

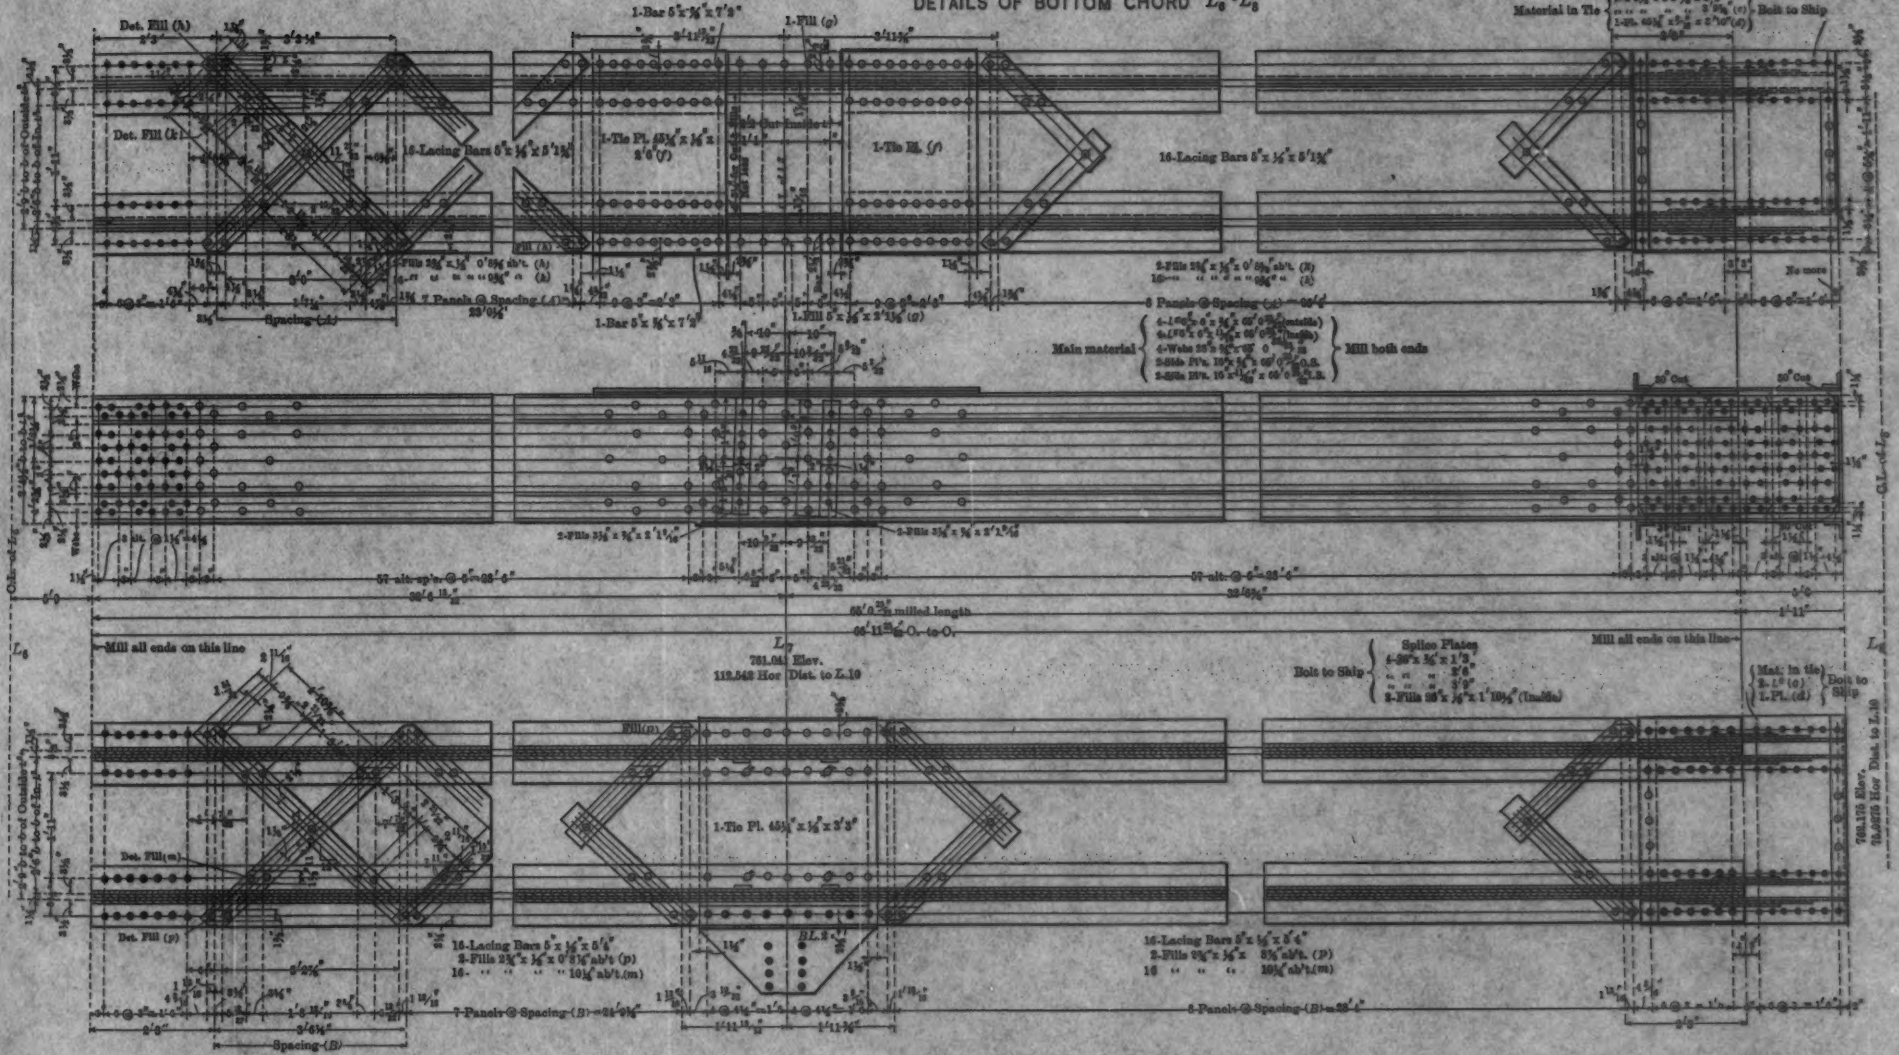
nearly equal to the maximum uplift for the finished bridge, with live load covering the cantilever arms and suspended span only, the eccentrics were adjusted and tap-bolted to the webs of the shoes when the traveler was at its extreme position. This adjustment proved to be efficient as well as extremely simple and inexpensive. It was well adapted for the conditions in this case, but would probably not be available in others.

Lower Chords.—In detailing the lower chords, an effort was made, with considerable success, to use a standard rivet spacing throughout, notwithstanding the variable panel lengths and camber increments. Plates XVI and XVII show the bottom chord members, L_4-L_6 and L_6-L_8. As may be seen, the rivet spacing, for a distance of 7 ft. 3 in. on each side of the main panel points and 15 in. and a fraction on each side of the sub-panel points, is fairly close, with thirty-three alternate spaces of 6 in. in the 25-ft. panels. (In the 37 ft. 6-in. panels there are fifty-seven alternate spaces of 6 in.) The twelve alternate spaces of 4½ in. on each side of the main panel points provided for all the lower chord splices in the cantilever and anchor arms except two. The splices in the lower chord were designed for about 50% of the strength of the members, and consequently increased in length toward the cantilever pier, L_{10}. The rivet spacing in the splices was 1½ in., alternating, which interspaced in the 4½-in. alternate spacing without changing the stagger. This permitted a considerable similarity in the rivet spacing of the different chord members without carrying the 1½-in. spaces beyond the required length of the splice-plates at any point, and made the spacing similar in all splice- and pin-plates. As the bottom chords were parallel with the grade of the roadway, and the intermediate posts and hangers were vertical, the riveted connections at the sub-panel points had a bevel equal to the grade, requiring an odd space on each side of the sub-panel points. This space was also made to serve the purpose of taking up the variation in length of the member due to the camber increment and to the angle between the axis of the member and a horizontal line, thus concentrating all the fractional spacing at one point.

Lower Chord Lattice.—The contract plans required the lower chords to have a double lattice, at top and bottom, made of 6-in. channels, at 10½ lb. per ft., for the anchor and cantilever arms, and of 5-in. channels, at 6½ lb. per ft., for the suspended span. This was changed

to 5 by ½-in. flat bars in the lower chord sections between L_0 and L_{14}, due to the change from four to eight angles in the main chord sections, as has been mentioned. In developing the details, it was found that the 5-in. channel was not wide enough to accommodate a sufficient number of rivets, and it was also considered that the metal of the webs was entirely too thin. The effort to find a satisfactory substitute, without increasing the weight, resulted in the use of single angles flattened at the ends where they connected with the main member and at the center where they crossed each other. Experiments showed that, when the ends were flattened out, the center of gravity of the angles was in the plane of the under side of the flattened portion.



Four full-sized comparative compression test pieces were then fabricated and tested. A 3½ by 3½ by $\frac{5}{16}$-in. angle was compared with a 6-in., 10½-lb. channel, and a 3 by 3 by $\frac{5}{16}$-in. angle was compared with a 5-in., 6½-lb. channel, the former intended for the anchor and cantilever arms and the latter for the suspended span. These test pieces were made of the exact length, from center to center of inside rivets, that the lattice bars would have in the finished bridge, and were riveted to shoes adapted to bear on the plattens of the testing machine, so as to bring the compressive stress on the test piece in the same line, as nearly as possible, as would occur in the work. Of course, these tests did not represent the conditions of stress to which lattice bars would be subjected in a member of the bridge, but they furnished comparative tests, as nearly as it was practical to make them. An excess of rivets was used in the connections, because the object was to test the sections and not the riveted connections. Table 2 gives the results of these tests.

TABLE 2.—Results of Tests of Channels and Angles.

	Ultimate Strength.		
	Total.		Per square inch, actual, in pounds.
	Computed,* in pounds.	Actual, in pounds.	
6-in., 10-lb. channel	53 600	55 500	17 950
3½ by 3½ by 5/16-in. angle	47 750	47 050	22 820
5-in., 6½-lb. channel	32 200	30 450	15 620
3 by 3 by 5/16-in. angle	38 700	46 070	25 870

* These were computed by Tetmajer's formula for the ultimate strength of small columns, as given by C. C. Schneider, Past-President, Am. Soc. C. E., in his report on the Quebec Bridge, $f = 44\,100 - 162\,\frac{l}{r}$, modified by the calculated effect of eccentricity of connections.

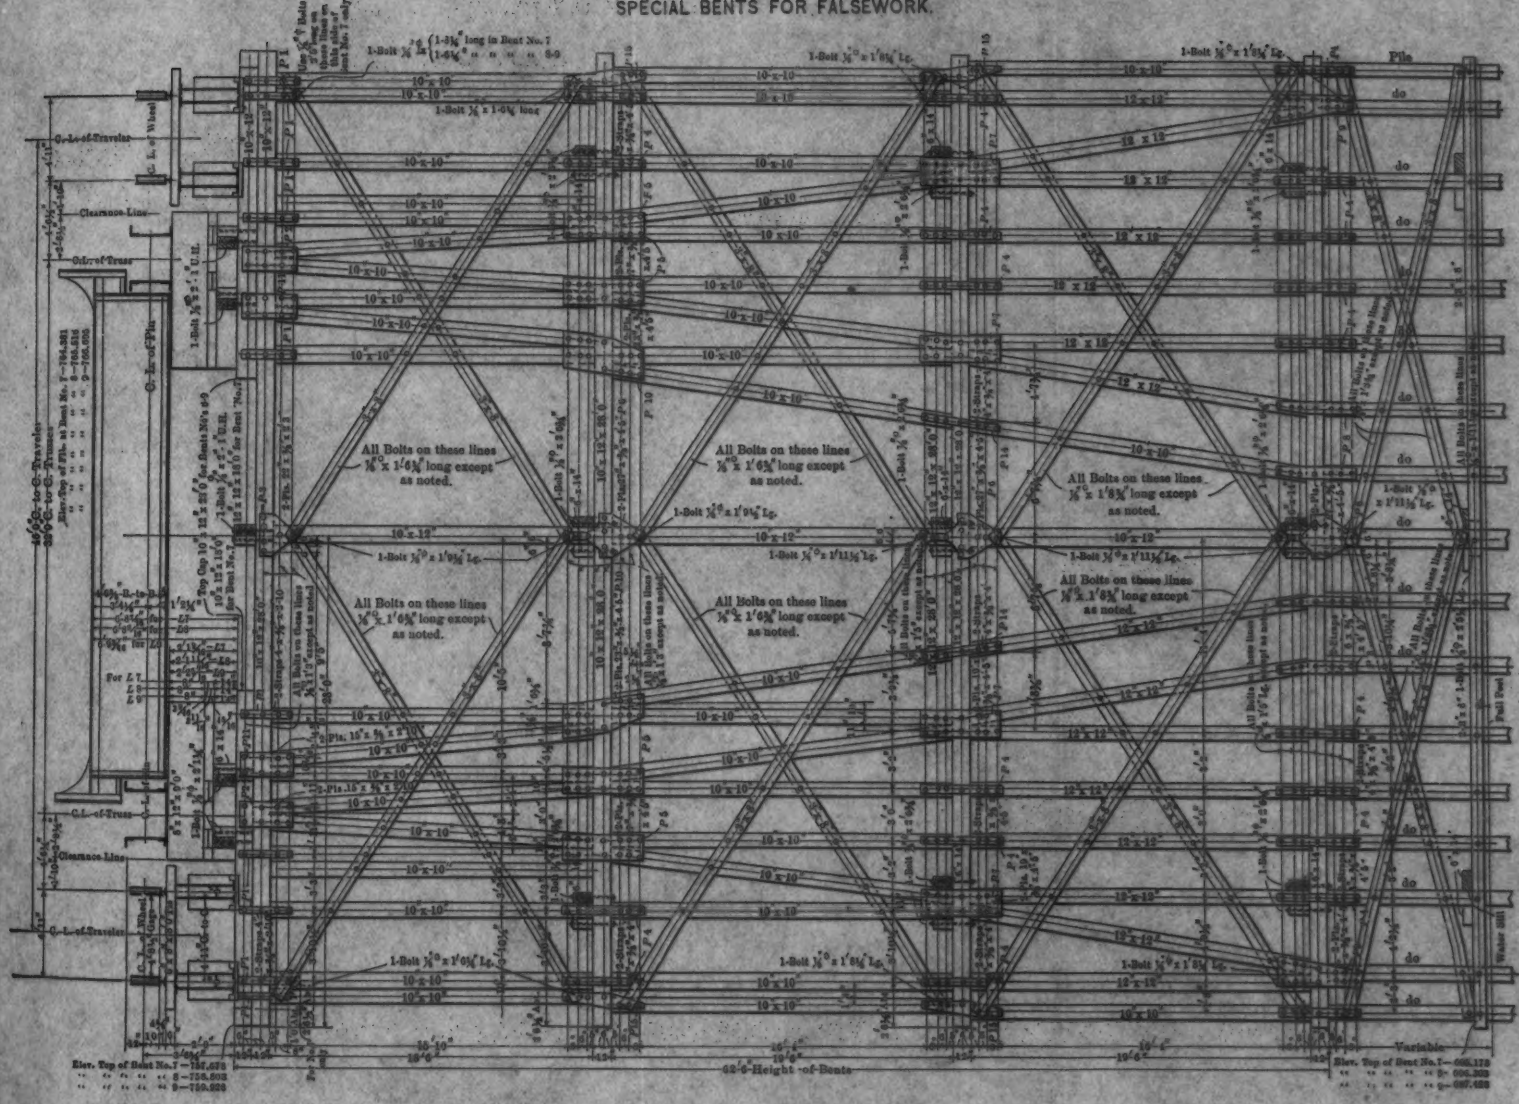
DETAILS OF BOTTOM CHORD L_6-L_8

These tests indicate an efficiency for the angles of from 30 to 50% greater than for the channels, and the computations show that this is due to the very small eccentricity of the angle connections.

The deflections were recorded and the load removed with each increment of 5 000 lb. up to 30 000 lb., at which point the 6-in. channel showed a permanent set, whereas the 3½-in. angle did not. At 40 000 lb. the 6-in. channel showed a flexure 25% greater than the 3½-in. angle. The permanent set of the 5-in. channel and the 3-in. angle was not obtained. The flexure was always in the direction indicated by the slight eccentricity of the riveted connections, except for the 3-in. angle, which began to deflect in the opposite direction; but, after the load reached 40 000 lb., the eccentricity of the connection caused the flexure to reverse. Between the shops and the testing laboratory, this angle had been bent in handling or shipping; therefore it was a defective test piece at the start. The test, however, proved that this initial bend was in the direction which neutralized the effect of eccentricity until the load reached 40 000 lb., and it is probable that the ultimate load was greater than would have been the case if the angle had been straight. All these test pieces failed by column flexure, the back of the channels and the root of the angles being concave. On the basis of these tests, the angle sections were approved and used instead of the channels in the lower chords from L_0 to L_6, and from L_{14} to L_{22}. They afforded ample room for the riveted connections, and the saving in weight fully compensated for the additional cost of fabrication. It also avoided cutting and splicing at intersections, which is an objection to the channel lattice bar.

Shoes and Connections of Floor-Beams and Sidewalk Brackets at L_{10}.—The shoes at L_{10}, which carry the entire load that comes on the cantilever piers, are built up of plates and angles with three ribs and three diaphragms, and take their loads through 14-in. pins. They have a base of 8 by 9 ft., and a height, to center of pin, of 8 ft. 6½ in. The thickness of the bearing of the three ribs is 17¾ in., and the shipping weight is 37 860 lb. The shoes are connected across the pier by box struts, 4 ft. deep and 2 ft. 6 in. wide, latticed on four sides and riveted to the shoes. The end connection plates of these struts are extended up to form a seat for the floor-beam at L_{10}, bringing the end reactions of this beam directly to the shoes. This detail was adopted in order to avoid the almost impossible field connections of the floor-beam to the tower columns, as contemplated by the contract plans. The brackets support-

ing the sidewalk at the tower, L_{10}, were also supported directly from the shoes for the same reasons.



Forked Connections at Main Panel Points Common to Two Diagonal Compression Members.—To meet problems of packing, and to facilitate erection, the sub-diagonals, M_7-L_8 and L_8-M_9, were connected at L_8 on common pin-plates which formed a fork. This was shop-riveted to L_8-M_9 with field-riveted connections for M_7-L_8, 3 ft. 6 in. from the pin center. The same detail was used at L_{12} and L_{18}. The detail at L_{10}, for the members, U_9-M_9-L_{10} and L_{10}-M_{11}-U_{12}, is similar, except that the fork is a separate member with field-riveted connections for both of the main members.

This detail introduced some secondary stresses, which were duly considered and provided for. In this case these were neither excessive nor difficult to handle, but, with heavier members, the secondary stresses might be objectionably large.

Trussing in Center Cross Panels of Suspended Span.—The contract plans called for cross diagonal eye-bars, without adjustment, in the center panels of the suspended span, U_{22}-M_{23}-L_{22}. As in all other parts of the bridge the lower sub-diagonals were compression members, and as it was necessary to introduce adjustment in these panels, the upper sub-diagonals, U_{22}-M_{23}, were made of adjustable eye-bars connecting on the pin, M_{23}, outside of all the other members. The lower sub-diagonals on the north side (the first side erected) carried shop-riveted pin-plates at M_{23}, which plates were provided with field-riveted connections for L_{22}-M_{23} (south side), U_{23}-M_{23}, and M_{23}-L_{23}. This member was erected on the north side, and was held in position by the adjustable diagonals, U'_{23}-M_{23}, engaging the pin, M_{23}. In closing the bridge, all the other members connecting on M_{23} came together automatically and without any difficulty, except that required to guide them into the connection plates. As soon as the suspended span was swung, the upper adjustable diagonals on the south side were slipped over the ends of the pins and the nuts were then screwed on, completing the connection.

Connection of End Post to Top Chord of Suspended Span at U_{18}.—The end posts of the suspended span have, shop-riveted to their upper ends at U_{18}, and integral with them, a short section or stub end of the upper chord. The main chord section is field-riveted to this piece 3 ft. 7 in. forward of the pin, U_{18}. The short section of upper chord is extended back of the panel point 5 ft. 3 in. to take the subsidiary pin to

SPECIAL BENTS FOR FALSEWORK.

which the toggle bars connect. This detail permitted all the connections to be made on the pin, U_{18}, without the necessity of supporting a long section of upper chord projecting out. It also permitted the traveler to be erected with its principal reaction at U_{18} before connecting the upper chord section, U_{18}-U_{20}. This short section or stub end of upper chord is connected to the end post with heavy gusset-plates, sufficient to take care of all secondary stresses which occurred at this point during erection. The separate pin, U_{18} *A*, for the toggle bars, permitted the triangle, U_{16}-L_{16}-U_{18}, to be connected and made self-supporting before making the pin, U_{18}.

Provisions for Wind Shear in Bottom Frame.—Except at L_{16}, where there is a slip joint, the wind shear in the bottom frame is carried by the buckle-plates and their connections to the stringers and floor-beams, and is transmitted to the lower chord through the connections of the floor-beams to the vertical truss members and of the latter to the lower chord by pins at the main panel points and by riveted diaphragm connections at the sub-panel points. These connections were all investigated and found to be ample, except at the sub-panel points, L_7, L_9, L_{11}, and L_{13}, where the sub-verticals were somewhat deficient in transverse strength to transmit the load safely; but, as there is a considerable excess of strength at the main panel points on each side (L_6, L_8, L_{10}, and L_{12}), it was assumed that the stringers and their connections, particularly the lines adjacent to the trusses, would take up the excess shear at these sub-panel points and distribute it to the main panel points.

The wind shear at L_{16} is transmitted to the lower chords at L_{15} through a triangular frame which has its apex in a cross-head sliding between two brackets at the center of the floor-beam, L_{16}. This detail is not novel, but was worked out independently, before the description of a similar one had been published. The legs of the triangle are composed of four angles latticed in an I section. They are braced laterally, by a frame, to the bottom chord or erection strut just back of the wedge pin, serving to brace the latter during erection. This is shown on Fig. 6.

Erection.

General Plan.—Naturally, the erection of steel began at each side with the riveted pony truss spans, of which there were three, 75 ft. long,

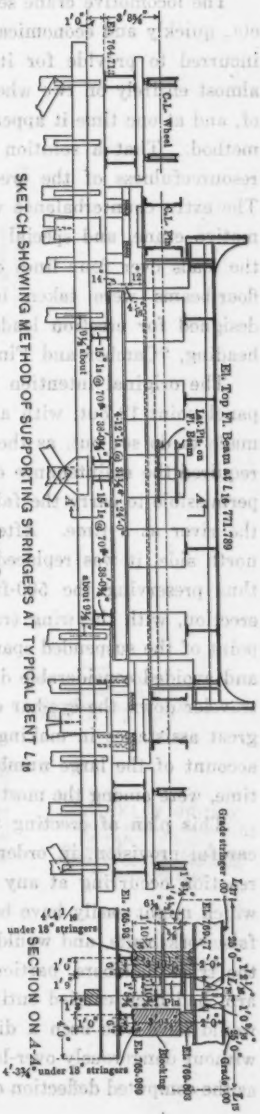
on the Sewickley or north side, and two of 75 ft. with one of 118 ft. over the Pittsburgh and Lake Erie tracks, on the south side. These trusses were assembled on the ground and lifted into place with the 30-ton locomotive crane. In setting the 118-ft. trusses, the locomotive crane was assisted by a boom derrick.

Falsework.—The falsework for the anchor arms was assembled in single stories and lifted into place by the locomotive crane, the piles having already been driven and cut off level. Plate XVIII shows the bents under panel points 7, 8, and 9, and Fig. 7 shows the provision for supporting the stringers and locomotive crane at panel point 16. As soon as the upper story on each bent was completed, the necessary blocking was arranged and the floor-beams and stringers were set thereon in final position and bolted up. The buckle-plates were then placed and bolted, and on them the track was laid for the advance of the locomotive crane. This operation was repeated, bent by bent, until the falsework reached the cantilever pier or one or two panels beyond. The wing or gantry traveler was then erected on the falsework, stock I-beams being used to support the traveler tracks on each side, as shown in the plans. As the erection of the steelwork for the anchor arm trusses proceeded, the locomotive crane continued to set the falsework bents and the floor-beams and stringers, out to panel point 18.



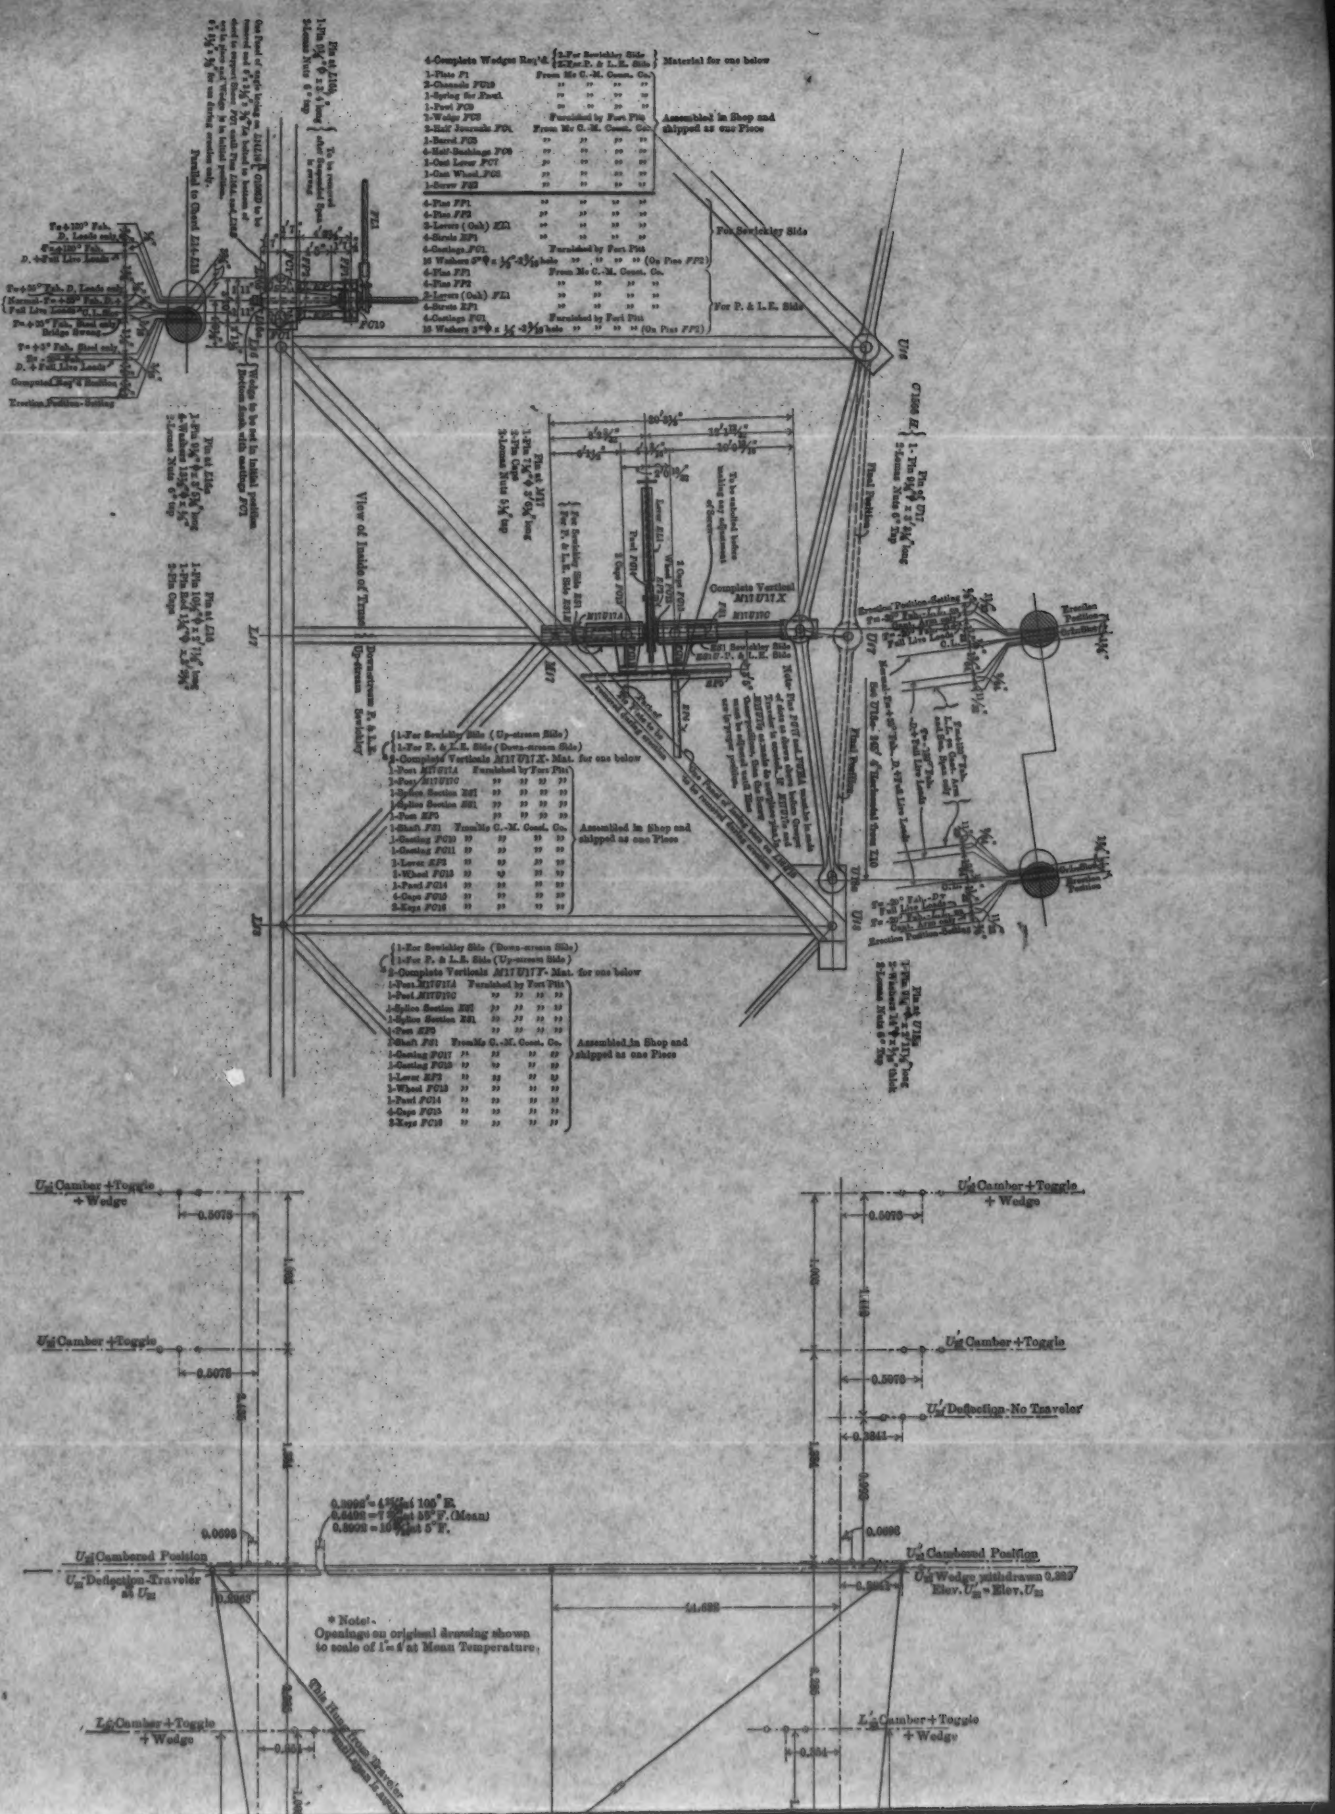


FIG. 7. SKETCH SHOWING METHOD OF SUPPORTING STRINGERS AT TYPICAL BENT L16

The locomotive crane set the falsework bents, floor-beams, stringers, etc., quickly and economically, fully justifying the trouble and expense incurred to provide for it. The heavy reactions, which often came almost entirely on two wheels of one truck, were difficult to take care of, and at one time it appeared to be impracticable to make use of this method. That a solution was finally reached is largely due to the resourcefulness of the erection department of the Bridge Company. The extra counterbalance was removed from the rear end of the locomotive crane, and special outriggers were provided which distributed the loads over four lines of stringers. The stringer reactions at the floor-beams were taken by shelf-angles with supporting stiffeners designed for erection loads. These have been referred to under the heading, "Camber and Finished Lengths of Truss Members."

The original intention had been to erect the cantilever arm, from panel point 12 out, with a creeper traveler, and some provisions were made to do so; but, as the restrictions on account of navigation only required the maintenance of a clear waterway of 500 ft., it was found permissible to carry the falsework out to panel point 18 on one side of the river at a time. After all the falsework was removed from the north side, it was replaced, out to panel point 18, on the south side, thus preserving the 500-ft. opening at all times. This method of erection, with the wing traveler on falsework out to the second panel point of the suspended span (18) was very economical and expeditious, and avoided considerable difficulty and expense in carrying the creeper traveler down the eye-bar chain of the cantilever arm. It also was of great assistance in making the panel points 16, 17, and 18, which, on account of the large number of members necessary to hold up at one time, were among the most difficult to close.

This plan of erecting the cantilever arm with falsework required careful provision, in order to avoid any possibility of a concentrated reaction occurring at any of the bents outside of the cantilever pier, which might easily have been caused by an unequal settlement of the falsework bents, and would have crushed the bents or buckled some of the truss members, particularly in the sub-panels. If the cantilever arm had been carried entirely by the falsework during its erection, it would have also been a difficult and hazardous operation to swing it without dangerously over-loading some of the bents and truss members, as the computed deflection of panel point 18, with the erection completed

VOL. LXXVI, No. 1256.
BUEL ON
THE SEWICKLEY CANTILEVER BRIDGE.

to that point, was about 0.8 ft. With panel point 22 erected, the computed deflection of panel point 18 was about 1.45 ft. Each truss was fully adequate to carry its own weight as a cantilever, together with the weight of the traveler at L_{22}, which, of course, they had to do in erecting the suspended span. Therefore, as each successive panel was erected by the gantry traveler, from panel point 10 to panel point 18, the wedges were backed out at all points outside of the cantilever pier so as to swing the span entirely. With every load added to the trusses great care was exercised to make sure that the wedges were not too tight, but they were kept in place for lateral stiffness only and to hold the falsework in line with the steel superstructure. From this it will be seen that the falsework under the cantilever arm, after the locomotive crane had set the floor system, never carried anything except the gantry traveler and the panel of steelwork being erected at any time, but not yet connected.

As indicated in the preceding description, the erection was carried forward from panel point 18 by the true cantilever method, with a cantilever or creeper traveler moving on the upper chords of the suspended span. This traveler was erected by the wing traveler at panel points 16, 17, and 18, and was supported over the toggle bars by special I-beam tracks.

As shown by Plate XII, the roadway grade on the anchor arms is 3% ascending, which was introduced in order to get the head-room under the channel span required by the Government regulations. The grade from panel point 13 outward is 0.8%, with a vertical curve between panel points 10 and 13. The wheel base of the traveler was 75 ft., with three trusses, and this required special arrangements to get it over the vertical curve without overloading the stringers of the traveler track or the falsework bents. This condition was mitigated by using in the traveler track a flatter and longer vertical curve than that of the roadway, and by arranging the longitudinal sway rods in the traveler so that by slackening one pair of rods the traveler would deflect and partly adjust itself to the curve. The traveler was sufficiently strong in all details to carry its entire weight on one pair of wheels at each side, but, to have made the stringers and bents safe for such a concentrated load would have cost too much, and the danger of derailment would have been increased. The deflection of the traveler in the direction indicated was somewhat restrained by the longitudinal

struts, but a computation showed that the latter were not sufficiently stiff to cause undue concentrations when the sway rods were slack. These struts, however, proved to be so much stiffer than anticipated that they were used for staging in driving pins, etc., in preference to the staging brackets which had been provided.

The clear space between the top of rail of traveler track and bottom of traveler sill was 22 in. The largest pin that had to be driven through this space was 14 in. in diameter. This only allowed from 4 to 6 in. of clearance at the top and bottom to provide for variations in elevation and settlement of bents, camber blocking, etc. Several inches of this clearance were taken up by the adjustment of the vertical curves in the traveler track.

Much consideration was given to the hazard due to floods and other causes which might have destroyed the falsework. One of the provisions made for this was for swinging the anchor arm before the cantilever arm was erected. Erection ties were inserted, from U_2 to M_3 and from U_4 to M_5, and were removed as the shear in these panels was reversed, and the lower sub-diagonals were reinforced to meet this condition; but it was recognized that the greatest danger concerned the bents under the cantilever arms. These bents, 11 to 18, inclusive, did not carry any part of the steelwork after it had been fully connected, and therefore the hazard was practically confined to the possible loss of the falsework, provided only that the warning should afford sufficient time to run the traveler back to panel points 12, 13, and 14, lash it to the trusses, knock out the blocking, and let the falsework go. For floods and ice there would be sufficient warning for this. The trusses were more than able to carry this load except during the short time when panel point 18 had been made and the creeper traveler erected. With the two travelers on the cantilever arm at one time, there would have been some overloading, but this critical period was confined to the short time between the erection of the creeper traveler and the dismantling of the wing or gantry traveler. The work was planned so that this critical period was not encountered during ordinary times of high water. Fortunately, however, it did not become necessary to resort to any of these expedients.

Erection Deflections, Changes of Lengths, and Adjustments.—The deflections and elevations at the top of the floor-beams were computed analytically for the conditions of no load, for four conditions of loading in the finished bridge, and for seven conditions of erection loading.

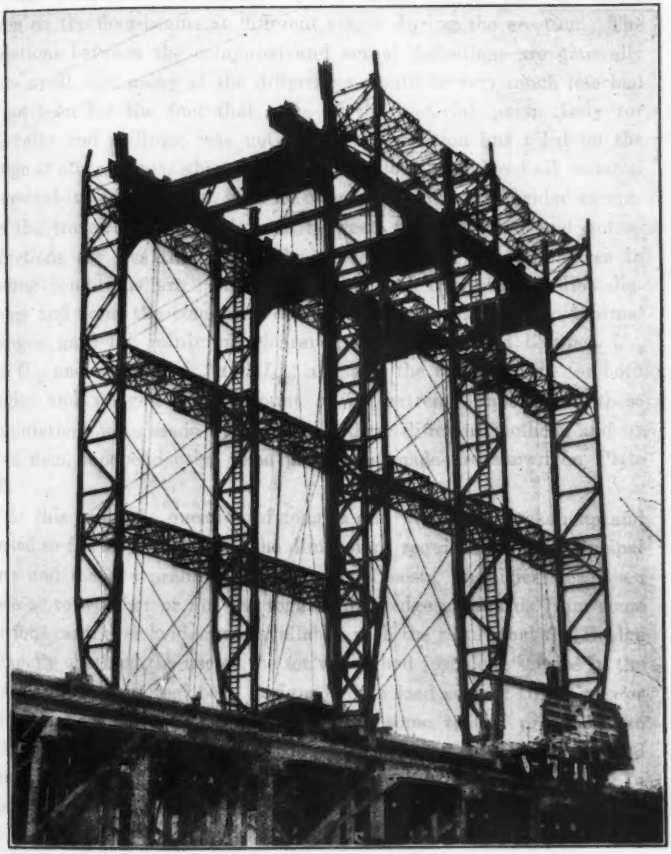

FIG. 8.—THE WING TRAVELER, SEWICKLEY BRIDGE.

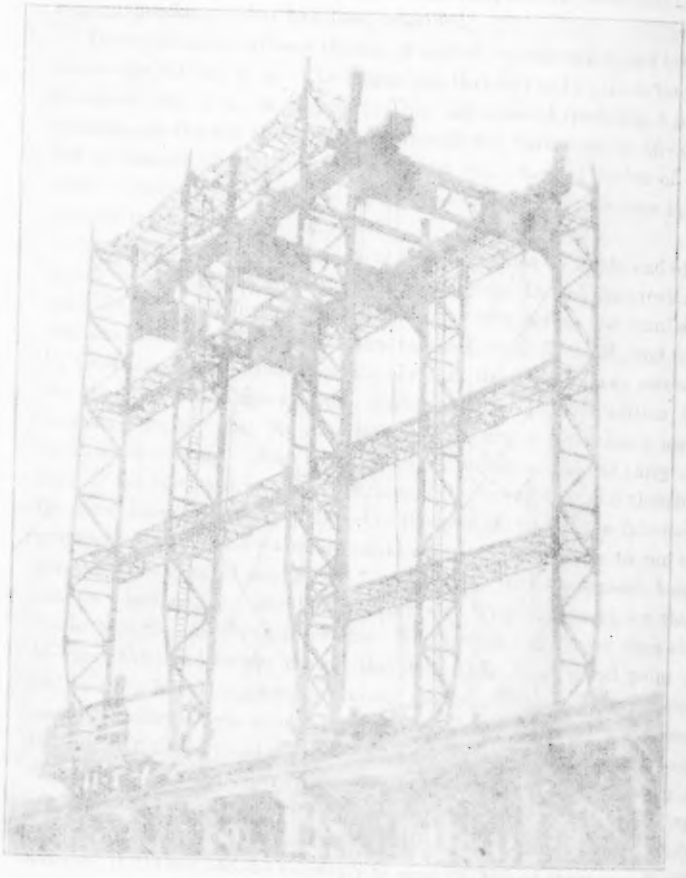

Plate XIX shows the deflection profiles for erection conditions. Williot graphical diagrams for displacements were also made for five conditions, the vertical co-ordinates being compared with and checked by the computed deflections. Plate XIX shows the elevations taken on the floor-beams at different stages during the erection. The variations between the computed and actual deflections are generally quite small, and many of the differences would be very much less had it not been for the fact that some of the material, particularly for sidewalks and railings, was not erected in position but piled on the bridge at other points, whereas the computations considered all material as erected in final position, with no other material on the bridge excepting the traveler. The variations between the computed and actual deflections are less than might be expected when the differences in loading conditions are considered. The data from the Williot diagrams and from the computed deflections, Table 3, added to thermal changes, gave the minimum clearance or play required between U_{16} and U_{18} and between L_{15} and L_{16}, and also the run required for both toggles and wedges. On account of its extreme importance, these computations were made five times, by three different methods and by three men, independently. The provisions made are shown on Plate XX.

At this point the question of toggles and wedges was taken up and carried so far as to determine the dimensions required for the principal parts and make a preliminary estimate of cost. Inquiries were then made as to whether or not the toggle and wedge apparatus from some previous cantilever bridge was available, with the result that the Bridge Company obtained the use of the set which had just done service in the Beaver Bridge. It had been designed for a load several times greater than the Sewickley Bridge, and required some special provisions to make it available, but there was the satisfaction of knowing that it had been tested under a much greater load than it would have to carry in this bridge. It is essentially the same as all the toggle and wedge devices that have been used in cantilever erections for the past ten years.

On May 15th, 1911, the lower chord of the suspended span was closed by driving the pins, L_{23}. The distance between U_{22} and U'_{22} was then measured and found to agree very closely with the computed clearance. The top chord was closed and the suspended span was swung on May 16th, 1911. During the entire work of erection, nothing of consequence

occurred which had not been foreseen and provided for. There were no losses of either men or material, and no serious injuries were reported. One man fell into the water, but was rescued without serious results.

General Directions for Erection, and Order of Closing Operations Issued to the Erection Department on May 19th, 1910.—The spaces for pilot nuts, L_{18}, L_8 to L_{12}, etc., are somewhat scant. They had better be started off before the pin is entirely home, that is, ⅜ in. back of the final position, or just flush.

The bottom chord splices of the anchor arm must be bolted and drifted before the anchor arm is swung.

The expansion pockets for stringers on beam L_0 are not heavy enough to take the weight of the locomotive crane, and the stringers must be blocked up from the pier.

The eccentric and pin at P_1 must be well greased and covered with canvas to prevent rusting before the adjustment is completed.

Fully bolt and drift the top chord splices at U_{18} before advancing the creeper traveler beyond that point.

The locomotive crane must not be run out past the tower, L_{10}, after the creeper traveler is erected.

While the traveler is at U'_{22} (north side), and before moving it, connect the counters, U'_{22}-M_{23}, and the lower sub-diagonals, M_{23}-L'_{22} (which have shop-riveted gusset-plates at M_{23}), on pin M_{23}.

Be sure that the counters, U'_{22}-M_{23} (north side), are screwed up to just the right length, and that they are not too short in any case. If they are $\frac{1}{16}$ to $\frac{1}{8}$ in. too long, it will be better than to have them too short, because, if too short, L_{22}-M_{23} (south side) cannot be connected in closing.

With the traveler at U_{22} (south side), make the pin, L_{23}, engaging L_{22}-L_{23}, L_{23}-L'_{22}, and M_{23}-L_{23}.

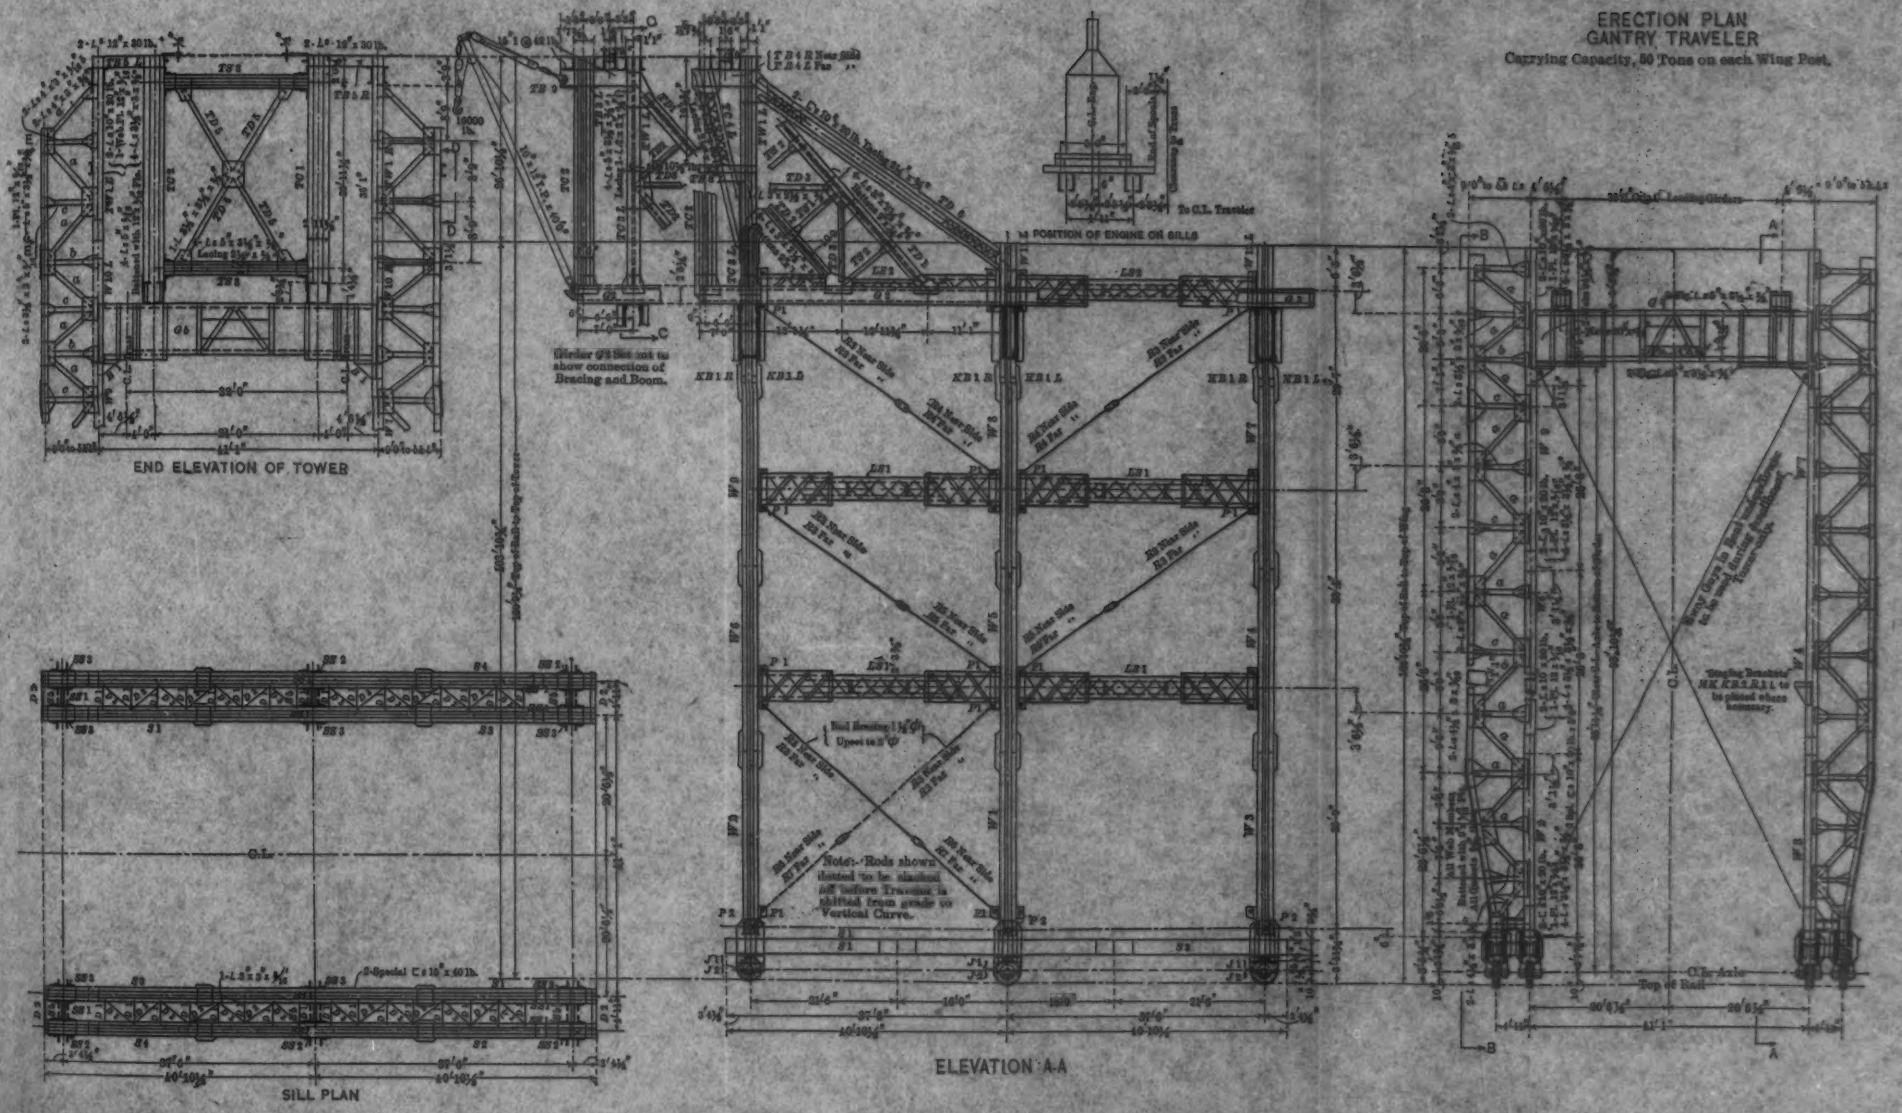
The lower sub-vertical, M_{23}-L_{23}, having a field-riveted connection at M_{23}, will have to be tied up or supported until the span is swung.

Bring U'_{22} level with U_{22} by backing out the wedges on the north side at L'_{16}.

Set the upper sub-vertical, U_{23}-M_{23}, bolting it to the gussets at M_{23}.

Set the top chord, U'_{22}-U_{22}, bolting up the splice to U'_{22}-U'_{20} and to the top of U_{23}-M_{23}. It will then be self-supporting, its half-length, U_{23}-U_{22}, projecting toward the south side as a cantilever.

Set and bolt the top lateral struts, U_{23}-U_{23}, and the top laterals, U'_{22}-U_{23}.



Release the toggles until the top chord, U'_{22}-U_{22}, is in bearing at U_{22}, and bolt the splice.

The top laterals, U_{22}-U_{23}, must be put in place as soon as possible after the top chords, U_{22}-U'_{22}, are set, and before the toggles are fully released. When fully released, the span is changed from cantilever to span with both ends supported, and the conditions of the lateral frame change. With the traveler on top, this is serious, and it is very important to place the laterals as directed above.

After the top chord, U_{22}-U'_{22}, is set, and the center panel top laterals are in place, and the top chord splices are bolted (with toggles partly released), it is very important to continue slacking off the toggle screws until the toggle bars are in a straight line (*i. e.*, entirely slacked off), before leaving the bridge, because, in the position above described, a drop in the temperature would cause the top chords to act as suspension cables and probably cause a disaster.

PLATE XXI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1252.
BUEL ON
THE SEWICKLEY CANTILEVER BRIDGE.

ERECTION PLAN
GANTRY TRAVELER
Carrying Capacity, 50 Tons on each Wing Post.

The operation of slacking off the toggle screws may continue uninterruptedly after the top chord is connected.

The wedges should then be entirely slacked off before bolting M_{22}-L_{23} on the gusset at M_{23}.

After the span is swung, it will be necessary to lift the weight of the members on the pin, L_{23}, to take the sag out of the lower chord at this point before L_{22}-M_{23} can be bolted at M_{23}.

The counters, U_{22}-M_{23} (south side), can be slacked with turnbuckles and slipped over the ends of the pin, M_{23}, as these counters are outside (next to the pin nuts).

NOTE.—Prime (′) refers to the north side.

The Wing or Gantry Traveler.—An investigation having shown the impracticability of rebuilding the steel traveler which the Bridge Company had used during the previous year, so as to adapt it for the Sewickley Bridge, the following question was proposed: "Is it practicable to design a traveler adapted for the erection of spans of variable dimensions and weights?" Before the prices of materials and labor had advanced to their present values, and when good bridge timber was plentiful and cheap, it was common practice to build a special timber traveler for each job; but, in recent years, it has been found more economical to build travelers of steel, and they have generally been made without a sufficient range of adjustment to fit widely varying cases, although, in several instances, they have been designed with some adjustable members.

The foregoing question was answered by the proposal that, "a steel traveler is a tool or machine which should be provided with such adjustments as to make it available for the erection of all spans within a comprehensive range." A little preliminary work demonstrated the fact that it was entirely practicable to construct such a tool, and the result is the traveler first used on the Sewickley Bridge. The Bridge Company had a considerable quantity of stock which it was desired to use for the travelers. Some of this stock was perfectly good material, but of unusual sections rarely called for, and some of it, while good enough for a traveler, would hardly be acceptable for contract work. It was also desired that the material from the old steel traveler should be used in the new one, as far as available. These considerations required a number of unusual adaptations of details, but did not affect the general design materially.

Plate XXI shows the general elevations of this traveler, together with the extension on top, designed for the erection of the

towers. Fig. 12 shows the top view and plan of loading girders with and without tower. Plate XXII shows the details of the adjustable longitudinal struts.

The shoes which carry the boxes of the main wheel journals and the pins connecting the lower ends of the wings can be adjusted for panel lengths varying by 6 in. For the Sewickley Bridge, it was bolted up for panels 37 ft. 6 in. long. The maximum reach is two 40-ft., and the minimum two 24-ft., panels. For two 32-ft. panels, one of the 16-ft. sections of sill would be removed and the center shoe shifted to the center of the remaining 16-ft. section. For two 24-ft. panels, the other 16-ft. section would be removed. The projection of the sills beyond the ends is thus kept within 8 ft. 3 in. The traveler may be used with two trusses or wings instead of three.

The wings were designed so that when bolted up in a total length of about 100 ft., and lying down flat, they can be supported on one point at their center. This provision was made so that they might be tripped up from the bottom pin with a tackle made fast to one point.

The longitudinal spacing in the wings is uniformly 5 in. from end to end, with 2½ in. edge distance at the ends of the sections, and bolts are used instead of rivets throughout all sections where the transverse girders might come. This permits the height from traveler rail to transverse girders to be adjusted to any distance up to about 95 ft., by variations of 5 in. The capacity of the traveler is sufficient to permit the addition of other sections of wings, so that the clear height could be extended up to about 125 ft.

The transverse box girders have open lattice in their center 10-ft. panels and solid-plate webs in the end panels. The latter are engaged by another set of web-plates with separate flange-angles, arranged to bolt on the outside of the center section. The holes in both sets of web-plates are punched, so that they can be bolted in any position to give clear widths of from 30 ft. 3 in. to 49 ft. 3 in. between the traveler wings. For the Sewickley Bridge, they were set at 40 ft. 3 in. clear. It is intended that these adjustments shall be made at the shop for each job, before shipping the traveler.

The loading girders were designed to give a large moment of inertia sideways. Their make-up was determined by the stock on hand. Open holes were provided in the webs to fix the saddles and prevent them from sliding longitudinally when drifting a load. Open holes were also

GANTRY TRAVELER

FIG. 12.

provided in the end diaphragms for bolting on brackets to carry Chicago boom seats. These booms were used to set the top lateral system between U_8 and U_{12}, after the traveler had moved forward, and also to assist in supporting one end of the upper chord, U_{10}-U_{11}. The loading girders were riveted up complete at the shop, but it proved so difficult to handle them that, before taking down the traveler on the north side, the rivets connecting them through the diaphragms were cut out and bolts were substituted when they were set up again on the south side. This reduced the weight necessary to handle at one time to about one-half.

The most difficult adjustment to work out was that of the longitudinal struts (Plate XXII). The center section of these struts, which is 2 ft. 3⅜ in. deep and 7 ft. 9 in. wide, back to back of angles, telescopes into the two end sections, which are 3 ft. deep and 8 ft. 7 in. wide, back to back of angles, eight clip angles, 3½ by 3½ by ⅜ in. and 13½ in. long, at each end, providing a good long connection and 1 in. of clearance between the sections. In making this adjustment, which will generally be done at the shops, the clip angles will be removed and replaced in the required positions.

The only parts of this traveler which are not adjustable for spans of different dimensions are the 1¼-in. round lateral and longitudinal sway-rods. It was considered preferable to avoid complications incident to introducing adjustments of wide range in these rods because it is very simple to make new pieces for the short ends, and the discarded pieces will be good stock which can be readily reworked.

The eight saddles for the main hoists were designed so as to travel on the loading girders with four wheels on two axles, and two of them were thus constructed. The other six were constructed with cast shoes and two 3½-in. pins to transmit the load to the girders. These pins are identical with the axles of the two fitted with wheels, so that they can be used either with wheels or with stationary shoes.

The twelve main traveler wheels were made with cast-iron centers or treads and double steel-plate flanges, riveted through, and with 7-in. journals, calculated to carry the maximum load when lifting. These wheels gave good service and no trouble. The two Mundy hoisting engines, one on each side, had three drums and four spools, and were set up on the sills in the forward bay, the longitudinal sway-rods being omitted in this bay. It was intended to use blocking between the sills

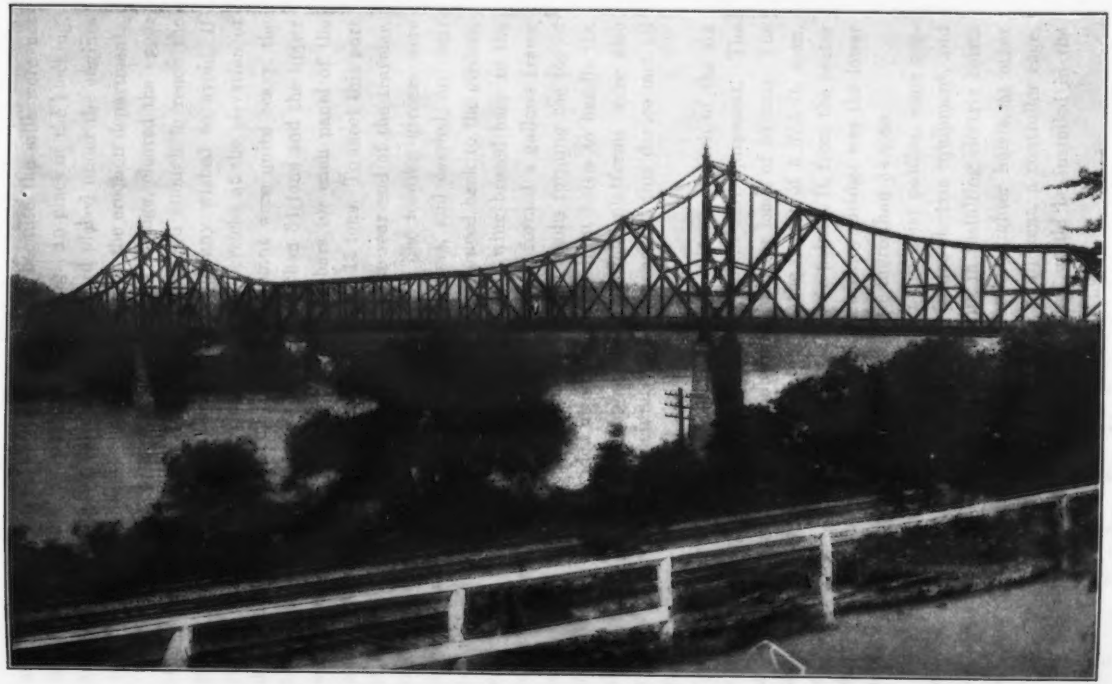

FIG. 13.—THE SEWICKLEY BRIDGE OVER THE OHIO RIVER. NEAR VIEW.

and the traveler track under the engines, because the sills were not sufficiently stiff to carry them when working. In place of the blocking, an extra pair of smaller wheels was afterward placed under the engines on each side. This improvement was made by the erection department.

The traveler, as set up for the Sewickley Bridge, cleared the upper chord panel points, 8 and 12, but was not high enough to reach the pins, U_9, U_{10}, and U_{11}. The Bridge Company wished to avoid, if possible, the risk incident to rigging boom derricks at the elevation of the top of the traveler. The lifts at this point were quite heavy, the lower sections of the tower weighing more than 34 tons and the upper sections more than 31 tons each. The eye-bars for each panel of the upper chord at the tower weighed more than 13 tons. To meet this part of the problem, an extension was built on the rear end of the traveler, as illustrated on Plate XXI and Fig. 12. The loading girders were shifted toward the center, to clear the trusses, and carried, on their 7-ft. outlook or overhang, a pair of columns braced back to the girders, which, with an extension section on the rear wing braced back to the center wing and a batter post from the same, formed a gallows frame centered over the trusses. Extensions of the beams forming the top of this gallows frame provided attachments for light hoists to handle the pins, driving rams, etc. Supports for scaffold platforms were also arranged at a convenient height. The efficiency of this device met all expectations.

This traveler was designed for loads of 50 tons at each of the six wings at one time, in addition to its own weight and equipment. The saddles for the main hoist were also designed for loads of 50 tons. The loading girders are good for 23.3 tons at the center of a 37.5-ft. span, and for more than 50 tons on the outlook at a point 4 ft. from the center of support. The heaviest piece in the Sewickley Bridge was the lower section of the towers which weighed a little more than 34 tons.

In designing the loading girders and main hoist saddles, some consideration was given to the possibility of future electric equipment, and it is thought that there will be no difficulty in installing electric hoists on top of the main hoist saddles and, for the lighter hoists, at other points on the upper deck. With electric equipment, a controller cage, located so as to give the best field of view, would be installed in the wings.

diagrams of the creeper traveler. It was carried over the toggle bars on I-beam stringers supported at U_{16}, U_{17}, and U_{18}. From U_{18} it was supported on a track laid on the upper chord of the suspended span. This traveler was so simple that further description seems unnecessary. It met the expectations fully, and all the members of the erection force were pleased with it.

Credit for the results secured from the design and construction of this bridge is due to all the engineers who were connected with the work, both on the part of the County and of the Bridge Company, and the writer received material assistance from them in the preparation of this paper. G. Gudmundsson, Assoc. M. Am. Soc. C. E., Consulting Engineer, was associated with Mr. J. G. Chalfant, County Engineer, in the preparation of the contract plans. H. R. Blickle, M. Am. Soc. C. E., is Secretary and Chief Engineer of the Fort Pitt Bridge Works.

DISCUSSION

Mr. Le Conte.

L. J. LE CONTE, M. AM. SOC. C. E. (by letter).—There is apparently nothing whatever to show why the cantilever type was selected for this simple bridge site. As far as one can see by the plans, there are no local physical conditions which call for it. It seems to the writer that three simple spans, approximating 450 ft. each, would cover the ground and furnish a stiffer, far better, and cheaper structure in every respect. He ventures to say, moreover, that the probable saving in first cost would have been fully 25%, if not more; consequently, he naturally cannot see the propriety of building such a structure at such a site.

It is natural to presume, therefore, that the taxpayers of Sewickley Borough and Moon Township, who paid for it, have substantial grounds for complaint.

Mr. Worthington.

CHARLES WORTHINGTON, M. AM. SOC. C. E. (by letter).—The writer would like to inquire what provision was made in this bridge to take care of the secondary stresses which develop in a cantilever truss of this type?

In the old Quebec Bridge, these secondary stresses were of such magnitude as to destroy the structure when the direct or axial stresses were about one-half the elastic limit of the material.

In the Beaver Bridge,* a very expensive roller bearing was provided under the main pier supports to reduce the secondary stresses.

In the Sewickley Bridge the members seem to have been proportioned for the axial stresses only. The writer has investigated a few of the members shown on Plate XIV, and finds that the sections agree pretty closely with those required by the stresses given on that plate and the unit stresses given in the body of the paper.

Consider, for example, the bottom chord member, L_{10}-L_{11}. Its length, l, is 900 in., and its radius of gyration, r, is 9.22 in. The unit stresses, as determined by the author's text, are then as follows:

$$\text{For live load, } 12\,000 - 40 \times \frac{900}{9.22} = 10\,040 \text{ lb.}$$

For dead load, double this, or 20 080 lb.

For live load, dead load, and wind load combined,

$$10\,040 \times \frac{20}{12} = 16\,750 \text{ lb.}$$

* "The Pittsburg and Lake Erie Cantilever Bridge over the Ohio River at Beaver, Pa.," by Albert R. Rayner, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 136

So that the required sectional area of the bottom chord member, L_{10}-L_{11}, is as follows: Mr. Worthington.

Dead load.....	1 467 400	at 20 080	=	73.0 sq. in.
Live "	623 600	" 10 040	=	62.0 " "
				135.0 " "
Wind "	966 100			
Total	3 057 100	at 16 750	=	183.0 sq. in.

Taking the greater of these required areas, 183.0 sq. in., it will be seen that the actual area of 190.2 sq. in., is only 4% greater than that required, so that practically no excess of material has been added to take care of the secondary stress in this member, and the only provision for it lies in the unit stresses themselves. The writer does not think that 24 000 for dead load and 12 000 for live load, properly reduced for columns, are low figures for direct stress in steel of the character probably used in this structure.

The eccentric used at the L_0 point is in itself a source of secondary stress. If this eccentric were to be fixed in position so that the offset of centers of ½ in. lies in a horizontal direction—a very possible condition—there would be developed at this point a bending moment of $240\,000 \times \frac{1}{2} = 120\,000$ in-lb., which, measured in terms of the area of the two 10 by 1½-in. bars multiplied by the stress in the extreme fiber of the bar, is $120\,000 \times \frac{6}{10} = 72\,000$ lb.

The axial stress in these two bars is constant at 384 000 lb., so that this secondary stress of 72 000 lb. amounts to some 18.7% of the axial stress. This secondary stress may not develop while the bridge is new, on account of the lubrication applied to the eccentric, but it will certainly develop later. Taking the coefficient of friction between the pin and the bar at 0.4, the resisting moment to be overcome before the bar would rotate on the 9¾-in. pin is, $384\,000 \times 0.4 \times 4.87 = 750\,000$ in-lb., or about six times the amount necessary to develop the moment of 120 000 in-lb., due to eccentricity in application of the load to these bars.

THEODORE A. STRAUB, M. AM. SOC. C. E. (by letter).—The results obtained from the methods used in the construction of the Sewickley Bridge were so satisfactory that a few words from the writer may be of interest. In all the departments of the Fort Pitt Bridge Company —the drafting-room, shop, and erection—the results were economical in the broadest sense of the word. These methods also aided materially in establishing that complete confidence and hearty co-operation which is so desirable and effective in the execution of work of this kind among all persons connected with it. Mr. Straub.

Mr. Straub.

Duplication of structural steel members cannot often be controlled, but it is frequently possible to duplicate the parts which compose such members, even if there is a marked difference in their final make-up. This may or may not be the duty of the purchaser's engineer, but, if it is, the latter, by the stand he takes in settling questions of detailed shop drawings, can often make a seemingly inexpensive piece of work very costly to the fabricator, or *vice versa*. It will be noted that a special effort was made to secure such duplications, and the consequent economical results were due to the latitude allowed to the Bridge Company by the County Engineer.

Where possible, all field connections were reamed in their final relative positions in the shop. This resulted in securing good fits and finish, and obviated the necessity of the correction of mistakes in the field. The writer might say, in passing, that this is the general practice of the Fort Pitt Bridge Works on all work of any magnitude, and it has always been felt that it is an economical method of procedure. All field connections were made in the manner planned, without trouble and interferences, the final connections and adjustments being especially satisfactory.

The writer believes that the special angle lacing bar, as described by Mr. Buel, was used for the first time, as such, in an important bridge member. In sufficient quantities, its fabricating costs are not excessive, and the bars can be made in any blacksmith's shop which has a power hammer or press. This lattice bar is compact, efficient, and neat in appearance; it also has the additional advantage of readily shedding water.

Referring to Plate XIX, entitled "Profiles for Erection": These data were used freely, and were found to be especially helpful throughout the erection of the structure. They proved a ready check at all stages, and satisfied the engineers and erectors at all times that the work was progressing properly and safely.

The simple and inexpensive anchorage arrangement required the efforts of one man only in making the adjustment, thus giving extremely satisfactory results.

Both the wing and creeper travelers responded at all times to the duties planned and imposed on them in a very economical and efficient manner. It was also found that the adjustable features of the wing traveler, as well as the extra weight, did not affect the cost of its operation materially. The Bridge Company anticipates its use for future erection, and considers it a very good and efficient tool.

Complete harmony existed at all times among the engineers of the County and of the Bridge Company, and this was not the least of the pleasing results obtained by the methods used. All points in question were discussed freely and openly, and were settled promptly. Much credit is due to all in this regard and they deserve praise.

C. W. Hudson, M. Am. Soc. C. E.—It would be of interest to structural engineers to know how much it cost to make the anchor arms of this bridge self-supporting in case of a wash-out of the false-work. This expense, whatever it amounted to as a percentage of the whole cost, was in the nature of insurance against the loss of these arms, and against the loss due to the consequent delay in completing the structure in case of such wash-out. Mr. Hudson.

V. R. Covell, Assoc. M. Am. Soc. C. E. (by letter).—Referring to Mr. Le Conte's discussion of the type of structure used, the following conditions controlled: Mr. Covell.

The Act of Congress relative to bridges across the Ohio River, approved December 17th, 1872, as amended February 14th, 1883, requires that bridges above the mouth of the Big Sandy shall have at least one channel span with a clear waterway of 500 ft. between piers, measured at the low-water line, and with a clear height of 90 ft. above low water and 40 ft. above local highest water. The demands of the river shipping interests and the ruling of the War Department fixed the span at 750 ft., from center to center of piers. The local conditions were unfavorable for a suspension bridge, and the cantilever was adopted.

Henry H. Quimby, M. Am. Soc. C. E. (by letter).—Two of the features of the subject treated in this paper suggest some experience that may be of interest as a discussion. One is the construction of the floor, and the other is the deformation of the trusses in erection. Mr. Quimby.

The character of the floor construction of such a bridge is not the least important part of the design, because of the special value of lightness as well as of durability. The use of wood blocks is commendable, if the base be substantial. The paper does not state the size and character of the buckles of the floor plating. The thickness of the concrete paving base is said to average 3 in., which probably allows about 2 in. over the flat portions. If the plates are multiple-buckled, are the ridges or divisions between the buckles depended upon for cross-support, or is transverse stiffening provided?

Buckled floor-plates, as originally used, were in single buckles turned up, forming vaulted arches, and were supported on all four sides. Later, the custom arose of turning the buckles down and using long plates with several buckles in each, and without any cross-beams under the divisions. The strength of such a member is not easy to figure. It depends in part on the narrowness of the divisions, and in part on the thickness, and therefore the distributing value, of the concrete over them. The divisions must obtain support from the arch action of the inclined sides of the adjacent buckles. If a division be wide and have only a thin non-distributing paving over it, the corners or edges of the division will yield successively and alternately down and

Mr. Quimby.

up under rolling loads. Only a slight movement of this character is required to crack and ultimately crumble cement concrete. When this stage is reached, the pavement is near to destruction.

Such a case occurred recently in the asphalt paving of a new deck on an old bridge where $\frac{5}{16}$-in. plates were used, supported on stringers, 5 ft. 6 in. apart in the clear, buckles, 5 ft. 3 in. by 4 ft. 3 in., and divisions varying from 1 to 12 in. in width because of varying panel lengths of the structure. Considerations of dead load and also of established street elevation demanded a thin floor, and so the paving base was used only to fill the depressions of the buckles, and the asphalt binder coat—1 in. thick—was laid directly on the flat parts of the plates. The wearing surface was 2 in. thick. The vehicle travel was very heavy, and, for several months during the reconstruction of the other half of the deck, it was concentrated on one shoulder in a narrow line. Within two or three months it was observed that the paving was breaking in several places, and it was found that these places were the wider, flat portions of the deck plates. In time the paving at two points was sufficiently pulverized to become dislodged and form holes, exposing the plate. Then the dropping of wheels off the edge of the surrounding paving pounded down one edge of each division thus exposed.

The remedy applied was the placing of chair supports under all divisions—a floor member of the old structure being suitably situated below each point—and then repaving the whole shoulder, the grade, at the same time, being raised $1\frac{1}{2}$ in., so as to have a little concrete over the entire surface of the floor-plates.

The lesson seems to be, that if multiple-buckled floor-plates are used without cross-support, the divisions should be as narrow as practicable, and they should be covered with a bed of concrete, say, as thick as the width of the division.

It would seem that the provision for making the field connections of certain members is not covered in the paper. $L-U_{11}-U_{12}-L_{12}$ form a quadrangle, made rigid by $M_{11}-U-L_{12}$, diagonally across it. The camber allowances in the lengths of these members must have distorted the quadrangle so much, while the members were without stress, that neither pilot point nor drift would avail to get the diagonal connected up, unless an easement were made somewhere. By what means was this connection made?

In the Red Rock cantilever bridge, where the main span is 660 ft., with a panel similar in character, the writer accomplished the connection of the panel by designing the lower chord splice below it so that it constituted a slip-joint. About 2 in. opening of this joint was required to permit the closing pin of the panel to be driven, and it remained open until the traveler advanced far enough in the erec-

tion of the succeeding panels to stretch and compress the truss members sufficiently to close the joint, and then it was riveted up. During the time that the joint was open the splice-plates prevented lateral displacement, and an adjustable bridle took care of possible tension from wind pressure. Mr. Quimby.

A. W. BUEL, M. AM. SOC. C. E. (by letter).—The truss members of the anchor and cantilever arms and the suspended span of this bridge are pin-connected throughout, except where compression diagonals connect on forks forming common pin-plates at L_8, L_{10}, L_{12}, L_{18}, and M_{23}, and the connections of sub-verticals to the lower chords. The lower chords, from L_0 to L_{22}, and the top chords of the suspended span, are faced for square bearing under full load and spliced in the usual manner. Excepting the tower posts, $L_{10} - U_{10}$, which have 34-in. web plates, the maximum depth of these members is only 28 in. With these conditions, and reasonable care in detailing, no very large secondary stresses were found, and were not to be expected. Mr. Buel.

The 14-in. pin at L_{10} relieves the secondary stresses at that point in a manner fully as efficient as the segmental rocker bearing of the Beaver Bridge.

It is important to note that the weight and loads of the Beaver Bridge are about three times as great as in the case of the Sewickley Bridge; also, that the depths of main members of the Beaver Bridge are approximately twice as large as those of corresponding members of the Sewickley Bridge, and that similar deformations produce secondary stresses about in proportion to the depths. The same comparison holds substantially for the old Quebec Bridge.

In investigating the secondary stresses in the Sewickley Bridge, some important compensations developed, which made it unnecessary to increase the sections, except in a few instances. For example, take the secondary stress in the extreme fibers of lower chords, L_9, L_{10}, L_{11}, due to deflection of the trusses. With maximum live load on the bridge, the additional compression in the chords of the lee truss due to wind brings the stringers into action, relieving the chord. Another point that should be considered is the difference between the character of loading for railway and highway bridges, particularly as to the probabilities of maximum live load occurring simultaneously with maximum wind load.

The secondary stresses for all the points just mentioned, and for others, were investigated, and, considering the liberal provisions made for wind stresses, the comparatively small secondary stresses were sufficiently provided for, in the opinion of all the engineers connected with the work.

Regarding the eccentric flanged bushing in the pin-holes of the shoes at L_0, on the anchor piers, introduced to provide for adjust-

Mr. Buel. ment, a very little study of the description and illustrations should be sufficient to show that no eccentricity at all is caused by this in the anchor bars. It is true that a maximum of $\frac{1}{2}$ in. eccentricity may exist in the bearing of the shoes on the masonry, but, as the base plates are 69 by 54 in., and as the maximum possible reaction produces less than half the permissible load per square inch on the masonry, the effect of this eccentricity is negligible.

It is not strictly true that the stress in the anchor bars is constant after adjustment is made. It will be relieved by the deformations of the masonry and of the shoe with its pin-holes and pin. Although this can hardly be computed with precision, an approximate estimate indicates that the variation would be about 20% from the maximum.

Answering Mr. Hudson's question as to the cost of making the anchor arms self-supporting:

The cost of this provision may be taken, approximately, as that of the following items:

Erection ties:

$U_2 - M_3$. Two 8 by $\frac{9}{16}$-in. eye-bars.

$U_4 - M_5$. One $8\frac{1}{2}$ by $\frac{5}{16}$-in. plate.
Four 3 by $\frac{5}{16}$-in. angles,
plus details, about 25 per cent.

Reinforcing, for erection stress:

$M_3 - L_4$. Two webs changed from 15 by $\frac{5}{16}$ to 15 by $\frac{1}{2}$ in.
Four angles changed from 3 by 3 by $\frac{5}{16}$ to 3 by 3 by $\frac{3}{8}$ in.
Pin-plates and areas back of and through pin-holes reinforced.

$M_5 - L_6$. Pin-plates and areas around pin-holes reinforced.

The temporary ties, $U_2 - M_3$ and $U_4 - M_5$, were only provided for one anchor arm, as they were removed from the north side before the south side was erected.

It will be seen that, in this case, the cost of making the anchor arms self-supporting was not great. Besides the sense of security that it gave to all concerned—by no means of negligible value—it left the Erection Department more latitude in arranging the sequence of operations, thus making for economy in the field.

Although it did not become necessary to swing the anchor arms on account of high water and ice, there were two or three occasions when the hazard would have been very great had it not been for this provision. Moreover, as a matter of convenience, they were swung and the falsework removed before the stresses were reversed.

Mr. J. G. Chalfant, County Engineer of Allegheny County, has furnished the following data on the floor construction, and his experience with a similar floor which has been in service several years:

"The buckle-plates are $\frac{3}{8}$ in. thick, from 18 to 34 ft. long, with several buckles in each, and are supported and riveted at the sides and ends, with the buckles turned down. The width of flat plate, between buckles, varies from 3 to 8 in., with a width of 11 in. in four plates. In 95% of the cases this width is not more than 6 in. The minimum thickness of the concrete is 3 in. Mr. Buel.

"The efficiency of this detail cannot be determined by calculation, and conclusions must be based on experience.

"Bridge No. 1, Allegheny River, at Oakmont, has substantially the same detail, and, after three years of service, shows no sign of failure."

The problem of making the connections in the field was given very careful study, the conclusions of which were entirely justified by the actual results.

Before adopting the lengths of truss members computed for camber, as described in the paper, a Williot diagram for cambered position was constructed, the vertical displacements being checked by computed deflections. From this a careful analysis was made of the erection conditions for each panel and joint, with particular reference to sub-panel members and to riveted field splices, such as those of the lower chord and main compression diagonals. The elevations of each bent of falsework and of the camber blocking were computed accurately, with allowances for settlement, etc., based on experience, as were also the positions of all lower-chord pins in relation to the traveler sills and rails. These elevations, with the clearances allowed for, were shown on erection plans. After this work was completed and checked, the engineers of the Fort Pitt Bridge Works were satisfied that no unusual difficulty would be experienced in the field.

The following quotations from the erection reports give the recorded results:

"As a rule, and speaking generally, in all riveted connections about 90% of the holes were filled with temporary bolts and drift-pins. Drift-pins were used in the field connections of members taking tension during erection, as bolts would not take up the clearance allowed in the holes, but all riveted members were connected practically without the use of drift-pins.

"All pins were driven home quickly and without the slightest distortion or displacement of metal about the holes. Special rams, weighing about 2 000 lb., were sent to the site, but were never used, as it was found that all pins could be driven easily with a 15-ft. section of 85-lb. rail."

Although it is recognized that the problem of providing for the field connections in bridges of such proportions as the Beaver, Blackwells Island, or Quebec is quite a different matter from that met in the Sewickley Bridge, it may be worth while to consider the causes of the rather unusual facility with which the latter went together in

Mr. Buel. the field, even when compared with structures in its own class. There is no doubt that the shop methods, as mentioned in the discussion by Mr. Straub, had considerable to do with it, and the form and type of trusses and details contributed to the results; but the methods used for introducing the camber and for checking its effect on field connections, together with the care taken to set the falsework and camber blocking to correct elevations, seem to be the most important items in accounting for the exceptionally satisfactory results attained. The accuracy of all these computations, as well as of the shop work, is attested by the remarkably close agreements between the computed and actual deflections, as shown on Plate XIX.

Paper No. 1256

STATE AND NATIONAL WATER LAWS, WITH DETAILED STATEMENT OF THE OREGON SYSTEM OF WATER TITLES.*

By John H. Lewis, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Clarence T. Johnston, L. J. Le Conte, George L. Dillman, W. E. Moore, Morris Bien, Horace W. Sheley, Morris Knowles, Kenneth C. Grant, E. G. Hopson, H. T. Cory, O. C. Merrill, William G. Davies, W. B. Freeman, and John H. Lewis.

In all irrigation, power, and other developments involving the diversion and use of water, much attention is given by the engineer to a detailed study of the available water supply. Whether or not legal title to the necessary water can be secured, is a matter usually left by the engineer for the consideration of the project's legal adviser. The lawyer, as a rule, is unfamiliar with the units for measuring water, knows nothing as to the effects on the stream of diversions or of return seepage, and can make but little use of elaborate hydrographs and water supply data prepared by the engineer. He confines his studies strictly to the legal phases of the problem as he understands them, assuming that the engineer will attend to what he considers the technical part of the work. The inevitable result is that the promoter, who usually understands only the financial end of the project and is relying on his engineer and legal adviser to do their part, suddenly awakens to the fact that he has expended a large amount of money on a project where the legal title to a part or all of the water supply is in some one else.

* This paper was first presented at the Annual Convention at Seattle, Wash., and again at the meeting of November 6th, 1912.

In the seven years' experience of the writer as State Engineer of Oregon, many disasters have been observed where the primary cause was clearly a failure on the part of the promoter, or the engineer, to appreciate fully at the outset the importance of investigating thoroughly those engineering questions which are semi-legal in nature. The fault usually lies with the engineer in making a water supply report which purports to be complete, but does not treat of the legal relation between the proposed diversion and all other diversions and rights along the entire stream. The engineer is much better fitted by training and experience to cover this disputed territory than the lawyer.

In many States, however, it is absolutely impossible for any one to secure definite information as to water rights or titles. The water laws of such States cannot be found by a study of the statutes alone, but must be sought for in a long series of decisions by the State Supreme Court. These decisions are based more on the logic of judges than the statutes of the Legislature, and are usually so conflicting that able lawyers differ in opinion as to the most fundamental points. In such States, it is the duty of the Engineering Profession to lead in the movement for the enactment of better water laws. It is impossible for the lawyer or statesman to frame proper laws without the co-operation and assistance of the engineer, for he alone knows the difficulties to be overcome in undertaking a new enterprise; and he, of all classes, should know what legislation is needed to protect all interests engaged in such an enterprise. The legal profession has great reverence for precedent, and, besides, there are many lawyers who feel that a reform in the water laws would affect business seriously, by reducing the amount of litigation. It is said on good authority that the cost of litigation over water rights in some of the Western States has exceeded the original cost of the works. The recent collapse of the irrigation bond market is evidence of the fact that capital has awakened to the importance of definite water laws, so that a reliable abstract of water title can be prepared prior to construction. Therefore, looking at this matter only from the selfish standpoint, it is the duty of the engineer to lead in the reform of State and National water laws, so that the confidence of capital may be speedily restored and that development may proceed. The best lawyers in every community will always be found on the side of

reform, for they realize that their prosperity depends on the general prosperity of their community and State.

The wonderful progress made during the past decade in the reclamation of arid lands, through the agency of the Carey Act and the United States Reclamation Act, has served to educate the public as to the value of water and the importance of some interstate or National laws relating to diversions from interstate streams, or their tributaries. Formerly, hundreds of small diversions were necessary before any appreciable effects on a large interstate stream were noticeable in the lower State, but now, in some cases, the entire flow of a great river may be stored for several years in a reservoir, and the flow in the adjoining State is affected so suddenly as to be a shock and a menace to its citizens. Such enormous developments were not contemplated at the time of the framing of our State and National constitutions, and some new legislation must be framed and enacted to cover these contingencies, even if it necessitates the stretching or amending of these constitutions.

Some interstate legislation is absolutely essential if the highest development of our streams is to be accomplished. Each river, from its head-waters to its mouth, should be treated as a unit, regardless of State lines. For instance, it should be possible to store water in Colorado for use in Southern California, the stored water being protected by Federal or interstate law as it passes through three intervening States. Again, the construction of a power-plant, to utilize the entire low-water flow of a stream in one State, may interfere seriously with subsequent diversions for irrigation in the adjoining State immediately above such plant. A number of cases of litigation between States over a proper diversion of interstate streams have already been carried to the Supreme Court of the United States, and some definite action should be taken by Congress before these decisions become hopelessly confused, as is the case in most States where no statutory laws have been available for the guidance of the Courts. The National engineering societies should lead in the discussion of this important subject, and assist in the framing of necessary interstate water legislation.

Just as we have done away with county control of waters, for State control in Oregon, so must we supplement State control by some system of interstate or Federal control for interstate streams,

and the same system which has been found satisfactory for the State should be extended to interstate waters.

The water laws of Oregon, though not specifically referred to, have been endorsed as a model for other States by resolutions of the National Irrigation Congress. It required a four-year campaign, supplemented by the powerful club, the power of direct legislation through the initiative, now in the hands of the people of Oregon, to force this law through the legislature. It has now been in successful operation for three years, and the results accomplished have been far in advance of what was hoped for, even by the most sanguine of its supporters.

For the foregoing reasons it is believed that a brief statement of the fundamental principles underlying the Oregon system of water titles, together with the results thus far accomplished, will be of interest to the Engineering Profession generally, and may assist in the solution of some of the conservation and water-power problems which are now calling for the highest degree of statesmanship on the part of our representatives in Congress.

The value of this paper will be greatly extended if it receives careful consideration and full discussion by engineers in the Eastern, Southern, and Central States, as they look at these questions from an entirely different view-point. The general impression seems to prevail that a law suitable for the Western arid States would not be adapted to conditions in the Eastern humid States. It is high time that this notion be dispelled; for the diversion or storage of 100 sec-ft. of water from a stream for irrigation or domestic use in Oregon would have the same effect on lower appropriators as a like diversion for an eastern stream for any similar uses to which water may be put in such section. Until recently, the common law doctrine of riparian rights, in all its rigors, applied to conditions in the western or humid portion of Oregon, while the doctrine of appropriation for beneficial use prevailed in the eastern or arid portion of the State. The same law has now been made applicable to all parts of the State.

The writer will now endeavor to show that this same system of water titles, which is essential to development in the arid States, is equally applicable to Eastern and Southern States, so that this discussion may be of interest and perhaps of value to engineers in all parts of the country.

"The United States inherited from Europe two great systems of jurisprudence, one the Common Law, and the other the Civil Law. The eastern part of the territory of the United States began with the Common Law. The territory west of the Mississippi inherited the Civil Law, through the prior sovereignty of either Spain or France, or both. The Common Law has invaded most of the area of the Western States, formerly subject to the Civil Law, yet there are many great questions of both title and right still dependent there for settlement upon the rules of the Civil Law. Among the great questions thus dependent is the law of waters.

"The basis of the Civil Law which comes to any State of the American Union, is the law of imperial Rome. It will surprise any one who reads the translation of the Roman water law to see how perfectly and fully they understood the whole question. They had worked out every problem, and we may safely say that they understood the subject as well as we do to-day, and no one can say that the old Romans did not bring to their law of water a common sense and equity not exceeded by our courts to-day."*

The modern water laws adopted by a few of the Western States, including Oregon, are based on the Roman Law. The basis is priority of appropriation and beneficial use. The Oregon territory, however, was acquired by discovery, and therefore this State started off with the same system of jurisprudence—the Common Law—as the eastern part of the United States. The early decisions of our Courts were in harmony with decisions in the Eastern States, yet these decisions have been almost completely reversed in a State where occurs, perhaps, the heaviest rainfall (in Tillamook County, 139 in.) of any point in the United States. The writer, therefore, cannot see any reason why a law similar to that of Oregon cannot be adopted and upheld in any other State of the Union where it is necessary to divert water.

Our system of land titles is well understood in all States. We know the value of an abstract of title. Why should we not have a definite system of water titles in all States, and why not insist on just as definite showing of water title before the purchase of a water project, or before the investment of money in a new enterprise? Entire streams are now being diverted or stored in the Eastern States for municipal supplies, for supplying large canals, for the development of power, etc. In many cases, water is carried from

* Ware, on Roman Water Law.

one stream into another and from one State into another. Soon the State and Nation must join in the storage of water for the control of floods and to aid navigation. This water, in passing down the stream, will benefit many private power projects, and these should be compelled to contribute to the cost in proportion to the benefits received. It is the writer's belief that definite State and National laws relating to water would be of as great benefit to the Eastern as to the Western States.

Riparian Rights *versus* Appropriations.

Before going farther into this subject, it might be well to explain briefly the distinction between the common law doctrine of riparian rights, and the civil law doctrine of appropriation and use.

The common law doctrine of riparian rights originated in England, where it was not necessary to divert and use great rivers for the domestic supply of cities, where no extensive diversions were necessary for the supply of canals, or for water-power projects, as we know them to-day, and where irrigation was not necessary. It was more a question of drainage than of irrigation.

"Riparian rights" are such as follow or are connected with the ownership of the banks of streams or rivers.

"Every proprietor of land on the bank of a river has an equal right to the use of the water which flows in the stream adjacent to his lands, as it was wont to flow, without diminution, pollution or alteration, unless his right has been limited by grant, license or prescription. No proprietor along the bank of a stream, however, has a right to use the water to the prejudice of other proprietors above or below him, unless his right has been enlarged by grant, license or prescription. He has no property in the water itself, but a simple usufruct while it passes along. * * * Though he may use the water while it runs over his land, he cannot unreasonably detain it, nor give it another direction, and he must return it to its ordinary channel when it leaves his estate. These rights are inseparably annexed to the soil, and pass with it, not as an easement or appurtenance, but as a part and parcel of the land. This property right can be regarded only as a corporeal hereditament, belonging to and incident to the soil, the same as though it were stones or grass. The right does not depend on appropriation, and is not suspended or lost by nonuser, but may be lost by grant or prescription, or long adverse use; or in the semi-arid states, by condemnation."*

* Mills' Irrigation Manual, p. 18.

The doctrine of appropriation for beneficial use, as far as the United States is concerned, originated in California and other Western States, out of the necessities of the miners and early settlers. It is based on the familiar maxim that "he who is prior in time is prior in right." Water is treated as a wild thing which becomes the property of him who captures it first. It can only be retained by him so long as he puts it to beneficial use. If the supply is not sufficient for all, the ditch of the last appropriator must be closed to protect the prior appropriator. This system of titles is simple, easy of enforcement, and is the only system which is adapted to the needs of the people in this age of big developments.

These two systems are in direct conflict, and cannot both be applied on the same stream at the same time, for streams cannot flow undiminished to the ocean, and at the same time be diverted for beneficial use.

"From the history of this subject, dating * * * from the earliest period of Egyptian history, down to the period when extensive appropriations were made for mining and agriculture in the arid and semi-arid West, we are unable to find any controversy between those claiming as riparian proprietors and those engaged in diverting and conducting the water to non-riparian lands. It seems to have been an accepted fact that the water was the property of the public, and when the necessities of the people required that it should be conducted from the stream and applied to the soil for the production of crops, the right to do so was unquestioned."*

Early Laws.

Oregon was admitted as a State on February 14th, 1859. Its constitution contains no provisions relating to water. Many decisions had been rendered by our Supreme Court before the adoption by the legislature of the first water laws, in 1891. These laws were in harmony with the customs of the miners, and provided for the posting of a notice on the bank of the stream, setting forth the extent and purpose of the claims, and the recording of a copy of such notice with the county clerk. Work was to begin within six months, and no time limit was fixed for completion. There was no supervision by the county or State. As a result, each applicant usually claimed many times the water needed, and usually all the water in the stream at

*Mills' Irrigation Manual, p. 6.

that point. The records, therefore, were of no public value, and in one case a trip of 1 000 miles would have had to be made to consult all the records relating to a single stream. Litigation was constantly in progress on some streams. The decrees settled only the rights of the parties interested, and were not final because they did not involve all parties on the stream, including the State, which is vitally interested in the unappropriated waters, as trustee for future users. This litigation impoverished the water users, discouraged settlement and investments, and promoted community quarrels which threatened the peace and safety of the citizens. The term "water right" became in practice synonymous with litigation. To overcome these difficulties, a complete system of State control was provided in February, 1909, and is based on the police power of the State to preserve the peace and safety of its citizens.

The New Law.

All water within the State of Oregon was declared by law to be the property of the public. This declaration, it is believed, merely states the law as it exists to-day in every State of the Union. It is the purpose of this new law to regulate the use of this property in the interest of the public, without injury to prior vested rights. This regulation is possible under the police power of the State.

A board, of which the State Engineer is chairman, was created to have charge of this property.

It is the duty of this board:

A.—To determine and record all rights to the use of this public property which had become vested prior to the adoption of the law;

B.—To grant rights, for beneficial use in the State's unappropriated waters, to those who make proper application therefor;

C.—To protect recorded rights to the use of public waters by regulating diversions from streams.

The law and its operation will be discussed under these three heads, taking them up in order.

Determination of Old Rights.

A complete and reliable record of all old rights is the foundation for their protection as well as the basis for the State's administrative

system. Such a record is essential, in order that the public may know the extent of its unappropriated waters. As streams do not follow county lines, or begin and end in particular judicial districts, it was found absolutely necessary to create a special tribunal to ascertain and record these old rights. It is called the Board of Control, and is composed of the State Engineer, and the Superintendents of each of the two sections into which the State is divided.

The Board of Control is an administrative body having only subordinate judicial powers. While it has much the same powers as a Court, and follows, where practicable, the usual legal procedure, yet it is free to depart from such procedure where necessary to facilitate action. It operates in much the same manner as the Railway Commission, or the Board of Health. It knows what information is necessary for a proper determination of early rights. It goes after this information, and does not accumulate thousands of pages of useless and conflicting evidence. Its success has been due largely to its freedom in this respect. Any water user can submit his claim to the Board, if he so desires, without the necessity of employing an attorney. The Board assists him by preparing blank forms* and by making surveys and maps, so as to minimize his expense. In case of contests, the Board pays for the taking of additional evidence.

The determinations are not only inexpensive, but speedy and effective, as shown by the record. The members of this Board are employed by the people of the State for this particular work. It is to their interest, as well as that of the water user, that these determinations be made speedily, and that the determinations are effective.

The first step in the adjudication of water rights on any stream is to file a petition with the Board, signed by one or more water users, requesting that a determination be made. If conditions justify such action, and funds permit, the State Engineer is directed to make a survey as a basis for such determination. Maps are prepared showing each ditch, the location and extent of land irrigated, and such other information as may be necessary in defining the right.

Next, a form containing questions is sent by the Superin-

* A full set of the forms and instructions used in Oregon was furnished by the Author, but as they are too voluminous to be published here, they have been filed in the Library of the Society, where they may be examined by those especially interested.

tendent to each person or company claiming a water right from such stream. Each claimant is required, under penalty of forfeiture, to fill in the information necessary for a proper determination of his right. The Superintendent, at the time and place fixed in the notice, proceeds to collect these statements, which are certified under oath before him. The maps prepared by the State Engineer are at such time submitted to inspection by the water users, who must accept or reject them. If not accepted, maps must be prepared and submitted by the claimant showing the information as he thinks it should be. Certain fees are payable at this time.

After all claims have been filed on these forms, a second notice is sent by registered mail to each water user, fixing a time and place when these claims will be submitted to the inspection of all interested parties. Within 5 days after the closing of this period of inspection, any claimant may contest the claim of another, each being required to pay $5 for each day required in the taking of testimony in such contest. The deposit of the winning party is returned to him. In this way, the determination of early rights is practically left to the water users themselves, and trivial contests are discouraged. The new comer will contest vigorously any exaggerated or untruthful statement by any prior appropriator. The more these early excessive appropriations are cut down, the more valuable is his own right, and the more likelihood of his securing water. The early appropriator, knowing that his claim will be submitted to the inspection of his neighbors having subsequent rights, is usually modest in his claim.

The original evidence, with that taken in contest cases, is then submitted to the Board of Control, and, as soon as practicable, an order determining the relative rights of all parties is entered. This order becomes effective immediately, and can be enforced by the appointment of a water master.

The order, together with all testimony collected by the Board, is filed later with the Circuit Court of the proper county for confirmation. If no exceptions or appeals from the Board's determination are filed with the Court, an order is entered confirming the same. Otherwise, the decree remains in force until the exceptions or appeals are tried out, and a modified decree is entered. Appeals from the decree of the Circuit to the Supreme Court are provided for, if

taken within six months from the entry of the decree in the Lower Court.

On confirmation by the Court, and after the period for appeal has expired, a water right certificate is issued by the Board of Control to each owner of a right.

There is considerable demand for making the decisions, final with the Board, subject to appeal to the Courts, in the usual manner. Such procedure would greatly simplify matters, and hasten materially the issuance of certificates. It would be clearly constitutional, in the writer's opinion, as indicated by decisions in Wyoming and Nebraska.

Water Right Certificate.

The water right certificate is record evidence of the holder's right to water. It is to his water title what a patent from the United States is to his land title. Thereafter his title to water for irrigation passes with the land on which it is used. An abstract of land transfers will then serve to show chain of title to both land and water.

This certificate, which is issued to the claimant by the Board after final determination of his right, embodies all the fundamental principles of a water right. They are few and simple, and, if kept clearly in mind, will give a good understanding of the water laws of Oregon as well as of a number of the Western States.

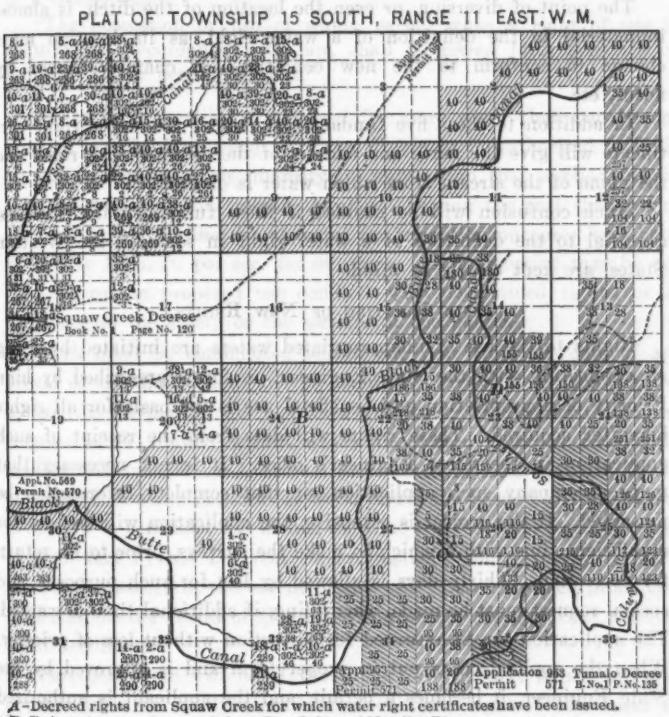
These fundamental principles are as follows:

Beneficial Use: { Priority, Purpose, Period, Place, and Quantity.

Beneficial use is the great underlying principle. Because of this principle, there are no water monopolies in Oregon. The barter and sale of water, apart from the use, and the holding of water without use, for speculative purposes, are unknown. Our water resources, greater perhaps than those of any other State in the Union, are still largely the property of the public, and are offered practically without price to him who will put them to use.

Priority.—The priority is expressed by a date. It is the most important element in considering the value of a water right. It is the date when the present owner or his predecessor first diverted

water or took the first legal steps to initiate his right. A ditch may have several priorities, if the original appropriation or intent has been enlarged at a later date.



Purpose.—The purpose, whether for irrigation, power, mining, manufacturing, or domestic use, is an important element of the title. A right acquired for one purpose should not be transferred to another without loss of priority. A change from power, which does not consume water, to that of irrigation, which consumes a large part of the water, will affect lower rights seriously. Such changes are against public policy. The user has no property right in the water, only a right for a particular use.

Period.—The period of use is important. A right for mining during the winter months cannot be extended to include summer use, as this would conflict with perhaps prior rights for irrigation. A right for spring irrigation of grain, and long used for such purpose, cannot be enlarged to include fall irrigation of alfalfa, without injury to others. The increased use at a different period would damage vested rights below.

Place.—The place of use is fundamental to a proper definition of the right. Water cannot be branded or fenced like cattle to show private ownership. The nearest approach to such system is to tie it to the place of use. Therefore all water should be made appurtenant to the place of use, otherwise there can be no stability of water titles, and the public records at Salem will be of little use. (See Fig. 1.)

No transfers should be permitted without loss of priority, except in the most extreme cases, and then only after proceedings and record before the Board of Control. The return water from prior appropriations is counted upon by subsequent appropriators as a basis for their investment. Even a relatively small displacement will affect the return seepage, as the laws of underground water are uncertain. There could be no stability of water titles if the law permitted indiscriminate transfers in the place of use. If the use terminates, the right should terminate. Even if a transfer is made after notice to all parties, it is unfair to the lower appropriator, as anticipated injury can seldom be proven. The public gains nothing, as new appropriators are always eager to put such water to new uses under a subsequent priority.

To permit a change in character of use, or change in the place of use, therefore, would serve to make water titles unstable, and open the way to the barter and sale of water, which is in direct conflict with the doctrine of beneficial use, on which the entire system rests. Unless water titles can be made definite and certain, capital cannot be expected to invest in new enterprises.

A—Decreed rights from Squaw Creek for which water right certificates have been issued.
B—To be watered under permit from Blue Lake and Metolius River.
C—To be watered under permit from Crater Creek and storage in Tumalo Reservoir.
D—Incomplete rights under Tumalo Creek adjudication; project not yet completed, including storage in Tumalo Reservoir.

FIG. 1.

Quantity.—The maximum quantity of water granted in the certificate is an important qualification to the general limitation of beneficial use. This is expressed in cubic feet per second, which is the standard unit for rate of flow. Water for storage purposes is ex-

pressed in acre-feet, which is the unit of volume. If a greater quantity than allowed is desired, this can be delivered by the water master under a rotation system, that is, where two or more combine, each using the total allotment, part of the time. If the water is being wasted, the water master is authorized to close the gate to such extent, permitting such water to flow down to others.

The point of diversion, or even the location of the ditch, is almost immaterial in the definition of a water right, as its location must change to conform to the new conditions of channel caused by floods, etc.

In addition to these five fundamental points, the water right certificate will give the name and address of the owner of the right and the name of the stream from which water is diverted.

Much confusion will be avoided if these fundamental principles, essential to the definition of a water right in some of the Western States, are kept clearly in mind.

The Granting of New Rights.

Rights to the use of unappropriated waters are initiated by filing an application with the State Engineer, on forms prescribed by him. Priority of appropriation and beneficial use is the basis for all rights hereafter acquired. These rights will date from the receipt of such application in the State Engineer's office. It is not necessary that maps accompany such application, or that complete information be presented. If the project is extensive, the application will be held for a sufficient time within which to make the surveys, prior to its return for correction. Thirty days is allowed by law for such purposes, and special request must be made, when filing, if additional time is wanted. The application can be returned for correction without loss of priority. When the application is put in proper form and is approved by the State Engineer, it becomes a permit, and the applicant is authorized to proceed with construction.

No right to the use of any public waters can be acquired without making such application and securing a permit. This is also true for the extension or enlargement of existing rights. Riparian owners must comply with the law the same as others. The owner of a spring tributary to a running stream must also make application. A reliable record of all new rights or extensions is absolutely essential for proper State control. It is the basis for new investments, as well as for the

protection of prior rights. To insure the reliability of this record, the following penalties have been provided:

"It shall be a misdemeanor to use, store, or divert any water until after the issuance of a permit to appropriate such water.

"Any person who shall willfully divert or use water to the detriment of others, without compliance with law, shall be deemed guilty of a misdemeanor.

"The possession or use of water, except when a right of use is acquired in accordance with law, shall be *prima facie* evidence of the guilt of the person using it."

No application will be approved for more water than can be applied to beneficial use, and the State Engineer is authorized to limit an application to a less quantity of water than that applied for, if there exists substantial reason therefor. During the past three years all applications for the use of water for irrigation purposes have been limited to 1 cu. ft. per sec. for 80 acres. An application may be denied where the proposed use conflicts with determined rights, or is a menace to the safety or the welfare of the public.

Work must be commenced within one year from the date of approval of the application, and be completed within a reasonable time, as fixed in the permit, not to exceed five years. Additional time after completion is allowed within which the water must be completely applied to beneficial use. Annual proof must be filed with the Board of Control to show progress of work under the permit. If the water is applied to beneficial use within the time allowed, final proof is taken of such fact by the Division Superintendent, and a survey is made in order to ascertain the extent of the use. Based on such proof and information, the Board of Control will grant to the applicant a water right certificate.

This certificate will be of the same form as that issued to early appropriators on final determination of their rights. The form of this certificate has been fully described above.

The fees paid to the State for the privilege of appropriating its public waters are small, but in the aggregate more than equal the appropriation for the office and department of the State Engineer.

Protection of Rights.

The primary object of making water rights definite and certain, through adjudications by the Board of Control, and through permits

issued by the State Engineer, as outlined herein, is to furnish a proper basis for the protection of such rights by the State.

The accomplishment of this object furnishes at the same time the only safe and reliable basis for new investments. Only the more expensive projects remain for development. For this reason no State which fails to provide such a system of water records, and public supervision of stream diversions, can expect to secure the highest development of its water resources. Private capital will not invest without such records and information, and public funds should not be invested, for obvious reasons.

To facilitate the distribution of water, the State has been divided into two parts, over which is placed a superintendent. These divisions are cut up into districts, as rapidly as the various rights are determined and the need thereof arises. On the petition of one or more water users of such district, a water master may be appointed by the Board, on the recommendation of the superintendent.

It is the duty of such water master to regulate the head-gates of ditches so as to insure the delivery of water in accordance with established rights, and to prevent waste. He has authority to make arrests, and to compel the installation of the necessary head-gates and measuring devices. When the water supply falls so low as to be insufficient for all, the ditch of the latest appropriator, having the poorest right, will be closed, so that prior rights may be protected. As the water falls, other head-gates will be closed, and these in turn will be opened in case of a rise in the river.

If water is stored at the head of a stream, and the natural stream channel is used in conveying such water to the place of use, it is the duty of the water master to set all head-gates so as to admit only the quantity to which each ditch is entitled, in order that the reservoir owner may recover at the place of use the water he turns into the stream, less the quantity lost by seepage and evaporation in transit.

Protection of the Public Interest.

Public interest demands that water be put to the highest use. In case of conflict between power and irrigation, the application for the former use can be referred to the Board of Control, on the ground that it is a menace to the safety or the welfare of the public, and the Board has power to direct its refusal, if public interest demands.

Likewise, an application for either irrigation or power can be denied if it is in conflict with the higher use for domestic supplies.

Oregon's Supreme Court has upheld the Board of Control on this interpretation of the law in the case of Cookingham *vs.* Lewis.* Recently, the Board directed the refusal of a prior water-power application which menaced the water supply of the City of Nehalem.

Water-power permits have not been issued on streams which are more valuable for irrigation purposes than for power, and where an abundance of power can be generated on the tributaries of such stream above the points where diversions for irrigation are possible. A comprehensive plan for the development of the State's water resources is essential, if waste is to be avoided and the public good promoted. To permit the construction of one or two low dams for the utilization of all the waters of the stream at a point which is the only practical place of diversion for irrigation will greatly retard development. The public, in permitting such power development, is selling its birthright for a mess of pottage. With a 15-ft. dam, 1 000 sec-ft. will generate 1 700 h.p., but, if held available for irrigation, would reclaim more than 300 000 acres of land with storage. The power grant, as far as the public is concerned, therefore, is equivalent to a free grant of 300 000 acres of land. It is true that the power grant may later be condemned, but why grant the franchise and delay the development only to buy the same later at an enormous franchise valuation in addition to its physical value, when the same power could easily be generated at a little greater expense on the tributaries of this stream, where no conflict with irrigation would ever occur. From the standpoint of taxable property, the relative merits of those two conflicting uses would be as thirty thousand is to thirty million.

Typical Water Record, Under New System.—Fig. 1 is a plat showing the clearness with which the character and extent of water rights can be defined for each 40-acre tract when the water is made appurtenant to the place of use. A similar plat for each township in the State is kept in a loose-leaf book, and is indexed for quick reference. On these plats all information relating to water is compiled as it accumulates.

If a prospective settler should write the State Engineer asking if the S. E. ¼ N. W. ¼, Sec. 18, T. 15 S., R. 11 E., had a water right, a

* 114 Pacific, p. 88.

reply could be dictated in a few seconds giving definite information that such tract had a vested right to water for 16 acres from Squaw Creek under Water Right Certificate No. 267. Such definite records make present rights more valuable, encourage settlement, and new development. The issuance of overlapping permits can be avoided. The making of water appurtenant to the land irrigated is the basis for this system.

The plat, Fig. 1, shows three different classes of water rights, as explained below the cut. It is peculiar in that no stream crosses its border, yet the lands will receive water from four different streams.

Lands not shaded must remain forever without water. Lands *B*, *C*, and *D* will not receive water unless the contemplated works are constructed within the time allowed. Purchasers buy with notice of this fact. A published record, by stream systems corresponding to this township plat record, will eventually be issued for gratuitous distribution. It will give the Priority, Purpose, Period, Place, and Quantity for each recorded right, with the name and address of the owner. Such a record of vested rights, together with a published record giving the total available supply for corresponding streams, is essential as a basis for the development of our water resources.

Results Accomplished.

The results accomplished during the first three years of public control in Oregon should demonstrate beyond question the value of the new system of water titles. No serious defects in the law have been discovered. It became effective on February 24th, 1909. Much of the first year was devoted to the preparation of forms and records, and outlining the system. Without a definite and comprehensive system, there could have been no hope of bringing order out of the former chaotic condition of water titles.

Old Rights Determined.

In three years, ninety-one petitions have been filed with the Board of Control, asking for the determination of old rights, so that the benefits of State protection could be had.

Surveys looking to this end have been undertaken on only twenty-three different stream systems. The Board is at present several years behind in its work. The present organization could handle a far greater volume of work if additional funds were available for employ-

ing clerical and technical help. The system is simple, but the filing, indexing, and tabulating of rights, and the correspondence with the numerous claimants, involve an enormous quantity of clerical work which requires office assistants who have had several years' experience in such work.

Thus far, complete adjudications have been made by the Board on fifteen different streams, involving 965 separate rights. These determinations affect title to water for the irrigation or 89 084 acres of land, at a total cost to the claimants of $9 119.

TABLE 1.—WATER RIGHT ADJUDICATIONS—CONFIRMED.

Stream.	County.	No. of rights involved.	No. of rights decreed.	Irrigation Rights.		Fees paid.	Average cost per right.
				Vested rights, in acres.	Incomplete rights, in acres.		
Willow Creek	Gilliam and Morrow	204	163	5 936	355	$2 056	$12.60
Mill Creek	Union	115	84	2 035	.....	659	7.85
Squaw Creek	Crook	110	80	7 072	9 408	1 085	13.56
Tumalo Creek	Crook	149	109	3 058	25 120	854	7.84
Paulina Creek	Crook	23	17	530	174	193	11.33
Cochman Creek	Grant	8	5	35	.....	25	5.03
East Branch Mud Creek	Umatilla	19	17	532	.....	156	9.15
South Branch Mud Creek	Umatilla	19	15	445	.....	114	7.60
Goodman Spring Branch	Umatilla	11	6	202	.....	59	9.79
Totals	.....	658	496	19 845	35 057	$5 201	$10.50

WATER RIGHT ADJUDICATIONS—COMPLETE BUT UNCONFIRMED.

Stream.	County.	No. of rights involved.	Irrigation Rights.		Fees paid.	Average cost per right.
			Vested rights, in acres.	Inchoate rights, in acres.		
North Powder River	Baker	134	20 496	499	$2 244	$16.74
Butter Creek	Umatilla and Morrow	62	7 712	.....	1 062	17.13
Cottonwood Creek	Malheur	4	173	.....	58	14.61
Sucker Creek	Josephine	87	2 162	2 391	428	4.92
Althouse Creek	Josephine	20	749	.....	126	6.31
Totals	.....	307	31 292	2 890	$3 918	$12.75

Nine of these determinations have been confirmed by the Circuit Courts in the respective counties, and 496 certificates have been issued. The average cost in fees to these certificate holders has been $10.50, and

the total area of irrigated land included in these final records amounts to 54 802 acres.

These nine adjudications have been completed without a single appeal to the Supreme Court. The streams involved are among the most complicated in the State. Heretofore, practically every water case was carried to the highest tribunal, and final decisions were delayed from five to ten years.

Surveys have been completed by the State Engineer and maps have been prepared showing all water right locations on twenty-three different streams, including the fourteen mentioned in Table 1. These surveys include 265 055 acres of irrigated land, or approximately 40% of the total irrigated area of the State, as shown by the recent United States Census. This irrigated area is served by 3 305 miles of main canals, and 2 361 separate diversions. The territory surveyed is scattered over 500 different townships.

The streams, including all their tributaries, which have been surveyed, in addition to those mentioned above, and on which the adjudication proceedings are well under way, are given in Table 2.

TABLE 2.—SUMMARY OF SURVEY MAPS.

Stream.	No. of diversions.	Length of main canals, in miles.	No. of townships covered.	Acres irrigated.
Crooked River	152	259	37	19 854
Rogue River	324	463	46	13 715
Umatilla River	259	397	38	15 902
Willow Creek, Malheur Co.	175	219	16	9 412
Powder River	791	879	52	86 112
Silvies River	208	228	24	64 130
Lost River	37	25	13	5 420
Bechdoldt Gulch	2	4	2	148
Cherry Creek	3	5	1	225
Totals	1 951	2 479	229	213 918

NEW RIGHTS GRANTED.

A total of 2 084 applications for permits to appropriate water have been filed with the State Engineer during the past three years. Of this number, 1 024 have been approved, becoming permits, and more than 400 have lapsed or have been cancelled from the records. These permits involve the construction of 2 500 miles of canal and 163 reservoirs, at a total estimated cost of $32 250 000. These works, if con-

structed, will ultimately irrigate 723 100 acres and develop 111 400 h.p. (theoretical). This area is 37 100 acres in excess of the total area which is now being irrigated, according to the recent United States Census. This remarkable showing is due perhaps largely to the confidence of capital in the new law, and it is the small investors, rather than the large ones, who have produced so startling a result in the aggregate.

The total fees collected to date, by the State Engineer's office, under the provisions of the new law, amount to $41 388.60, which is approximately $11 400 in excess of the appropriation for the department during this period. These fees are in themselves a reasonable guaranty that the proposed works will be constructed in accordance with the permits issued.

Protection of Rights.

There has been only one year's experience in the distribution of water by the water master under decrees of the Board of Control. In every case the people have been well pleased with the results, as compared with the old method of enforcing rights by injunction proceedings before the Courts. The law is a success only in so far as the administrative authorities can distribute the water in accordance with the decree, and at the times when it is needed.

Riparian Rights.

Approximately, 2 000 claims to water have been filed in these adjudication proceedings before the Board. All but four have been based on the theory of appropriation and use. These four claimed as riparian owners, but proved rights by appropriation. To the water user, therefore, the question of riparian rights is a dead issue in Oregon.

The riparian owner, under the decisions of our Supreme Court, cannot secure a decree of any definite quantity of water. He has only a reasonable use in common with all other riparian owners. The water to which he is entitled, therefore, is a fluctuating quantity, impossible to define or to protect. What are riparian lands one day, may be enlarged the next by purchase so as to extend even beyond the watershed of the stream. It is only a matter of time when our Supreme Court will declare that this common law doctrine is not applicable to conditions in Oregon, and therefore never has been the law of this State. Recent decisions tend strongly in this direction. "The rules

respecting the tenure of property must yield to the physical laws of Nature, whenever such laws exert a controlling influence."* The necessities of the people require that water shall be diverted for irrigation and other beneficial uses, owing to the peculiarities of soil and climate.†

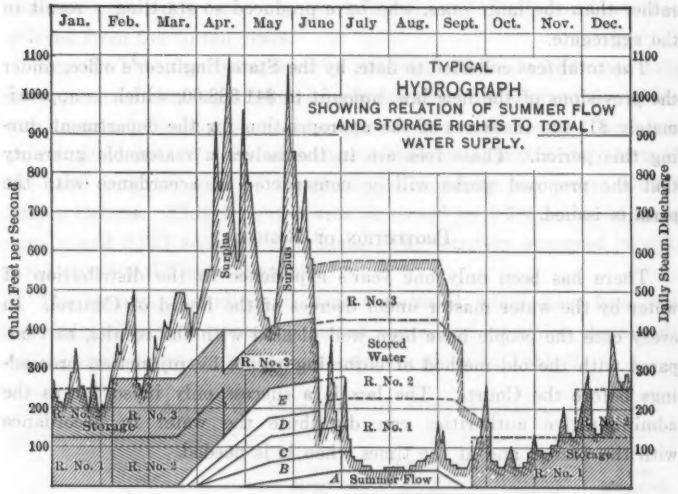


FIG. 2.

The riparian owner must conform to the State laws relative to the appropriation of water. Failure to do so would destroy the system of water titles and make State protection impossible for the water user. Lack of State control will result eventually in unending litigation and community quarrels over water. The new law amounts to an appropriation of all unappropriated waters, for disposal under the new system, and not otherwise. The preservation of the peace and safety of our citizens makes necessary the upholding of this system under the police power of the State.

WATER MAPS.

Water can be measured and shown graphically on a map with as great a degree of accuracy as can land areas. The water map (Fig. 2), or hydrograph, shows at a glance the total volume of water discharged

* Yunker *vs.* Nichols, 1 Colo., 551, 72.
† Walsh *vs.* Wallace, 26 Nev., 229; Twaddle *vs.* Winters, Nev., 85 Pac., 280.

by a stream at a given point; it also shows the discharge for each day in the year, the extent of the regular flow and storage rights which have become vested, and the surplus water available for new appropriations. On it can be shown graphically the character and extent of all diversions, whether from the stream for direct use (Ditches *A*, *B*, *C*, *D*, and *E*), or for storage (Reservoir Feed Canals Nos. 1, 2, and 3). The stored water will be released during the summer, and the extent to which the regular flow of the stream will be supplemented can also be shown graphically. Having careful records of daily stream discharge extending over a series of years, and accurate records of vested rights as determined by the Board of Control under the new system of water titles, it is a simple matter to construct hydrographs which will show with great clearness and certainty the volume of surplus water available for new appropriations. The new law provides a definite method for initiating rights to such surplus water, and grants full protection to such rights during the period of construction.

The Oregon system of water titles is of value because it is complete. Full power for determining old rights, for granting new rights, and for the protection of all rights, is concentrated in one Board. The records are uniform, in simple tables by stream systems, assembled in one central office, where they are thoroughly indexed and digested for quick reference. Every step is taken in harmony with a preconceived plan, and with the purpose of bringing order out of chaos.

The information as to the total water supply is of primary value in encouraging new enterprises. The State is co-operating with the U. S. Geological Survey in the joint expenditure of $56 000 annually on stream gauging work, the making of river profiles in aid of water-power development, and the making of topographic maps. Records of stream flow and of vested rights to water are absolutely necessary for the proper design of new works involving the use of water. We are beginning to realize that it is useless to expend money in the construction of hydraulic works unless water can be delivered with certainty at the time when it is needed. For these reasons, definite State control of all public waters has been undertaken in Oregon.

Interstate Rights.

Just as the lack of a definite system of titles to water within a State depreciates the value of works constructed for the utilization of

water, promotes litigation, strife, and occasionally bloodshed among its citizens, and discourages settlement and new development, so the lack of some interstate or Federal control as to interstate waters affects the territory adjoining such streams in either State, irrespective of whether one or both States have adopted a modern system of control for waters within their borders.

Already interstate troubles are beginning to loom large for the State of Oregon, and it is probable that almost every other State in the Union is similarly affected to a greater or less extent.

A statement of these difficulties will doubtless be of value in showing the need of some legislation in the near future relating to interstate waters.

The United States Reclamation Service has appropriated all the waters of Klamath River and its tributaries in Oregon for the irrigation of several hundred thousand acres of land in Oregon and California. The river, a short distance below, flows into California, where its waters are of value for power development. Power rights in the lower State may in the future be seriously affected by the diversion of water above for irrigation; but a more immediate cause of difficulty is the construction, by the United States, of a dam, at the outlet of Clear Lake in California, which will require three years for the reservoir to fill, when the waters will be turned backward, over a divide, into California, when they have heretofore flowed northward into Oregon and have been used largely for the irrigation of lands in Langells Valley.

Farther to the east, in Lake County, the State of Oregon has under consideration the reclamation of 100 000 acres of land in Warner Valley, under the provisions of the Carey Act. The water for this project will be derived largely from California and stored in a reservoir just over the line in Oregon. The remaining water will come from Nevada drainage. With this project completed, subsequent diversions in California and Nevada may seriously injure prior rights in Oregon.

A 3 000-acre private project on the East Branch of Lost River will depend on water from California, with storage on a tributary, which must be conveyed through California territory to reach the land in Oregon. There are many smaller projects along the southern boundary line which are more or less complicated.

Between Oregon and Idaho several complications now exist. Under

the Carey Act, this State has undertaken the reclamation of 50 000 acres of land in Jordan Valley, the water to be stored on Jordan Creek, just over the line in Idaho. Water can be diverted from this stream just above the reservoir and carried through a short canal in Idaho to Sucker Creek, down which it can be dropped to a reservoir in Oregon. Plans are under way to use this water, supplemented by Sucker Creek, for the irrigation of from 30 000 to 50 000 acres in Idaho.

Diversions from Snake River, in Idaho and Wyoming, in recent years have lowered the water surface so much near Ontario, Ore., that the Wilson Ditch cannot secure its accustomed water supply. Water-power permits granted by Oregon on the Snake River, later, may embarrass Idaho seriously in making diversions for the higher use, irrigation. Diversions from Snake River have affected navigation noticeably on the stream below Lewiston, in Washington.

A large canal has been constructed, tapping the Walla Walla River in Washington; it crosses into Oregon, and irrigates a large area in both States. This stream in Oregon has been in almost constant litigation for thirty years, and a case, started six years ago, and involving more than 400 parties, has just reached our Supreme Court.

Litigation is now in progress on Goose Creek in Idaho, involving Nevada waters passing through Utah. The most complicated case known to the writer is that of Bear Creek, which rises in Utah, flows through Colorado and Idaho, and terminates in Utah, and along which there are extensive diversions in each State and constant trouble over water.

These illustrations should be sufficient to show the real necessity for some legislation. In the Eastern States, no doubt, many similar difficulties have occurred over diversions for municipal water supplies, canal supplies, and for other uses peculiar to that section.

Character of Legislation.

We have paid dearly to learn that county control of waters was impossible. After the sacrifice of much valuable time and money, the destruction of interstate rights, the engendering of strife and bad feeling between States, and the retarding of development in the territory tributary to interstate streams, we may learn that State control of all waters within its borders is just as impossible as county control.

Streams do not follow county lines any more than they follow State lines. Such a division is impossible. We should be able to store water in Wyoming for the irrigation of lands in Malhuer County, Oregon, using the Snake River as a canal through Idaho, just as we can store water at the head of the John Day River in Grant County to be conveyed under State protection through other counties, for use at the mouth of such stream in Oregon. It should be possible to store the flood-waters of the Colorado River in the available basins in Colorado, where no use is possible in such State, and convey this water, under United States or interstate protection, for use in Southern California. The fullest development of streams will lag until such time as some legislation is provided affecting the determination, the granting, and the protection of interstate rights. We cannot expect the United States Supreme Court to work out and adopt some administrative system adequate to the needs in this respect. This is a problem for the legislative branch of the government.

The National Irrigation Congress at Boise, Idaho, in 1906, appointed a commission, of which the writer was a member, to investigate the subject of interstate rights and report the next year at the Sacramento meeting. The views of this commission, as herewith presented, are rapidly being accepted by a growing number of people as the only solution of this vexing problem:

"In view of existing conditions which place the burden of the admininstration of water rights upon the different States, your committee believes and recommends, as do a great many of those answering the interrogatories [replies to circular letters], that the different States affected by interstate streams take some steps looking to a more uniform system of laws affecting water rights, making those laws of each State agree as nearly as possible with those of sister States, and that there should be a general overhauling of all the laws of the arid States as to the matter of water rights, to the end that litigation as to this character of property may be reduced to a minimum, and that the greatest good may come to the greatest number in the matter of the use of water for irrigation.

"While it is true that, in the administration of water rights upon interstate streams by the different States, the right of appeal to the Federal Courts exists, that remedy is expensive, slow, and unsatisfactory. A decision of a Court, once rendered, remains fixed, and only settles the particular questions involved in that case, while the conditions surrounding irrigation on either side of the State line are

constantly changing, and the use of water for irrigation is rapidly growing.

"If there is to be any protection of priorities across State lines, it should be by a Federal administrative system corresponding in character to that needed for the establishing and protection of rights within a State.

"Respectfully submitted,
"ELWOOD MEAD,
"FRANK FREEMAN,
"MORRIS BIEN,
"JOHN H. LEWIS,
"Committee."

After six years of further consideration of this important question, the writer is of the opinion that such Federal administrative system should not be confined to the Western States, but should apply to all territory over which the United States has jurisdiction, and embrace all interstate waters and navigable waters, including the non-navigable tributaries of such navigable streams.

STATE OR FEDERAL CONTROL.

This brings us to a consideration of the question of State or Federal control of waters.

As to navigable waters, there appears to be no question as to the authority of Congress to enact any measure which, in its judgment, is necessary to preserve the navigability of navigable streams, even against any State action.

The Supreme Court of the United States, in the case of United States *vs.* Rio Grande Dam and Irrigation Company,* said:

"Although this power of changing the common law rules as to streams within its dominion undoubtedly belongs to each State, yet two limitations must be recognized: First, that in the absence of specific authority from Congress a State can not by its legislation destroy the right of the United States, as the owner of lands bordering on a stream, to the continued flow of its waters; so far at least as may be necessary for the beneficial uses of the Government property. Second, that it is limited by the superior power of the General Government to secure the uninterrupted navigability of all navigable streams within the limits of the United States. In other words, the jurisdiction of the General Government over interstate commerce and its natural highways vests in that Government the right to take all needed measures to preserve the navigability of the navigable water-

*174 U. S., 690-703.

courses of the country even against any State action. It is true there have been frequent decisions recognizing the power of the State, in the absence of Congressional legislation, to assume control of even navigable waters within its limits to the extent of creating dams, booms, bridges, and other matters which operate as obstructions to navigability. The power of the State to thus legislate for the interests of its own citizens is conceded, and until in some way Congress asserts its superior power, and the necessity of preserving the general interests of the people of all the States, it is assumed that State action, although involving temporarily an obstruction to the free navigability of a stream, is not subject to challenge."

If, therefore, under the interstate commerce clause of the Constitution, Congress has direct power to exercise control over navigable waters, as far as their navigability is concerned, it must follow by necessary implication that Congress can also exercise such control over the non-navigable tributaries of such stream as is necessary to preserve such navigability.

As pointed out previously, the diversions from Snake River, for irrigation, domestic, and other uses, have diminished the flow in the lower river to such an extent as to affect navigation materially. Likewise, diversions from the tributaries of the Willamette River, which is wholly within the State of Oregon, will affect navigation, by reducing the volume of water, and making dangerous certain rocks on shoals which would not otherwise be dangerous to navigation.

If private capital, or even the Reclamation Service, a branch of the United States Government, should construct reservoirs to store winter waters, and divert the regular summer flow to such an extent as to injure navigation, such diversions could doubtless be enjoined by Congress, or by appropriate action before the Supreme Court. It is high time that an end be put to this system of government by injunction, and that definite legislation be enacted so that capital can invest with safety, under proper Governmental sanction and supervision, in those large undertakings which will bring prosperity and happiness to the present generation.

"As to non-navigable streams within the State, which are not tributary to a navigable stream, it is difficult to find any possible grounds for the theory of State control. Where the United States has disposed of its public land, it has either transferred the water with it to the new owner, or has retained its right to it. There is no opportunity for the intervention of a State claim."*

*Morris Bien, U. S. R. S.

In the original thirteen States, the waters are either the property of the public, or are vested in the riparian owners.

It is true that in 1866 Congress recognized the rights of appropriators, and in 1877 dedicated waters on the public domain to appropriation and use, but no where do we find a definite grant of waters to the State. The nearest approach to a grant to a State occurred in the approval by Congress of the constitution of the State of Wyoming, containing these words, "all waters within the boundaries of the State are hereby declared to be the property of the State." This constitution was "accepted, ratified, and confirmed by Congress." In the absence of the words of an express grant, it is doubtful if the mere approval of a voluminous document will ever be construed by the Supreme Court to be a grant of public waters.

The case of Kansas *vs.* Colorado* apparently abolishes riparian rights as to the waters of all States, and at least as to all interstate streams. In this case:

"The citizens of Kansas insisted that large quantities of water were being diverted from the Arkansas River by the inhabitants of Colorado, a large number of whom were claiming as prior appropriators and diverting the water to non-riparian lands, as against Kansas, a riparian proprietor. In Kansas, the modified doctrine of riparian rights prevailed, while in Colorado, prior appropriation was and is recognized as the governing doctrine. The Court refused injunctive relief, and dismissed the bill, stating in substance that if the riparian doctrine should prevail in Kansas as against Colorado and against the non-riparian users whose rights were involved therein, Oklahoma and its citizens lower on the Arkansas River might invoke the same rule in opposition to both citizens of Kansas and Colorado, to their great injury, which doctrine, it is observed, would be ruinous in its effects. The Court, in dismissing the bill, indicated that no injunction would lie until a more substantial injury could be shown, and at the same time found that the interference by a large number of appropriators above in the State of Colorado, materially depleted the flow to the riparian lands of the plaintiff."†

There can be no misunderstanding of the clear intent of the Supreme Court to permit of the diversion of water in an upper State by non-riparian proprietors, even though such diversions materially deplete the flow to riparian lands in the lower State. From the definition of a riparian right, as heretofore given, we observe that it is a property right inseparably annexed to the soil, and passes with it, not

*206 U. S., 46.

†Hough *vs.* Porter, 51 Oregon, 409.

as an easement, or appurtenance, but as a part and parcel of the land. It is, therefore, a vested right to private property, which, under the Constitution of the United States, the owner cannot be deprived of without due process of law, nor taken for public use without just compensation. We must assume that this recent, able, and carefully considered opinion of the Supreme Court is not in violation of this section of the Constitution, and that it is applicable alike to all States. Therefore, we cannot escape from the conclusion that the common law doctrine of riparian rights, which has been assumed as the law by the Courts in many of the Western, and doubtless all of the Eastern States, is not the law, and therefore never has been the law, notwithstanding many decisions of the State Courts to the contrary, at least as to interstate waters. If it is not the law as to interstate waters within the State, it is difficult to conceive of any theory on which the State Courts could maintain such doctrine for those streams which are wholly within the State and are not tributary to navigable waters.

In summing up this case, the Court said:

"Regarding the interests of both States and the right of each to receive benefit through irrigation and in any other manner from the waters of this stream, we are not satisfied that Kansas has made out a case entitling it to a decree."

By this language, we believe that the Court had in mind, not alone irrigation, but all possible uses that water could be put to in the upper State, in any part of the territory under the jurisdiction of the United States.

The Courts of many of our Western States, long prior to this decision, had reached this same conclusion, but by a different process of reasoning.

"When the question of water rights was first considered in the State of Nevada, the Court held that the patentee of the government succeeded to all of its rights, and among these was the right to have the water of a stream, theretofore diverted, returned to its natural channel. But this case was over-ruled in Jones *vs.* Adams. And in Reno *vs.* Stevenson (20 Nev., 269) it was unequivocally declared that the common law doctrine of riparian rights was unsuited to the conditions of that State. In the leading case of Clough *vs.* Wing (2 Ariz., 371) it is said that the common law, so far as the same applies to the use of water, has never been, and it is not now, suited to conditions that exist here."*

* Wiel, on Waters, p. 188.

This same line of reasoning can and should be applied to every State of the Union, so that the atmosphere will be cleared for the enactment of a comprehensive system of titles to water for the United States as a whole, for in every State it is necessary to divert water for some useful purpose. If precedent and antiquity determines the law, then this common law doctrine should give way to the civil law of Rome, which is based on prior appropriation and use, and can be clearly traced to the earliest history of ancient times.

If, therefore, riparian rights are not considered as vested rights by the Supreme Court, then the inevitable conclusion must be that water is the property of the public, and that Congress, under the domestic tranquillity and general welfare clauses, has power to adopt a comprehensive system of titles to water which will obviate the present turmoil and confusion as to water rights, and will promote the general welfare of the Nation in proportion as the Oregon system outlined herein has promoted the general welfare in Oregon.

Equitable Apportionment of Benefits.

In summing up the conclusions in the case of Kansas *vs.* Colorado, the Court, after stating that Kansas had not made out a case entitling it to a decree against Colorado, said:

"At the same time it is obvious that, if the depletion of the waters of the river by Colorado continues to increase, there will come a time when Kansas may justly say that there is no longer an equitable division of benefits, and may rightfully call for relief against the action of Colorado."

The question naturally arises as to what constitutes an equitable apportionment of benefits, and who has the necessary authority to decide as to this matter.

There is no question as to the ability of the Supreme Court to decide this question in any case properly before it. To take to the United States Supreme Court every case which is now in controversy, is entirely out of the question. The time and expense involved would compel those suffering injury to endure the wrong rather than appeal to the Court. Such an appeal in most cases is entirely beyond their resources.

If in the Kansas-Colorado case, the Court refused to grant to the plaintiff the required relief, after consuming eight years' time in the

examination of 347 witnesses, the taking of 8 559 typewritten pages of testimony, and the making of 122 exhibits, at a cost of about $200 000, it might be a fair question to ask one who believes in this system of government by injunction, how much longer must Kansas suffer before making a second attempt to secure relief, and what would be the estimate of the cost, in time and money, to complete such second attempt.

This system of government by injunction is disastrous to progress. Let it be assumed that the State of Oregon brings suit against the U. S. Reclamation Service to enjoin the storage of water in its Clear Lake Reservoir, recently constructed in California, and wins; it is easy to picture its effect on future development along our State border. No one would dare to invest without prior sanction from some Governmental authority.

In the absence of any specific guidance in such decree, it can only be assumed that Congress must have power to prescribe by law what shall constitute an equitable division of benefits as to interstate waters. Any other view would make the decree ridiculous, as the Supreme Court could not expect that every interstate water problem would be submitted to it for decision. This is an administrative matter; the Court has decided the law, and it remains only for Congress to provide suitable machinery for carrying the law into effect.

If Congress should decide that the enforcement of the doctrine of priority of appropriation and beneficial use, subject in each case to the consideration by the administrative authorities as to the public interest and welfare, should constitute an equitable apportionment of benefits, it is conceivable that the Supreme Court would uphold such act, on the ground that the question involved is of a political nature and therefore not subject to review by the Court.

State control was not undertaken in our Western States until the patience of the water users had been exhausted so thoroughly by the exasperating delays and expenses of litigation, and the inability of the Courts to distribute the water through injunction proceedings, that they took the law into their own hands, with the result that many murders were committed. It is conceivable that war between States over the proper division of interstate streams may result, before Congress can find time to exhaust thoroughly all the possibilities for debate in this most complicated and involved subject. Decisions can

be found sustaining almost any view. It is easy, therefore, to get hopelessly involved in the details of this subject unless one keeps clearly in mind the ultimate objects to be attained, and proceeds on the theory of the greatest good to the greatest number.

The writer has thus analyzed the question of State and Federal control with respect to navigable waters, including their non-navigable tributaries, non-navigable streams wholly within the State and not tributary to navigable waters, and lastly, the question of interstate streams. He is led to the conclusion that Congress, under the present Constitution, can provide by law a definite system of water titles for the Nation, similar to that adopted in Oregon.

State's Rights.

The writer is aware of the criticism that will be urged against this doctrine by the advocates of State's rights, but he is unable to reach any other conclusion which will harmonize with the leading cases and the statutes as we now understand them. It may be of value, therefore, to inquire as to what extent, if at all, an individual State will suffer through the adoption of a National system of water titles.

Prior to the Kansas-Colorado decree, the State of Wyoming, which claims to exercise absolute control over property in water within its borders, would have had good ground to oppose such a system. The State is located on the Rocky Mountain Divide, and all waters originating within its borders flow into adjoining States. Without such National administrative system to restrain over-appropriations in Wyoming, to the detriment of prior appropriators in adjoining States, Wyoming may be considered to have an advantage, being the upper State, and therefore needing no protection from appropriations in adjoining States, while, on the other hand, with a National administrative board to pass upon interstate permits prior to construction, investments could be made without fear of being enjoined by lower States subsequently, and thus, through rapid and safe development, Wyoming would doubtless receive greater benefits from this new system than under the present lack of system. Just as the upper appropriator on a stream needs no protection from lower appropriators, so Wyoming needs no protection from other States; but few States are similarly situated.

If, by such Congressional legislation, the various States which have not yet assumed control of their water resources could be induced by outside pressure to adopt uniform State laws, such States, as well as the country as a whole, would be greatly benefited.

Congress having the power to legislate as to waters, it is difficult to understand how such a body, made up of representatives from the different States, could enact any law which would do great injury to any State or any section of the United States. The control and distribution of waters within the State will be left to the State's administrative authorities. The control of navigable and interstate waters, say in the Columbia River Basin, will be left to the State administrative authorities of this region in proportion as each State is interested, subject, of course, to the general laws, and the rules prescribed thereunder. The Federal administrative board could be composed of all State water authorities meeting annually in convention, or by a smaller board composed of representatives from different sections of the United States.

With the establishment of a National administrative system corresponding to that which has been proven a success in Oregon, Wyoming, and a few other Western States, a comprehensive plan for the development of our rivers in aid of navigation could be outlined and carried to completion without fear of entanglement over interstate rights. The public welfare as to any particular project on an interstate or navigable stream could be considered by the Federal authorities, and, upon approval, construction could proceed with certainty. Such Federal commission should have authority to determine and record all existing rights to water in those States where no such records are available, and should consider the relative value of unappropriated waters to the different States for domestic, irrigation, power, and navigation purposes, and have power to refuse any permit where the proposed use was a menace to the safety or welfare of the public.

Such a National system of water titles, with adequate administrative machinery to make it effective, would be of as great advantage to the Nation as the State system is to the individual State. The respective States would derive the same benefit from such system as the individual water user within the State does from the State system. We have priorities in rights to interstate waters, the same as for State waters. We have strong, aggressive, and litigious States endeavoring

through litigation to get some undue advantages over a weaker and upper State in the matter of interstate streams. We have upper States taking more than their rightful share of the interstate water supply, to the detriment of citizens in a lower State, and these citizens are compelled to suffer because of the lack of interest on the part of their State Government, or the National Government, or some other political or financial reason beyond their control. In other words, the "water hog" is not confined alone to State streams, but is beginning to make himself felt on the larger interstate streams. Here he is so intrenched behind technicalities of the law, and ignorance, due to lack of information as to the effect of numerous diversions on long rivers, that we fail to recognize him. Just as some people within the State, who have an undue advantage in water appropriations, oppose the enactment of State water laws, so we will have States opposing a National water law. Such law would be of no value if it did not restrain diversions in some States for the advantage and protection of others.

The argument of State's rights will be used effectively for a time against the enactment of a Federal water law. The individual State will, in the opinion of the writer, be benefited by such a law, and the Nation, as a whole, receive very great benefits.

Water-Power Policy.

The attitude of the United States toward the policy of water-power development is of particular importance to the Western States, for it is in the West that the greatest amount of undeveloped water power is located. The United States controls the major portion of this power through National Forest Reservations and the withdrawal of all vacant lands valuable for water-power sites. The State, in the absence of Congressional legislation, exercises control over the water, but it is impossible to use this water for power development without access to the stream. Right of way for such purpose cannot be secured without the consent of the United States, as condemnation cannot be resorted to.

Power sites in the National Forests can only be developed under revocable permits, and this is about as serious an obstacle to development as a complete withdrawal. In the streams of Oregon, the U. S. Geological Survey estimates that 3 317 000 h.p. are undeveloped. It

is of great importance to the development of the West that these restrictions in the path of development be removed as soon as possible. As the land is the property of the United States, there is no question as to the power of Congress to enact necessary laws, and such legislation need not await necessarily the adoption of a comprehensive system of water titles for the Nation.

That all power sites remaining on the public domain should be retained permanently by the Government, and be made to yield a material revenue, was suggested recently by the Commissioner of Corporations, at Washington, D. C. He states, further, that:

"Fuel-power will substantially fix the price of all power, because there is practically no considerable area in the United States where water-power can supply the entire demand for power. Of course, water-power cannot be sold above the price of fuel-power. On the other hand, if the price of water-power be fixed by law below that of fuel-power, not all the community, in most instances, can be served with cheap power, and an unfair discrimination must result."

Such policy would seriously injure the West, where water-power is plentiful and coal is dear. It is just as reasonable to argue that cheap coal development of the East should be made to yield a material revenue to the Federal Treasury, so that the West, where coal is dear, may not suffer a material handicap. Besides, such a policy is entirely antagonistic to the conservative theory of preserving to posterity a fair share of our exhaustible coal, oil, and timber supplies.

The views of Secretary Fisher should prevail, as approved by President Taft, and outlined in his message to Congress of February 2d, 1912. That the revenue derived from the development of water-power should be sufficient only to cover the cost of administration of that particular department, any surplus to be expended by the General Government for the improvement of the stream, and the benefit of the local community where the water-power site is located.

A more desirable policy, in the opinion of the writer, would be for the States, in co-operation with the United States, to develop this power and supply it at cost plus interest. There is no organization which could secure money at a lower rate of interest than these agencies, and, besides, the greater the scale of the development, the cheaper the original and maintenance costs.

The United States is now engaged in the development of hydro-

electric power, and is selling it at cost to municipalities in the vicinity of reclamation projects for light, heat, and other purposes. The winter rate, on the Minidoka Project of the U. S. Reclamation Service in Idaho, is so low as to permit the use of electricity for the heating of dwellings in competition with coal. The rate for heat, the writer is informed, is $0.50 per kw. per month, with $0.50 allowed to the private company for distributing the power within the municipality. If the States should join in furnishing funds, and in extending this organization, which has already made a success in this enterprise without the least suspicion of scandal, it would only be a few years until the entire United States would be covered with a network of transmission lines. This would be conservation on a grand scale.

For the encouragement of irrigation by pumping in the West, such a policy is indispensable. The cost of electrical power, under the most favorable circumstances, including interest, depreciation, and maintenance, for a pumping project, is very high, and a farmer is justified in undertaking reclamation by this method only under the most favorable conditions. Add to these obstacles the chance of paying an increased rate for his power at the end of the usual short-time contracts with power companies, and we have such unfavorable conditions as will compel much of our territory, which could otherwise be reclaimed, to remain arid indefinitely. Irrigation by gravity flow did not become a success in the West until the land and water were united in one by laws making water appurtenant to the place of use. Many communities under common carrier canals became so discouraged, as they watched the charges for water gradually increased in proportion to their ability to pay, that they abandoned their homes. This led to a reform in the water laws.

In 1870, 49% of the population of the United States were farmers. In 1900, only 29% were farmers. This is a most serious condition for our Government to face, if it is to endure. Some of the luxuries of life have come to be considered necessities. These must be supplied to the farmer at such prices as he can afford to pay. We are endeavoring to check this unhealthy trend by supplying good roads, telephone service, rural free delivery of mail, good schools, etc., for the farmer. The writer can conceive of nothing in addition to these which would make country life more attractive than the supplying of electrical

power to the farmer at cost. It can be put to almost immeasurable uses in the home, and on the farm generally.

Private capital will probably never be able to supply the farmer, owing to the relatively long transmission lines required for the limited market. Under State and Federal control, electric rates in cities could be lowered, even though the added cost of country service was assessed on all.

To prevent a threatened water-power monopoly, and to reduce electric rates, the Province of Ontario, Canada, created a Hydro-Electric Power Commission, in 1906, with full power to construct plants and to buy and sell power. This commission is now operating 281 miles of 110 000-volt main transmission lines and 180 miles of distribution lines, buying current from the Ontario Power Company, a private corporation at Niagara Falls, at $9 per horse-power per annum. The rates charged the municipalities to cover cost, vary from $18.10 to $29.50 per horse-power per annum, according to distance, and, at present, twenty-one municipal corporations are supplied with an aggregate of 30 500 h.p.

The two attempts of public developments of power and sale at cost, as here outlined, have been successful thus far. They should prove of value to the Nation in considering public control on a comprehensive scale.

Conclusions.

The distribution of water and the question of water rights are, at best, complicated matters. The present confusion seems to have arisen from the fact that heretofore we have left to the Courts the solution of all difficulties arising from the use of water, when, in fact, they should have been solved by the legislative and executive branches of our Government.

The Courts, having no knowledge of the practical difficulties involved in the dividing of streams for the different users, and approaching the problem only after investments had been made, to the injury of other investors, have established and maintained a system of law which is entirely repugnant to the diversion and use of water for any but the most primitive uses. Following sound rules of law which had been developed under entirely different conditions, the Courts have refused to the legislative branch the right to amend the Court-made law, on the ground that such statutes would be an inter-

ference with vested rights and in violation of the Constitution. Realizing the extreme necessity of diverting water from streams in the Western States, the Courts, in a few instances, have declared that what they had heretofore considered the law was in reality not the law at all. Now the Supreme Court of the United States, in a decision which applies alike to every State of the Union, appears to indicate that the Courts of all Eastern, and many of the Western, States have been mistaken as to the law of waters, and the way is now clear for the first time in many years for legislation. This legislation should be positive, and should approach the problem from the standpoint of the investor prior to undertaking development. The public interest should be carefully considered prior to the permitting of any new development.

All rights heretofore initiated in good faith for the application of water to any useful purpose should be determined, recorded, and thereafter receive the protection of the law, instead of each user being left to his own individual efforts.

The common error, made by a number of Western States which have attempted to legislate as to waters, should be avoided; that is, to assume that the determination of the facts (priority, purpose, period, place, and quantity), necessary for the establishment of a water right under the law, is a judicial matter, which can only be passed upon by the Courts. Such error would be fatal. These matters should be attended to by an administrative board which has complete jurisdiction of all matters relating to water. Every step thus taken will be in harmony with some preconceived plan, and the final results will be of correspondingly more value. Any error in law can be cured by the party injured through an appeal to the Courts. The lack of such appeals, from the administrative officers in Wyoming and Oregon indicates that but a few appeals will be necessary. If, in such system for the adjudication of old rights, the complicated legal rules of pleading and of evidence had to be followed, it is difficult to conceive the cost in time and money, and it is doubtful if a complicated adjudication could be carried through in an ordinary lifetime.

To illustrate, the leading case of Hough *vs.* Porter was before the Courts of Oregon for ten years, before a final decree was rendered. There were only forty-five parties to the suit, and an administrative

board could have secured all necessary information and decided the matter in one-tenth the time.

The State of Utah adopted a system of water titles in 1903, where the State Engineer was to make surveys and gather facts for the guidance of the Court in the adjudication of water rights. After nine years, and the expenditure of about $30 000 in the survey of the Weber River, involving about 400 ditch rights, not one right has yet been determined by the Court. This record is in striking contrast with the work of the administrative board in Oregon as outlined in this paper. In only a few years every early right in Oregon will be determined, and will receive the protection of the State's administrative officers.

The subject here presented relates more to the legal, than to the engineering, side of the water problem, and yet only the engineer can appreciate with full force the importance, to the country as a whole, of having definite and uniform State laws relating to water, supplemented by a National administrative system in harmony therewith. Therefore, he should take a leading part in the reform of State and National water laws. Streams do not follow State lines, and for this reason, these arbitrary political divisions must give way to the more enlightened policy, which is in harmony with the laws of Nature, of treating each stream system as a unit from its head-waters in the forests to its mouth on the coast.

DISCUSSION

Mr. Johnston.

CLARENCE T. JOHNSTON, M. AM. SOC. C. E. (by letter).—This paper deserves some comment from those who are interested in problems of stream control. The writer is glad to find, here and there, an engineer who has had sufficient experience in such work to convince him that the questions which arise are of a legal nature only in an incidental way. In its fundamental aspects, the supervision of water resources is of greater public concern than the protection of land titles. Water and watercourses are generally considered as public property, and, therefore, the demand for an engineering administration has not been felt, except where streams have been used to a large extent, and particularly where water has been diverted from natural channels. As controversies have arisen, the Courts have been appealed to, and to-day, particularly in the West, decisions of all kinds are made. Volume after volume is published dealing with theories which have been developed and played with by attorneys, until they can no more be applied in practice than water can be diverted from a stream without affecting its discharge.

We derive our common law from England. With that law we brought the doctrine of riparian rights, which guarantees to every owner of land abutting on a watercourse the right to demand that the waters thereof pass his property "undefiled in quality and undiminished in quantity." This is the true riparian doctrine. It is not suited to a country where large volumes of water must be taken from the streams. Regardless of this and regardless of the experience of other countries, lawyers and Courts have tried to make it fit every climate and every natural condition. A simple doctrine, which suits a country where large rivers prevail and where actual diversions are of little importance, has been distorted and juggled with by the Courts until it is no longer recognizable. The "modified" doctrine of riparian rights, as we have it inflicted on us, is often a convenient screen for crimes committed against the public and in behalf of those claiming "vested rights." A perusal of the statutes of various States referring to riparian rights, and quite generally the laws pertaining to stream control, will disclose the existing situation to the student. Much has been done to protect vested rights, but reference is seldom made to public rights. The idea that the public ever obtains a vested right would never be gleaned from reading the statutes dealing with stream control in a majority of the States. This condition arises from the fact that the lawyer, representing those who claim many special rights and privileges, often reaches the Legislature where he exhibits marked ability in inserting such clauses as the following: "This chapter shall in no wise be construed as impairing or abridging any rights already vested in any person or persons, company, or corporation, by virtue

Mr. Johnston.

of the law heretofore in force." After a training of this kind he develops an instinct which enables him to protect private property rights without study or deliberation. Should such a man be elevated to the bench, he displays the same tendencies, and some of our remarkable decisions may be attributed to Courts so constituted.

Streams and lakes are not like land, in so far as private possession is concerned. Land can be measured and privately controlled. Water is constantly shifting, and the supply changes every day. The public must bridge streams and provide harbors. The public must protect fish and provide for the safety of dams. We use water to-day only to lose it to-morrow when it runs on, a continuous blessing to the public. It cannot be owned privately, and no State should ever permit individuals or corporations to claim such ownership. It is plain that injustice would be worked should one nation have exclusive ownership of one of the great oceans. It is equally plain that injustice would result should one State control an interstate stream or lake. The same rule applies when one individual or corporation is permitted to assume control of any local water supply, yet the local public is often slow to act in its own defense. The engineer should appreciate these facts. He should be a leader in questions of stream control. Unfortunately, engineers have not assumed the responsibility that naturally belongs to their Profession. We may criticize the Legal Profession and the Courts—and possibly they deserve it in some degree—yet we must remember that the engineer is depended on for information; and further, that where engineers have studied these important problems and given the Courts the results, reforms favoring public control have begun to appear. Too many engineers have been blinded by what seems to them to be the best policy at the time for their employers who appeal to the Courts. Too many engineers fail to see that principles which insure justice to the public protect water users generally. The water rights of private users are best insured where public control is most rigid. Engineers have been as tardy as the Courts in recognizing this.

When the National Constitution was framed, the States ceded to the General Government the control of navigable waters. The Nation, as a matter of development and defense, must control navigation when necessary. Non-navigable streams remain in the possession of the States. The States have not properly administered the smaller streams which they own. It has been so apparent that streams and lakes are naturally property of a public character that, for a long time, particularly in localities of large rainfall, the necessity for public supervision has not been called to the attention of lawmakers. Regardless of the public character of streams and lakes, private interests have assumed to take possession here and there, and the claims thereby arising are still to be settled. The great questions relating to State

administration of waters are yet to be determined. Some Court decisions would appear to be final and in favor of a private monopoly of public property of this kind, yet the end has not been attained in a single important case. Mr. Johnston.

Because the States have been slow in asserting the doctrine of public rights in property which is essentially of a public character, we need not fear that the public has lost title in any way. Because some individual or some corporation has been using this property for a term of years, there is no reason to hold that the users have secured title thereto. It would seem that such users would owe the public a vote of thanks at least. Many troubles have been precipitated because the owners of riparian lands have been permitted to claim more than the true riparian doctrine would admit in itself. Because the General Government has not meandered every small stream—a physical impossibility—the subsequent patentee of riparian lands has assumed that he owns the land to the center or entirely across the channel of the natural waterway. Where, through ignorance of the naturally public character of streams, the Courts have seemed to confirm claims of this nature, an error has been made, but such errors will be corrected in time.

Water must be used by individuals and by corporations. The public should realize this and consent thereto. The public and all users should appreciate the difference between the use of water and the ownership of water. All uses should be of such character, and secured under such restrictions, that the authority and ownership of the public are manifest in every transaction and apparent to all concerned. When the time comes for the public to assume full control of its property, private interests should be recompensed according to the estimated cost of replacing the works constructed by them, and which, under the new order of things, are to be operated by the public. Valuation work of this kind has also fallen largely to the engineer. It is a new science, and engineers have not reached an agreement as to the principles which should be applied in determining just valuations.

Principles are of so much more importance than details of law, methods of procedure, or exact character of administration, that the writer does not feel inclined to discuss National, State, or even more localized control of streams. Under present conditions, there can be no question as to the responsibility of the General Government and of the States in work of this kind. The essential facts which should determine any question which may arise are of an engineering, rather than of a legal, nature. They are simple and, as a rule, not difficult to obtain where an engineering administration is provided.

The writer has followed the development of the public control of streams of the West for many years. Wyoming, under the able leadership of Elwood Mead, M. Am. Soc. C. E., took the first step which

Mr. Johnston.

relieved the Courts from all initial proceedings in questions relating to the use of water. Only appeals from administrative officers go to the Courts in that State, and these appeals are so few that during the past twenty years they can be counted on the fingers of the two hands. During that time the State Administration has studied and determined more than 15 000 claims and, at the same time, has protected all public rights. As Dr. Mead's Assistant for a term of years, and as State Engineer for nine years, the writer was able to give some thought to the principles which should underlie the laws relating to stream control, and the following matter from his last report* to Governor B. B. Brooks contains a discussion of the elementary principles:

"Some reference should be made at this time to Sections 724, 725, and 726, Wyoming Compiled Statutes, 1910. These sections were added to the irrigation laws of the State by the Legislature of 1909. The bill before the Legislature was known as 'House Bill No. 66.' All who have studied this legislation agree that it represents the most important action of the law-makers of the State since the original statutes were enacted in 1891. While the purpose of the act is fresh in the minds of those who were in the Legislature and among those who prepared the bill, some public record should be made of its purpose so that when its provisions are interpreted, there will be no mistaking its object.

"The Act reads as follows:

"CHAPTER 58.

"*Water Rights.*

"724. *Water Right Defined.* A water right is a right to use the water of the state, when such use has been acquired by the beneficial application of water under the laws of the state relating thereto, and in conformity with the rules and regulations dependent thereon. Beneficial use shall be the basis, the measure and limit of the right to use water at all times, not exceeding, in any case, the statutory limit of volume. Water being always the property of the state, rights to its use shall attach to the land for irrigation, or to such other purpose or object for which acquired in accordance with the beneficial use made and for which the right receives public recognition, under the law and the administration provided thereby. Water rights cannot be detached from the lands, place or purpose for which they are acquired, without loss of priority. (L. 1909, ch. 68, Sec. 1.)

"725. *Preferred Uses Defined.* Water rights are hereby defined as follows according to use: Preferred uses shall include rights for domestic and transportation purposes; existing rights not preferred, may be condemned to supply water for such preferred uses in accordance with the provisions of the law relating to condemnation of property for public and semi-public purposes. Such domestic and transportation purposes shall include the following: First—Water for drinking purposes for both man and beast. Second—Water for municipal purposes. Third—Water for the use of steam engines and for general

* Biennial Report of the State Engineer to the Governor of Wyoming, 1909-10, pp. 17 to 29.

railway use. Fourth—Water for culinary, laundry, bathing, refrigerating (including the manufacture of ice), and for steam and hot-water heating plants. The use of water for irrigation shall be superior and preferred to any use where turbine or impulse water-wheels are installed for power purposes. (L. 1909, ch. 68, Sec. 2.) Mr. Johnston.

"726. *Change to Preferred Use.* Where it can be shown to the board of control under the provisions hereof, that a preferred use is to be made, the procedure for a change of such use shall embrace a public notice, an inspection and hearing if necessary by and before the proper division superintendent, a report of such superintendent to the board of control, and an order by said board. If the change of use is approved, just compensation shall be paid and under the direction of the board, proper instruments shall be drawn and recorded. (L. 1909, ch. 68, Sec. 3.)

"The act is plain in its terms. There may be some confusion, however, in the minds of those who have not followed the history of the development of irrigation law in this State. The constitution of the State, which has the approval of Congress, says:

" 'Section 1, Article VIII. The water of all natural streams, springs, lakes or other collections of still water, within the boundaries of the State, are hereby declared to be the property of the State.'

"This provision of the constitution has been discussed from various standpoints. The State has never held that the water which it owns should be disposed of for profit. It is not deemed wise to administer this natural resource for revenue. It is presumed by the law-makers of Wyoming that the water the State possesses is for the use of the people. However, the State has a greater responsibility. Wyoming has discovered and placed on the statutes of the State the first definition of essential principles that should govern the use of water. So that the State, not only owns the water and permits of its use without charge to her citizens, but the State sees to it that all users are given equal protection. One man cannot be permitted to expand his use without interfering with the rights of a community. The State early discovered the danger of permitting water or water rights to be treated as personal property. If water rights are owned separate from the land irrigated, or such other use as may be made of the water, then the personal element enters and there is no such thing as public supervision and no such thing as the protection of the community against the greed of a few who may be powerful or influential.

"We cannot review the decisions of the Colorado courts without feeling that they have failed to enunciate such doctrines as will protect the water user. For instance, we find in the case, 'Laramie County Res. Co. *vs.* People *ex rel.* Luthe,' 8th Colo. 614, the following definition of 'appropriation.' 'Appropriation is the intent to take, accompanied by some open, physical demonstration of the intent, and for some valuable use.' The court evidently understood that a diversion from the stream without actual beneficial use of water could not give the right to use water. It was manifestly plain to the court that there was something necessary in addition to a claim, which we assume to be the manifestation of the 'intent.' The court did not see that an investment in irrigation works can be protected without giving the

Mr. Johnston.

investors ownership in water. It saw that a time must lapse between the filing of the claim, or the expressing of the 'intent,' and the use of the water. Hence the priority would date from the time the claim was filed. The company, unless disturbed by some agency, would secure title to water under that priority date providing it completed the irrigation works. There was no limit to the demands the company might make on the stream, except its financial ability in ditch and reservoir construction. There was nothing in the plans submitted to tell where the prospective beneficial use was to occur and absolutely nothing to protect those who were to be the actual water users. It might have occurred to the court that the State could by law provide that a company be given a certain time to show its good faith and upon the final showing being made, that it be given a certain time to sell interests in the irrigation works constructed. It might have occurred to the court that this would have enabled each water user to have obtained water rights dating back to the time the claim was filed in some office of public record; it would have enabled the company to have obtained a reasonable profit; it would have left the water rights in possession of the water users, each having an interest in proportion to the land reclaimed; it would have given the irrigation works to those who should for all time rightly be held responsible for maintenance. How the construction of irrigation works without any arrangements being made with prospective users or without any reference to the proposed beneficial use, can give the builders a right to the water is a problem that is too complicated for the average man to grasp. The court saw the danger ahead and it tried to do something to avoid it. The trouble was that the court gave the company everything in sight, under certain conditions. It is like giving a railroad an entire valley on condition that transportation facilities be provided. The railroad has a right to demand lands which it uses or is to use. The ditch company has this right. Water is more valuable than land. The railroad company is not entitled to all the land in sight, when it cannot use the land. The ditch company cannot use all the water it can divert. It has no right, therefore, to be placed in position where it can sell water which it has never acquired by beneficial use. A railroad company which secures an entire valley receives a rich reward. It can sell the lands to those who can cultivate them. This arrangement should be very pleasing to the railroad company. It was doubtless as pleasing to the ditch company to get title to water. It could sell this water to those who either had to buy it or face financial ruin. There is absolutely no reason why an irrigation company, or any individual, should have title to any property except the physical works it constructs or acquires. The court did not see this. It did not see how the water users could be protected under the priority obtained by the initial filing except by giving the company title to the water. This is so simple and it works out so easily where the States have an administrative system which manages streams for the benefit of the public, that any other plan would never be discussed if it were not that living examples of a dangerous type are so close at hand. The Colorado court decisions go a little further than to give everything to the company which builds the irrigation works. The rights of the consumer are discussed in a number of cases. This

admits of some intimation of rights that others, aside from the irrigation company, might hold. If the court, in the first place, had held that the plans submitted by the company must be based on good engineering and that specifications for every structure must be filed; if it had then compelled the company to designate the lands that were to be reclaimed and dedicated the water to the benefit of those lands, a foundation would have been laid that would have supported every principle that might be necessary to protect those that were to follow the company. There is a library of speculation over this subject of appropriation in the Colorado decisions—yet no two complete discussions are in entire harmony. All indicate that there is something that should be reached and in every decision this something is just beyond the grasp of the court. To prevent too much injury being done the water users, the State Legislature has given the county commissioners authority to regulate the price paid for water. Because the court could not fathom the problem before it, the future of every project is left with administrative officers, who may or may not be able to determine what price is fair. The county commissioners may be connected with the company and they may be water users under the system in question. It would seem much better to make the water rights attach to the land and establish the price which the water user is to pay for an interest in the irrigation works in the beginning. Mr. Johnston.

"Let us study an individual case so that its history may be approximately complete. The Colorado courts dealt out water, rather than water rights, with a lavish hand. The courts did not know what volume of water was necessary to satisfy with justice the needs of each claimant, and they did not know what principles should govern in the adjudication of rights. No person can arrive at any other conclusion after reading closely the court decisions of the State. For instance, a water claimant is given a right to 35 cubic feet of water per second. The court does not say that this water belongs to the land or that the water right belongs to the land, but the person is given a kind of title to so much water. As the country grows the person so favored finds that the court has given him a large volume of water that he has never used. He therefore applies for a change in point of diversion. This may be opposed in the courts, but he generally wins out. He then proceeds to use this water on new lands, water that others have for years past been using. Those who are injured may be able to protect themselves if they have means. If not they must suffer the consequence. This person, who is so fortunate to get possession of water that he has never used, then proceeds to use it in another way that injures the community still further. Because the court has given him 35 cubic feet of water, he holds that he can store all of the excess that he does not need in the irrigation season for direct application from the stream. This is a happy thought. In the meantime possibly enough reservoirs have been built to store all of the excess flow of the stream. This makes no difference to this fortunate person. He stores, for his own use and for speculation, 35 cubic feet of water per second, except during the irrigation season, thus depriving other persons of his community of water that they have been using.

"He has probably secured the 35 cubic feet of water per second when

Mr. Johnston.

he only irrigated 160 acres of land. Two to two and one-half cubic feet per second during the irrigation season would be ample for this area. Even should he be able to apply three cubic feet per second, he would have left 32 cubic feet per second for speculation during the irrigation season. This would supply water for 2 000 acres of land and be worth $80 000.00 at least. By storing 35 cubic feet per second for nine months he would impound 18 900 acre-feet of water. If a fourth of this, or 4 725 acre-feet of water are lost by seepage and evaporation, he would have left 14 175 acre-feet of water for further speculation. This would irrigate fully 6 000 acres of land and be worth $240 000.00. The court, therefore, through ignorance, and without considering the rights of any person except the claimant, gives him $320 000.00 worth of water that he has never used and which has been used by others. This value of $320 000.00 cannot be given to one claimant without taking it from another.

"What is the situation in Wyoming? An agricultural community begins to develop. Each applicant for water rights obtains permits which describe lands to be irrigated. The water rights are finally adjudicated and dedicated to the use made. The water used for irrigation belongs to the lands reclaimed. It remains attached to that land. When the land is sold it goes with the land. The law places a maximum limit on the use that can be made—one cubic foot of water for each seventy acres of land irrigated. The public must see to it that waste does not occur. This maximum limit cannot be exceeded at any time and the use is restricted to such volume less than the legal limit as can be beneficially applied to the lands to which the water right attaches. There is no way to expand the use. There is no way by which an individual or a company can speculate at the expense of a community. All rights are matters of record and there can be no serious cause for dispute.

"Because certain lands have water rights direct from the stream during the irrigation season does not mean that these lands are entitled to water throughout the year. The first reservoir built in compliance with law secures the first right to store water to its capacity. This reservoir can be filled at any time that the stream furnishes a supply that is not used. The second reservoir then has its turn, and so on. Reservoirs store water—not water rights. Ditches carry water—not water rights. Water stored in reservoirs simply augments the supply during the season when needed and this water leads to the perfection of water rights which belong to the lands reclaimed and to the other uses made, the same as though the stream supplied an ample volume during such seasons.

"Section 724 states that 'beneficial use shall be the basis, the measure and the limit of the right to use water AT ALL TIMES, not exceeding, in any case, the statutory limit of volume.' This means that when the community needs protection the public control must be such as to limit all users to the volume that can be beneficially applied. The certificates of appropriation, issued by the Board of Control, describe the lands to which the water right belongs and specifies what the maximum allotment of water is to be. It also says in conformity with the law that the use shall consist of the application of such part of the maximum allotment as can be beneficially applied.

Mr. Johnston.

"Water is the property of the State and no charge is made for its use. When water is used for irrigation or for any beneficial purpose for a term of years, the user should feel thankful to the public that conditions are such that he has been able to do business without being subjected to a special tax on the water. Because the public has enabled this to be done, is there any reason why any person or company should be given the additional right to sell the water or water right he has been enjoying? The community cannot be injured as long as the use continues as it has always been, but that use cannot change without having some effect on the rights of others. Because the last sentence of Section 724 states that water rights cannot be detached from the lands, place or purpose for which acquired without loss of priority, it is held by some that the act is unconstitutional. Under the constitution cities and towns can condemn water rights for municipal purposes. When a city or town needs water it gets it and always gets it regardless of priority or the character of the right. Under this same act, municipal uses are made preferred uses. It may often serve the purpose of a town to condemn a water right that belongs to some land not enjoying an early priority. For instance, the early rights may all be near the source of a stream. This is an ideal condition. The town may be twenty miles below the lands having these rights. There may be irrigated lands near the town that can be condemned to furnish a water supply for the municipality. The water right obtained by the city or town under such circumstances cannot affect the early rights at the head of the stream, yet the town has secured an adequate supply. Should it be necessary to condemn one of the early rights at the head of the stream, this could be done, at any time later. The idea is this—nothing should be done by the State to give an added value to the early rights. There are so many conditions affecting the flow of a long stream, that cities and towns can often be supplied without interfering with the early irrigation development. A town might buy an adjoining farm with whatever water rights it may have. If the use of this water for municipal purposes will injure other water users, outside of the town, then they should be recompensed. After a city or town buys water rights, they become preferred uses, so that the priority of the right makes but little difference. The main object is to see to it, at the time the transfer is made to the town or city, that all who might be injured by this change are taken care of at once. Section 726 provides that these changes shall take place under the direction of the Board of Control. This means that an inspection will be made by the Superintendent, all users will be notified and the final record will embrace a settlement that will be in harmony with physical conditions and with justice to every allied interest in the stream. One thing should be remembered—preferred uses are to be protected in seasons of scant water supply. When a change is made of any inferior right to a preferred use, all who might be affected should be made acquainted with the purpose of those who represent the preferred use and all precautions taken while the matter is before the board to secure whatever redress may be justifiable. It should also be remembered that preferred uses require small quantities of water compared with uses for irrigation. For instance, suppose a man owns 160 acres of land to which a water right attaches. Assume that he covers

Mr. Johnston.

this to a depth of two feet during an irrigation season of 90 days. This is 320 acre-feet of water, or 104 544 000 gallons. This volume of water would furnish a water supply for a town of 3 000 people for a year, estimating that each person requires 100 gallons of water per day of twenty-four hours. Since the irrigator does not use water from the stream, except during the irrigation season of say 90 days, he has no right to the water during the remainder of the year. The town can file an application for the necessary supply outside of the irrigation season and the permit secured gives rights that cannot interfere with the rights of any other user, unless other rights have been secured which depend upon diversions outside of the summer season. The water right for 160 acres with the additional flow that could be secured under permit would supply a town of 12 000 people, if the water could all be used without loss. Certainly this should be a preferred use. The value of a city of 12 000 people to the State and to the public as locally represented, is far in excess of the value of any 160-acre farm, no matter how highly it may be cultivated.

"Another point should not be overlooked in this connection. The State does not permit the use of the legal maximum flow—one cubic foot per second for each seventy acres of land reclaimed, except when this volume can be beneficially applied. The owner of irrigated land cannot charge except for the value of the land with a water right, compared with the land in its former arid condition. He cannot, in other words, transfer to a municipality or to any preferred user, the maximum limit of his water right. This must be fixed by the board of control at such hearing as it may conduct. The city may buy the land outright and the entire tract of say 160 acres may be irrigated. The land may be of such character that one acre-foot per annum will raise crops and this volume may have been the maximum that has ever been used. Manifestly this is all the municipality obtains.

"It is believed by those who understand natural streams and the effect of diversions therefrom that it is much better to permit preferred users to purchase any rights that may be available rather than to place a premium on the first right, as has been the custom. For instance, if the first right were at the head of the stream and the city at or near its mouth, the irrigators above would lose all return seepage from the lands irrigated under the early right should this be transferred to the municipality. The early right and all other rights might continue undisturbed should it be possible for the town to secure a comparatively inferior right nearer to its boundaries.

"This legislation was not prepared on the spur of the moment. It represents the result of many years of study. It received the consideration of irrigation authorities throughout the West. It was given very careful study by the committees on lands and irrigation and by individual members of the Legislature of 1909. This act does not represent the personal views, only, of any individual or by any class of individuals. It represents in concrete form the wisdom of water users, students of irrigation and legislators. It passed the Legislature of 1909 with but seven dissenting votes altogether. No attempt was made to frame a measure of the kind until the views of the water users of Wyoming had been obtained. The responses received to letters mailed

to thousands of irrigators throughout the State laid a foundation for the bill as it was submitted. Mr. Johnston.

"It has been said that other States and that courts do not recognize the principles embodied in this act. It must be admitted that Wyoming stood for something of the kind long before any such doctrines were heard of outside of the State. It must be admitted that because other courts failed to get down to the proper fundamental principles, our courts had no guide, except in so far as our law-makers prepared the way. However, these doctrines are spreading. We need not search in vain for decisions that have the fundamental principles clearly defined. On March first, 1910, a decision was handed down in Arizona which should be read in full by every student of irrigation. The title of the case is 'Patrick T. Hurley, the United States, Intervenor, *vs.* 4 800 other water users.' It relates to the settlement of claims to use water from Salt River. The Reclamation Service is constructing one of its large projects in the valley of this stream, hence the United States intervened in the suit. The Supreme Judge of the Territory, acting as District Judge, heard the evidence and made the decision. It is remarkably complete. The definition of principles appearing on pages 8 and 9 of the printed copy of the decision is worthy of careful study and consideration. We quote this in full as follows:

"'The doctrine of riparian rights does not obtain in Arizona. The right of the owner of land to divert from a natural non-navigable stream the flow of water therein and to apply the same to beneficial use upon such land, is and always has been recognized in this territory. Such diversion and use is termed an appropriation of water. Whatever may be the steps necessary to take to initiate such a right or to evidence the intent to initiate it, the appropriation itself only becomes complete and vested when the water is actually diverted from the stream and placed to a beneficial use upon the land. The right given by such an appropriation is strictly not a right to the water itself, but a right to the use of the water. Its application to a beneficial use upon the land is as necessary in order to complete the right as is the diversion thereof from the stream. An appropriation of water, therefore, for the purpose of the irrigation of a parcel of land may not be established and completed by means merely of a declaration of intention or by the posting of notices of appropriation, nor may it be made by a canal owner or by a canal company as such alone, independent of its ownership of the land; but as application to a beneficial use upon the land is necessary to complete the appropriation, it follows that such appropriator must be an owner of land or have a possessory right thereto. Furthermore, since the land to which the water is to be applied is a necessary integral part of the appropriation and a factor by which the amount of the water appropriated for use is measured, it follows that when the water is no longer applied to the land for which it was diverted, the right of appropriation of such water for such land ceases. The right of appropriation further depends upon a supply of water that is unappropriated. It follows, therefore, that the first in time of appropriation is the first in right to appropriate, since water previously appropriated by another is no longer available for a subsequent appropriator. The extent of the appropriation is limited by the beneficial use to which the water can be applied. The actual amount

Mr. Johnston.

of water that may be appropriated for irrigation, therefore, is the amount that the land owner can and does actually use in the necessary and economical irrigation of his land for cultivation. This much and no more may he have; and this much he may only have when there is sufficient water available to supply first those prior in date of appropriation. The fundamental principle in the doctrine of appropriation of the normal flow of water in a stream for irrigation is its application by the land owner to the land for a beneficial use. The right to appropriate is a right that belongs to the land owner, but the water appropriated is appropriated for the land, and when so appropriated its use belongs to the land and not to the appropriator. The method of diversion from the river and the means of carriage of the water to the land is immaterial in the establishment or maintenance of the right; it may be done by the individual appropriator or by an association of individual appropriators, or by a canal company, or by any person or corporation; and the means of carriage or the point of diversion from the river may be changed from time to time to suit altered conditions without impairing the right of appropriation already made, provided prior rights of others are not interfered with. There being in this territory no private property in water, but water being a public property subject to the uses before defined, in so diverting and carrying the water such person, association or corporation acts merely as the agent of the appropriator and acquires no right of appropriation to the water itself, and no rights as against the appropriation made to the land, except a right to proper compensation for such diversion and carriage.'

"This decision marks distinct progress in court decisions relating to the use and diversion of water from natural streams. The principles upon which the decree is rendered afford protection to every claimant, yet when they are applied in practice no man is given a weapon whereby he may destroy the prosperity of his neighbors. The personal element is eliminated. The welfare of the community, through the protection of each individual in accordance with the nature and extent of beneficial use of water, is taken as the criterion for the settlement of rights rather than the claims of individuals regardless of the character of the irrigation development they may have been responsible for. Because the federal government intervened in this case and because the judges were at the time federal officers, the decision has a value that is more far-reaching than would ordinarily be the case. The entire decision is recommended to the consideration of those who are interested in the settlement of water right claims and controversies.

"It has been held by those who do not support the principle which unites water rights to the land reclaimed that the act of 1909 does not apply to water rights which were perfected prior to the passage of the law. This is the old argument that supports 'vested rights' regardless of the welfare of the public. The public and communities generally will protect individuals in their rights if the public and the community is made supreme over the individual. If the individual is superior he will take advantage of his position to injure the community. If the State cannot make laws affecting the administration of its own property, then it certainly cannot enact statutes which have for their purpose the collection of taxes, for instance, which relates to

the raising of revenue from property in private possession. It cannot quarantine live stock belonging to private parties even for the protection of communities. It cannot pay bounties for killing predatory wild animals or defray the cost of protecting game animals. To say that the State cannot regulate the use of water by the enactment of new legislation, even after water rights have been acquired for various purposes, is on par with the claims of certain people who held that because they began the use of water prior to the admission of Wyoming to statehood, the State had no control. This contention led certain claimants in Johnson County to refuse to submit proof before the Board of Control and to attempt at a later date to secure certain rights by litigation. The case was finally decided by the Supreme Court of the State, 9th Wyoming Report, 110. This decision is plain. It indicates that the State can regulate the use of water regardless of when the claim was initiated or under what laws water was first used. It is not presumed that the Legislature will injure water users by the passage of any general laws. It is not believed that it will ever be necessary to injure any water user to protect a community. It is essential to have water rights defined in such a way that the individual will never presume to have such rights as will enable him to even threaten the prosperity of a community. If no water user has rights in excess of those that attach to his lands as limited by beneficial use, the community need never fear any trouble. The danger in irrigation matters never begins with the community, or the State. It has its birth in the greed of one or two who, through the weakness of supervision in behalf of the public, are able to get what they are not entitled to, thereby enriching themselves at the expense of their neighbors. Mr. Johnston.

"The fundamental principles which provide equal protection to all and special privileges to none, are so simple and their number is so small, that it is surprising that they are not stated in every irrigation statute and in every text book dealing with the use of water. Yet we look almost in vain for any discussion of them. All that need be borne in mind is that the right to use water should be limited in accordance with the beneficial use made and the right should belong to that use rather than to the user. All other matters relating to the right are questions of fact that are easily obtained."

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—Every great hydraulic project calling for a large expenditure of money demands the employment of three distinct classes of Man, namely, a good promoter or business man, a good lawyer, and a good engineer. Each of these men attends to his own particular line of business, and, as a final result, the scheme is a success. This seems to be the experience everywhere. Mr. Le Conte.

Of late years, however, the universal knowledge demanded of the engineer has grown to such an extent that, in order to be thoroughly up to date, he has to be well nigh omniscient. The time now seems to be fast approaching when the engineer in charge of a large scheme will be compelled to acquire the necessary knowledge of all three of these classes of men.

Mr. Le Conte.

The author says that Court decisions are based more on the logic of judges than on the statutes. This calls to mind the lamentable fact that almost everywhere all the law that the general public gets, at best, is judge law, pure and simple.

The author calls on the Engineering Profession to come forward and take active lead in the movement for the enactment of better water laws. This is badly needed everywhere, and certainly engineers are, by experience, better fitted for the task than men of any other class.

The author says that many lawyers fear that the reform in water laws would spoil their business, which is true; but it also shows—a well-known fact—that members of the legal profession, as a rule, make their living by feeding on the misfortunes of the public. It is natural, therefore, that they should object to anything that cuts down the business of the Courts.

It is highly desirable that interstate or National water laws should be framed and enacted as soon as possible, inasmuch as all large projects are now halted and waiting for results. The new State water-right laws of Oregon certainly seem to be simple and effective, and, apparently, they fulfill all public requirements very satisfactorily. It now remains to enact similar laws to cover the needs of interstate streams.

It will be remembered that the City of New York contemplated getting a new water supply from the Housatonic River, which, to a large extent, is in the States of Massachusetts and Connecticut. After much wrangling in the Courts, the scheme was abandoned, and the city was forced to go to the Catskills, which project is now being developed on a grand scale.

The report of the Committee on Interstate Water Rights to the National Irrigation Congress, held at Sacramento, Cal., in 1907, seems to be highly commendable. The equitable suppression of the drastic law of riparian rights seems to be absolutely necessary for the public welfare.

Finally, the writer would respectfully suggest, in keeping with what he has stated before, that the Administrative Board, which will have complete jurisdiction of all matters relating to water, should be composed of good engineers, good business men, and good lawyers, all of whom are reputable citizens. The reason for this is that it is now practically impossible to find one class of men gifted with all these qualifications combined.

The members of such a Board, of course, would shoulder grave responsibilities, and their compensation should be ample, so as to enable them to give their time exclusively to the Board's business.

Mr. Dillman.

GEORGE L. DILLMAN, M. AM. SOC. C. E. (by letter).—This paper brings up a subject which is most pertinent and timely. If it results

Mr. Dillman.

in a solution, more good will have attended it than can be put in dollars and cents, and everybody concerned will benefit: the investing public, the constructing companies, the consumer who ultimately pays the bills—everybody but the professional litigant.

Some years ago the writer was employed as engineer for one of two strong litigants on a water-right case in Southern California. The usual slow course in the Courts was followed for years; a final verdict seemed impossible for years to come. Somebody, at a "psychological moment," suggested compromise, and, as far as the legal adjudication of the case is concerned, it will never be settled. After the case was dropped, one of the attorneys was asked: "What can make a good water right in California?" The reply was: "Nobody has any right to such a thing who is not prepared to fight for it at any and all times. There is no such thing as a perfectly defensible water right."

Two strong corporations in Kern County agreed to disagree over the water rights of Kern River, a large stream with many diversions for irrigation purposes. Their case was in the Courts for several years, during which time the small claimants allied themselves with one side or the other. Many thousands of dollars were spent, and the case was withdrawn without a verdict. The principal litigants agreed to divide the whole waters of the river between themselves, and the small fry were shut out. The legality of the dispute is not settled, but both big companies together stand ready to make it interesting for all adverse claimants. They have acquired adverse claims by prescription now, therefore, there is no question as to their "rights."

In California there are thousands of doubtful rights, involving millions of dollars, which would be settled if it could be done with small or reasonable expense. The owners of new diversions, changes of use, or changes of point of diversion, are not safe in their investments until their rights are prescriptive. Only a few days ago, one of the leading lawyers of California stated that the best water right to be had was by prescription and continual use, that filing rights and riparian rights were so indefinite that their defense was always doubtful.

There will never be much conflict between uses for power and irrigation in California by reason of the physical conditions, provided the power water is returned to the stream after use. In a large majority of cases the power sites are above the irrigation diversions. Where considerable areas of irrigable land lie in valleys above power sites, their irrigation will generally result in the steadier flow of streams below. Where power necessitates storage to increase low-water volume, this storage will benefit the irrigation below, because the irrigation season is generally the time of low water. Therefore irrigation and power uses can be made mutually beneficial.

Mr. Dillman.

This same question is international in places. Recently, the papers announced that the Mexican Company had shut the water from California in Imperial Valley. Only a few years ago the United States and Canada came to an agreement over the respective quantities to be diverted at Niagara Falls.

While agreeing with the author on the desirability of definite laws, uniform if possible, respecting water rights, there are some suggestions in the paper which seem wrong.

A National Board, if formed, should certainly have its jurisdiction limited to strictly interstate waters. The difficulty of getting action by any Bureau in Washington hardly warrants the establishment of a new one.

If the Government would grant permits for power development, considering the companies as public service corporations, and regulate them as completely as they regulate the railroads, the farmer would get his power much cheaper than under Government ownership.

There is a crying need for something definite in water-right law. The experts cannot tell what the law is, and the Court decisions are very contradictory. The engineers of California will all be glad of something that is determinable. The State Commission seems to have made progress in Oregon. Perhaps others will elsewhere. We should welcome an interstate commission if its jurisdiction covered only strictly interstate questions; but, please deliver us from any more Government Bureaus. Those we come in contact with are pernicious.

Mr. Moore.

W. E. Moore, M. Am. Soc. C. E. (by letter).—Mr. Lewis has contributed a most valuable paper. The need of legislation along these lines has been felt for several years in all the Western States, and will be felt sooner or later in every State in the Union. It is not any exaggeration to state that there is not a single country on the globe which has a water law in accordance with present-day needs.

Oregon certainly has the best law governing water rights of which the writer has any knowledge. It is a long step in the right direction. With its general outline he agrees most heartily, but thinks it does not go far enough—does not cover as much ground as it should. In some respects it should be more specific, for example, in defining the duties of the engineer in granting a right on a stream before he becomes thoroughly familiar with that stream. It requires several years to learn all the characteristics of any stream, and the writer is opposed to any one granting a water right unless the water is there to fulfill the grant. It is true that, in case of a shortage, the Oregon law shuts off the latest appropriators, but these appropriators ought to know whether they will get water for a part of every year, and what part. As every one knows, the low-water flow of every stream varies from year to year, and such data should be available in

the office of every State Engineer in order that the water users of that stream will know on what to depend. Mr. Moore.

There is a growing belief that every State law should limit the water in every case to the least quantity necessary. This is desirable for various reasons; it admits of a wider use of the waters, and, consequently, more water users, and it tends to prevent waste which sooner or later becomes a menace to the public health.

In the writer's opinion, every water contract should be submitted to the State Engineer for approval. In this way many of the contentions between unscrupulous promoters and *bona fide* water users will be avoided. He would also make all plans for the construction of hydraulic works subject to the approval of the State Engineer. There has been a great deal of speculating on water rights granted by State Engineers in several of the Western States, when in reality the grants amounted to nothing. The time has come when such a thing should be impossible. When the State Engineer grants a water right for any purpose, investing capital should be able to rest assured that the water is there, and that the system or plant by which it is to be used will be constructed along right lines. This is just as essential for the water user as it is for investing capital, for it is the water user who ultimately pays the bills, and the better he is protected in his rights, the better will it be for the lasting prosperity of the community.

That Federal legislation is needed on interstate streams is certainly patent to every one. The problem cannot be handled equitably by the different States until the nature of the human race is radically changed. These waters can be apportioned properly between the interested States by the National Government, and that certainly ought to be done without delay, as the problem becomes more complicated from year to year and retards progress very materially.

The writer certainly does not agree with Mr. Lewis in advocating the construction and operation of power-plants by either the Federal or State Governments, unless such work can be entirely and absolutely eliminated from politics.

One of the most valuable features in the operation of the Oregon law is shown by the fact that during the three years it has been in force, it has clearly demonstrated that practically all the contentions over water rights can be satisfactorily settled outside of the Courts. Even the legal profession admits that legal practice has become entirely too complicated and cumbersome, thereby causing injurious and frequently fatal delay. It is obvious, therefore, that anything that will hasten the settlement of contentions and lessen their cost will be a benefit to the community. The writer has no desire to deprive the legal profession of anything that rightfully belongs to it, but it is just as reasonable to contend that the engineer could settle legal

Mr. Moore. questions as it is to argue that the lawyer could settle engineering questions. It is a fact that many engineering questions are intimately connected with legal questions and cannot be separated from them, but as far as possible they should be kept apart. To the writer's mind this is one of the most important problems with which the Engineering Profession has to deal at the present time, and he feels very grateful to Oregon for the many valuable lessons it has given us.

Mr. Bien. MORRIS BIEN, ESQ.* (by letter).—This paper is very valuable in summarizing the present situation regarding water rights in the Western States, and will enable both engineers and lawyers to grasp more fully the great importance of the problems which are yet to be solved in regard to the determination of rights to the use of water.

In a country where most of the land is practically valueless unless it can receive a water supply for irrigation, it seems strange that it should take so long to provide for a satisfactory and conclusive record of water titles comparable with the record of land titles. The first step in this direction was taken by the State of Wyoming in 1890, and some of the other arid land States have followed along the general lines adopted there.

Large investments, running well into the millions, in connection with irrigation and water-power construction in the arid regions, depend fully as much on the title to the use of water required as on the title to the land whereon the structures are built.

Many enterprises of considerable importance have found themselves compelled to defend in the Courts their right to the use of water essential to the enterprise, the usual examination of the record in such cases giving practically no indication regarding the true condition of the water supply.

So long as it is possible in a number of the arid States for any one to place on record a claim to a quantity of water to be diverted from a particular stream far in excess of its flood flow, and entirely regardless of the fact that all or a large part of the available water supply may have been put to beneficial use, just so long will disastrous failures of water supply be encountered.

Even the Courts of some of the Western States have so far placed faith in such records as to issue decrees declaring water rights vested in litigants which could call for a water supply of many times the greatest known discharge.

The modern system of water law designates the State Engineer as an expert witness to determine all the features necessary for fixing the extent of the vested water rights and the quantity of unappropriated water which may be available for future enterprises. His findings are conclusive, if not appealed to the Courts, and, when thus

*Supervising Engineer, United States Reclamation Service.

appealed, his expert determination of the essential facts would not be disturbed except on proof of error. Mr. Bien.

This is radically different from the bewildering and contradictory statements by ill-qualified witnesses regarding flow of water, capacity of ditches, areas irrigated, etc., which even now are characteristic of litigation regarding water rights in a number of the Western States.

The system which is now being worked out in Oregon and in some of the other Western States will ultimately provide a record of titles to the use of water as reliable within the necessary limitations as our records of title to land under the most up-to-date systems, substantially equivalent to the Torrens system of land title records. The right to the use of water differs from a fee simple title to land in two essential particulars: first, there is no ownership of the *corpus* of the water as there is of the land, the right in the former case is only a right of use; second, the water of the streams is not fixed, but transitory, and, moreover, the quantity available fluctuates from day to day and year to year. Nevertheless, it is possible to provide for an adjustment of the respective rights to the use of the water, and to make such rights as easily determinable as the ownership of land.

The questions of transfer of the place of use and changes in the method of diversion are of extreme difficulty, and before transfer or changes are permitted without loss of priority careful expert investigation is essential.

In one case a considerable area of land bordering on a small stream with the appurtenant water rights was purchased and the place of use and method of diversion were radically changed. Instead of small ditches diverting the water short distances from the stream and after irrigation allowing return seepage to the stream, the entire quantity of water thus claimed was diverted in an iron pipe and carried to another water-shed. It is claimed by water users below this point of diversion that they have suffered a serious diminution in the quantity of water which had formerly been used on the land above and returned to the stream to become available for their use. They claim that the purchaser of the upper lands could not take a large proportion of the water out of the drainage area without seriously impairing their rights. It will doubtless require a decision of the Courts to settle this question.

The determination of water rights on interstate streams is one which, at an early date, should receive the attention of the Federal and State Governments. The plan suggested by Mr. Lewis is undoubtedly the only logical solution of the problem, and these two Governments must co-operate in working out its details.

The principle that water rights on interstate streams must be adjudicated independently of State lines, while indicated in a general way by the decisions of the United States Supreme Court, is not wholly settled.

Mr. Bien. In the case of Kansas *vs.* Colorado, the Supreme Court took the first step, but without definitely announcing such a principle. In the case of Bean *vs.* Morris (221 U. S., 485), the Supreme Court assumed that the States would recognize prior vested rights in another State affecting a stream common to both States.

The question, however, is not decided definitely by these cases, and it may be that the United States Supreme Court will lay down this rule definitely in the case recently begun in that Court by the State of Wyoming against the State of Colorado which seems to rest almost wholly on this question.

Mr. Sheley. HORACE W. SHELEY, ASSOC. M. AM. SOC. C. E. (by letter).—For the sake of clearness, the writer has divided his discussion of this timely paper into five parts. Although he has made special mention of irrigation rights, he believes, with Mr. Lewis, that the same principles can be applied to the use of water for other purposes.

1.—Measurement of Water.—Before it will be possible to make water rights definite, certain modifications in the units of measurement must be made. Most of the Western States have already abandoned the variable "miner's inch" for the cubic foot of water per second, commonly called the second-foot, but this is a rate of flow and not a quantity; this term conveys no more meaning than the answer "sixty miles an hour" would give to a question about the distance by railroad between two cities. So far as the writer knows, Nevada is the only State which has named a quantity of water, instead of a rate, when fixing water rights. In that State the unit of measure is the acre-foot. Some other States mention the acre-foot in the regulations of their State Engineer's Offices, but do not give it in their statutes.

A further step remains, namely, to fix the maximum rate at which a given quantity of water may be taken; this corresponds to the "peak load" of electrical engineers.

2.—Place of Measurement.—For new irrigation enterprises it is generally better to name some point near the place of use as the point of measurement, in retailing water, because then the wholesaler, or constructor of the irrigation works, cannot be accused of not having properly constructed his reservoirs and canals so as to prevent seepage and waste in transit. If this method had been followed by a certain large company in one of the arid States, it would not now be in legal difficulties over the failure of the floor of a reservoir to hold water, because it could deliver the requisite quantity from another reservoir.

Measurement at the place of use makes it possible for a later comer to improve the ditch of the old appropriator, and take the water formerly wasted in transit for use on his own land. It is an incentive to the older appropriator to make these betterments himself, lest some one else do it and take this water from him.

Mr. Sheley.

3.—Changes in Place or Manner of Use.—Because of his experience, both in Utah, where changes in the place and manner of use are permissible, and in adjoining States, where the water is appurtenant to the land, the writer believes that the Utah policy is the better, leading to higher duties and more economical use of the water.

If a farmer has more water than he needs for a given tract, as a result of an excessive appropriation in the beginning, of a change in crops, of more thorough cultivation, or of a rise in ground-water, he will continue to use all the water if he cannot transfer all or part of it to other land without loss of priority. If the law permits the transfer under proper safeguards to others, it leads to greater duty for the water.

On the other hand, if the water is appurtenant to the land, so that the owner cannot transfer any part of it, it will be necessary for any one desiring to use it to go to the Courts or to a special tribunal, in order to do so, and the difficult burden of proving that the present owner is not applying the water to the best advantage will be on the new comer.

It is sometimes desirable *pro bono publico* to change the manner of use. The laws of Wyoming recognize that some uses are more important than others, and state the preferences, as follows:

"First—Water for drinking purposes for both man and beast. Second—Water for municipal purposes. Third—Water for the use of steam engines and for general railway use. Fourth—Water for culinary, laundry, bathing, refrigerating (including the manufacture of ice), and for steam and hot-water heating plants. The use of water for irrigation shall be superior and preferred to any use where turbines or impulse water-wheels are installed for power purposes."

4.—Adjudication of Water Rights.—In 1908 the writer assisted the Hon. Caleb Tanner, State Engineer of Utah, in the tabulation of the statements of 1 200 or 1 300 claimants of water rights in the Weber River water-shed, and since then he has had small respect for the truthfulness and reliability of the claims of owners of water rights. Most of the claims were exorbitant. Our Courts have not been averse to granting absurd claims, and in one instance a judge decreed more than 14 ft. depth as the necessary quantity for a tract of land, where 3 ft. would have been ample.

The system of adjudication in Utah has failed completely, thus far, through lack of money to complete the adjudications and the inherent defects in the method used there. The surveys for the adjudication of the Weber River system were started in 1903 or 1904, but the matter has not even reached the District Courts.

The writer believes that the system first used in Wyoming and later modified and used in Oregon, is the only one that is practical.

Mr. Sheley.

5.—Interstate Rights.—The position taken by Mr. Morris Bien in the quotation given by Mr. Lewis, to the effect that the States have not now, and never have had, a right to control the waters within their boundaries, seems to be extraordinary, in view of the fact that the United States Government permitted the Territorial Legislatures to make water laws, and it has applied to the States for water rights, as if it were a private corporation, when undertaking irrigation enterprises under the Reclamation Act. Possibly the context of Mr. Bien's statements would explain the paragraph quoted.

All who have had any experience with the red tape and delays at Washington will hesitate about surrendering any State rights to it, unless absolutely necessary.

In conclusion, the writer agrees with others who are studying water laws and the use of water, believing that the principles of preferential use, beneficial use, and priority can and will ultimately be adopted in the determination of rights both in one State and between States.

Mr. Knowles.

MORRIS KNOWLES, M. AM. SOC. C. E.—The speaker is particularly grateful to the author for his clear exposition of the doctrine of appropriation as practiced in Oregon; and is personally interested in the discussion of this important question, as he has the honor of being President of an Association, one important object of which is the improvement and rationalization of the water laws of Pennsylvania. The paramount importance, at this time, of flood prevention and protection, power development, water supply, improvement of navigable rivers, and the whole broad subject of water conservation in every part of the Union, points to the necessity of adopting in every State a well-considered, comprehensive plan, based on adequate State and National legislation.

The speaker agrees most heartily with the suggestion that the Engineering Profession generally, and engineering societies particularly, not only can, but ought to lead in the discussion of every phase of the subject, and lend their aid to the framing of legislation on such a matter, for the consideration of which their members are peculiarly fitted, in many respects better than any other class of citizens. It is time we were putting into action in this field the policy urged by President Ockerson at the Seattle Convention.

Prior Appropriation vs. Riparian Law.—On one point, however, the speaker holds an opposite opinion from the author, which illustrates the peculiar situations that may arise when engineers undertake the discussion of the intricacies of the law.

The case of Kansas *vs.* Colorado did not, in the speaker's opinion, declare that "the doctrine of riparian rights, * * * is not the law, and therefore never has been the law," even of interstate waters. On the contrary, Kansas *vs.* Colorado definitely followed the principles of

riparian rights, as between Kansas and Colorado. The fact that the Colorado use in question was on non-riparian lands did not affect the issue. The Court considered the decision from the point of view of the rights of Kansas as a State against those of Colorado as a State, and not of the rights of individual riparian proprietors in Colorado. These individual rights come under the rule previously enunciated in Anderson *vs.* Bassman (140 Fed., 22) and later affirmed by the Supreme Court in Rickey, etc., Co. *vs.* Miller (218 U. S., 258) that the riparian owner deduces his rights from the law of his own State and that the private right is "not in his own right, but by reason of and subordinate to the rights of his State" (Turley *vs.* Farman, 114 Pac., 278). In the case of Rickey, etc., Co. *vs.* Miller, which involved the rights of riparian owners in California and appropriators in Nevada, the rule followed was that Mr. Knowles.

"the enforcement of either right beyond the boundary of its State must depend upon the concurrence of the other State. Unless the upper State (California) will voluntarily impose conditions upon its citizens in favor of users in the lower State (Nevada) the latter have no right in the matter other than to complain that the lower State as such (and not merely the plaintiff) is not receiving an equitable share of the benefit of the stream."*

The language of the Court in Kansas *vs.* Colorado makes plain that the principle of equal rights, which is the basis of riparian rights, was followed. For example, referring to the law in Kansas, which is the law of riparian rights, Justice Brewer said:

"As Kansas thus recognizes the right of appropriating the water of a stream for the purpose of irrigation, subject to the condition of an equitable division between the riparian proprietors, she can not complain if the same rule is administered as between herself and a sister State."

(The use of the word "appropriating" here appears to the speaker to be somewhat unfortunate, but need cause no confusion, for it bears no connection whatever with the doctrine of "appropriation" as practiced in other Western States. Apparently, the word "diverting" would have expressed the idea of the learned judge without danger of confusion.) And again, referring to the statement quoted by the author, from the conclusion of the Court, in the Kansas *vs.* Colorado case,

"* * * it is obvious that if the depletion of the waters of the rivers by Colorado continues to increase, there will come a time when Kansas may justly say that there is no longer an equitable division of benefits, and may rightfully call for relief against the action of Colorado."

No support is given by this language to the theory that there may exist here any exclusive right by priority. This is the language of the riparian rights doctrine.

* Wiel, "Water Rights in the Western States," 3d ed., p. 364.

Mr. Knowles.

Then, since the premise is in error, the conclusions that "riparian rights are not considered as vested rights by the Supreme Court," and that "if Congress should decide that the enforcement of the doctrine of priority of appropriation and beneficial use, * * * should constitute an equitable apportionment of benefits, it is conceivable that the Supreme Court would uphold such act," must fall. In the speaker's opinion, such an act, in the light of the present generally accepted views of the powers of Congress, would be unconstitutional, both as outside the enumerated powers of the Federal Government, and as an invasion of the right of private property. In fact, the Kansas *vs.* Colorado decision says:

"It [each State] may determine for itself whether the common law rule in respect to riparian rights, or that doctrine which obtains in the arid regions of the West of the appropriation of water for the purposes of irrigation shall control. Congress cannot enforce either rule upon any State."

We of the East and the country at large must look to other measures than the adoption of the law of appropriation in its entirety for the development and conservation of our water resources.

Executive Board vs. Court Administration.—On the other hand, the speaker agrees with the author in believing that water laws may be better administered by executive boards than by the Courts and by injunction; and he believes that it might be not only lawful, but very serviceable, for Congress to provide the machinery for administering the law with respect to interstate waters, provided the law can be said to be already determined by Court decision. This, however, does not give ground for the broad assertion that "Congress must have power to prescribe by law what shall constitute an equitable division of benefits as to interstate waters." In fact, as already stated, it would seem plain from Kansas *vs.* Colorado that Congress does not have that power—a very different one from the power to provide the machinery for administering the law after the decisions of the Supreme Court have prescribed what shall constitute an equitable division of benefits.

This does not in any sense mean that the speaker does not believe that the Federal Government, under the Constitution, can co-operate with the States in exercising its control over the navigability of streams, and their tributaries also, in such a way as to secure great collateral benefits. On the contrary, he holds that opinion most strongly, and believes in the propriety of the adoption by Congress of the Newlands River Regulation Bill and similar measures.

There may be a question, also, as to whether the law has become sufficiently determined to justify the creation of an administrative commission. The doctrine in Kansas *vs.* Colorado was clearly stated; but whether this would apply under all conditions is rendered some-

what doubtful by the following from the decision in Rickey, etc., Co. *v.* Miller (218 U. S., 258, 261). Mr. Knowles.

"It is conceivable, to be sure, that the decisions of this Court may determine that the States have rights as against each other *in invitum* in streams that flow through the land of both. (Kansas *v.* Colorado, 206 U. S., 46, 84; Mo. *v.* Ill., 200 U. S., 496, 519, 520.) The rights may vary according to the system of law required by natural conditions. They may be more or less analogous to common law rights between upper and lower proprietors, where irrigation is not necessary, as in most of the older States. (See N. Y. *v.* Pine, 185 U. S., 93, 96.) There may be some, perhaps limited, right of appropriation in the upper State, at least in the water-shed of the stream, where irrigation is the condition of using the land. (See Kas. *v.* Col., 206 U. S., 46, 100-104, 117.) But whatever this Court may decide, if a private owner should derive advantage from such a decision, it would not be in his own right, but by reason of and subordinate to the rights of his State. * * *"

If it be true that the law for all cases has not been determined, it would appear almost certain that any important contest between States, before an administrative board, would be appealed to the Supreme Court, until the universal law had become established, and a Commission might therefore be of no value at present. In addition, it is debatable whether enough important contests between States will arise to require the continuous service of a Commission.

State Commission Administration.—None of these objections applies, however, to administration of intra-state water laws, on a basis of equitable apportionment, by State Commissions. States undoubtedly have power to determine by law what shall constitute an equitable apportionment of the use of water within their borders; and the delegation of this power to a commission cannot be opposed on the ground that it must be exercised only by direct action of the Legislature, any more than the regulation of public utilities by Commission, now so firmly established, can be so attacked. The words of Justice Timilin, in Minneapolis, etc., Railway Co. *vs.* Wisconsin Railroad Commission, are applicable:

"It is argued that the power to fix rates is a legislative one and can never be anything else; * * * that the legislative power is by the Constitution vested in the Senate and Assembly, and cannot be set apart except as expressly provided for in the Constitution; but when we add to this that, because of the multitude of detail, the intricacy of the subject, the expert knowledge required, the numerous separate investigations of inter-related questions of fact which are necessary * * * a legislative body * * * would find it an actual rather than a legal impossibility to fix just and reasonable rates, it becomes apparent that this position tends to the conclusion that the State * * * was shorn of some of its usual and necessary power of sovereignty and became impotent to exercise the power of regula-

Mr. Knowles.

tion. Regulation by direct action of the legislature has been tried and found impracticable and its attempt generally abandoned."

The speaker has not yet attempted to work out the details of such an administrative riparian system, but believes that it may be possible, by making simple and rapid the determination of riparian rights and of the terms of an equitable division by a suitably constituted commission, and by making proper provision for the condemnation of such rights for public uses under the supervision of such a board, to develop a system which will lead to a full utilization of the waters of a State, with ample protection both to the public and the investor, and with a possibility of obtaining in some instances great collateral public benefits in the way of flood protection, development of water power, improvement of navigation, improvement of quality of water, etc.

The feasibility of such a scheme appealed to Wiel, who says:*

"This system of law would seem to offer a field for administrative legislation; in fact, a readier field than the law of prior appropriation. Where the test is what is reasonable in each case, discretion must necessarily come into play, whereas where parties have exclusive rights measured by priority there is * * * little room for the exercise of discretion by administrative officers * * *. Where the common law applies the test of reasonableness, legislation is apt and readily applied; as, for example, in dealing with public service companies. The common law says their rates and regulations must be 'reasonable,' and accordingly public service commissions and similar bodies are created. Likewise under the new law of percolating water 'reasonable use' has become the test, and statutory regulation based thereon is being adopted. As yet, however, there has been no attempt to provide a statutory system governing the reasonable use of water by riparian proprietors among themselves, in jurisdictions applying that system, though there would seem a clear field for such legislation if desired."

Limit of Appropriation by Reasonable Use.—The speaker would like to call attention also to the unmistakable tendency (illustrated by the "Pro-rating" statute of Washington, the constitutional limitation of the right to appropriate in Idaho, and such decisions as Basey *vs.* Gallagher, 87 U. S., 670; Union Mining Co. *vs.* Dangberg, 81 Fed., 73; Anderson *vs.* Bassman, 140 Fed., 14; and Schodde *vs.* Twin Falls L. & W. Co., 161 Fed., 43) to depart from the strict law of prior appropriation, and to limit appropriation by a requirement of reasonableness, which is doing much to narrow the gulf between the doctrines of appropriation and riparian rights. It appears to him that, as density of population increases in the Far West, this tendency will increase; and that uniformity in the administration of State laws will be approached, in spite of differences in form, by the application of the "rule of reason" to both systems of law, rather than by the abandonment of either one in favor of the other.

* "Water Rights in the Western States," 3d ed., p. 880.

Mr. Knowles.

On this phase of the subject, Mr. Morris Bien, Supervising Engineer of the U. S. Reclamation Service, speaking before the National Irrigation Congress at Spokane, in 1909, said:

"The doctrine of rights by prior appropriation has been adopted in nearly all the States where irrigation is required; but this doctrine as now generally understood will necessarily require modification. * * *

"In the Yale Law Journal for January, 1909, is a discussion of the idea of reasonable use, whether under the doctrine of riparian rights or the doctrine of appropriation. It shows that the courts have frequently called attention to the fact that the doctrine of appropriation must be modified by the idea of reasonable use which is also a fundamental limitation of the riparian doctrine. This idea of reasonable use will undoubtedly become an important factor in future years when valuable interests depending upon the entire water supply have grown up within many of the irrigation districts, and it becomes necessary to protect these interests in cases of temporary deficiencies which sometimes continue for a number of years in succession. * * * The qualification of the doctrine of prior appropriation by the idea of reasonable use, and the application of the same idea to the riparian doctrine will undoubtedly bring these opposing doctrines much closer together in actual practice, and is likely in the end to cause a practical uniformity in the governing principles of all the irrigation States."

Best Development of Water Resources.—In conclusion, the speaker wishes to raise the question whether the "Water Power Policy" advocated by the author is necessary to attain the desired ends. If so, the speaker would agree that "the States, in co-operation with the United States," should "develop this power and supply at cost plus interest." But, if it is possible to attain the same ends in other ways and without the tedious delays that must precede such a consummation, the speaker does not see the necessity of adding further commercial enterprises to the burdens of our State Governments. In the belief that, under a rational, well-defined system of water laws, and with wise State regulation in the interest of the people, private capital would construct the works necessary to the conservation of water, the Pennsylvania Water Conservation Association has been formed. This Association, including in its membership capitalists, publicists, civic bodies, power companies, and water companies, has for its object the formulation of a plan for the development and utilization of the water resources of the State, by means of private capital, under improved laws and State supervision, in such a way as to offer a safe, attractive field for investment; to insure reasonableness of rates and safety of construction; to secure, wherever possible, by supervision of designs and operation, prevention of floods and improvement of rivers; and to serve by a broad, far-sighted policy of conservation the public interests of this and of future generations.

Mr. Grant.

KENNETH C. GRANT, ASSOC. M. AM. SOC. C. E.*—The speaker is particularly interested in this valuable paper because of the direct applicability of the fundamental principles therein stated to the broad policy of water conservation which is now being advocated so strongly in Pennsylvania by the Flood Commission of Pittsburgh and the recently organized Water Utilization Association of Pennsylvania.

The Flood Commission was organized by the Chamber of Commerce of Pittsburgh, in 1908, to investigate the causes of, and damage by, the frequent disastrous floods at Pittsburgh, and to study and decide on methods of relief. After four years of exhaustive investigation, for which about $125 000 (obtained from county and city appropriations and by private subscriptions) was expended, the report of the Commission, published in April, 1912, recommended the construction of storage reservoirs on certain tributaries of the Allegheny and Monongahela Rivers. The flood relief which would be obtained by these reservoirs, naturally, would not be confined to Pittsburgh, but would extend to many other communities on the rivers above and below that city. Moreover, the proposed reservoirs would not only provide this flood relief, but would cause an increase in low-water flow which would add greatly to the usefulness of the streams for navigation, water supply, and power purposes.

The Commission pointed out, therefore, that the solution of the problem was so broad in its scope, and so far-reaching in its benefits, that it did not concern the City of Pittsburgh alone, but demanded State and National consideration and co-operation. The decisions to which these investigations have led have been aptly stated by the author when he says:

"Some interstate legislation is absolutely essential if the highest development of our streams is to be accomplished. Each river, from its head-waters to its mouth, should be treated as a unit, regardless of State lines."

The Water Utilization Association of Pennsylvania was formed for the purpose of framing and obtaining legislation which should bring about the fullest development of the water resources of the State, and at the same time preserve and dedicate the benefits of such development to all the citizens of the Commonwealth.

This Association and the Flood Commission have given careful consideration to the same thought as that embodied in the author's statement:

"Soon the State and Nation must join in the storage of water for the control of floods and to aid navigation. This water, in passing down the stream, will benefit many private power projects, and these should be compelled to contribute to the cost in proportion to the benefits received."

* Now M. Am. Soc. C. E.

Mr. Grant.

These bodies, in their work, have also in mind the natural converse of this statement, that private water-power companies, proposing to construct large storage works which will assist in providing flood relief and will improve the rivers for navigation, water supply, and water-power purposes, should receive corresponding co-operation and assistance from the State and National Governments. There are instances in Europe where private water-power companies have been assisted in the construction of their storage reservoirs by the Government in return for a certain amount of additional storage capacity to be constructed and kept empty for flood control. Private users of water for domestic or industrial supply, or for power, located below such large storage works, should also contribute to the cost of their construction in proportion to the benefits received. If effective legislation providing for such co-operation can be framed and enacted, it will ensure the fullest development of the water resources of the State.

Legislation tending toward this end has in fact already been passed in Pennsylvania. At the last session of the Legislature, a bill, drafted by the Flood Commission, was introduced and passed, enabling counties to borrow and expend moneys for the construction of works for flood relief, and also to enter into contracts with each other, or with the State, with other States, or with the United States, for the purpose of carrying out the necessary works.

It is hoped that legislation broadening the powers of the Water Supply Commission of Pennsylvania may be obtained at the coming session of the Legislature. This Commission, in operation since 1905, is charged with obtaining such complete knowledge of the water resources of the State as shall enable it to provide for their most equitable distribution. It has power over the granting of charters for water-supply and water-power companies, but has no authority where the water is taken by corporations for their own use, by private individuals, or by municipalities. Its effectiveness, in carrying out the purpose named in the act creating it, therefore, is considerably restricted. Its jurisdiction should be widened to cover all users of water.

Within the limits of its powers, the Water Supply Commission of Pennsylvania has done most admirable work, some of it along lines similar to that of the Board of Control described by the author; for example, the work of the Oregon Board for the protection of the public interest, of which the author says: "Public interest demands that water be put to the highest use. * * * an application for either irrigation or power can be denied if it is in conflict with the higher use for domestic supplies," is identical in principle with the attitude of the Pennsylvania Commission in considering applications for charters. There are instances in Pennsylvania where prior applications for charters for water-power companies have been refused on

Mr. Grant.

the ground that the stream involved was needed for domestic supply. There are also cases where applications for charters for water companies for domestic supply have been refused, because they interfered, perhaps purposely, and certainly needlessly, with proposed water-power projects.

Charters for water-power companies have also been approved, with certain conditions. For instance, the charters for a large water-power project in Western Pennsylvania were approved recently, on certain conditions, notable among which were the protection of the interests of navigation and of riparian owners below the dam by the maintenance of a suitable minimum stream flow, the presentation, within 12 months, of data showing the extent to which the proposed reservoirs can be used to ameliorate floods, and the placing of the operation of the reservoirs, in so far as the control of floods and the maintenance of low-water flow is concerned, under the direction and jurisdiction of the Water Supply Commission. Had a similar commission been in existence in West Virginia, the plans of a large water-power project, recently chartered and about to begin actual construction, might readily have been enlarged and modified, to the great advantage of both the water-power company and the general public.

A thorough knowledge of stream flow throughout the State is also being acquired by the Water Supply Commission, through the operation of a large number of gauging stations. A complete collection of all existing stream-flow data, some of the records extending back for many years, is now being compiled, and will shortly be published. The Commission has also collected and filed complete statistics of all water and water-power companies in the State, including municipal water supplies. These data are also briefly shown on large-scale county maps of the State, which are convenient for reference in studying the relation of proposed to existing uses of water in a given region. It is evident, therefore, that in Pennsylvania, there is already in existence a body which, if given larger powers, can effectively protect the public interest and assure the most equitable distribution of the waters of the State.

Referring again to the treatment of a stream as a unit from its source to its mouth, there are several interesting and instructive examples of this broad policy in Europe, which the speaker has had the opportunity to examine on two occasions during the last few years.

The largest stream thus treated is the Ruhr River, which empties into the Rhine on the right bank at Ruhrort, in Western Germany. This stream has a length of 143 miles from source to mouth, and drains an area of 2 041 sq. miles. It flows through the great industrial region of Germany, around Essen and Mülheim, and is extensively used as a source of domestic and industrial supply and for power. The demands on the stream became so great that during low water

the supply threatened to be inadequate. In 1897, after long deliberation and much difficulty, a voluntary association was formed by the users of the Ruhr water for the purpose of improving the flow of the river. The membership of this association includes cities, factories, water-power companies, etc. There are eleven dams on the tributaries of the Ruhr, ten of which were built by smaller associations of the water users on the respective tributaries, and one, now nearing completion, by the Ruhr association. These smaller associations were formed under a Prussian law. After two-thirds of the water users below the proposed dam have agreed to form such an association, the other third is obliged to join with them. The main association of the Ruhr, called the *Ruhrtalsperrenverein*, was formed voluntarily, without such a law; but it can compel users of water from the Ruhr to pay into the association, in the case of water-power plants, according to the head and the quantity of water used, and, where water is taken for domestic or industrial supply, according to the quantity used. The assessments on the members of the smaller associations on the tributaries are made in a similar manner. The main association of the Ruhr pays about $70 per annum per 1 000 000 cu. ft. of storage capacity of the reservoirs to each of the ten associations on the tributaries. Mr. Grant.

Another example of similar co-operation in river regulation is to be found on the Wupper River, the next tributary of any size emptying into the Rhine on the right bank above the Ruhr. It has a drainage area of about 240 sq. miles, and flows through the thickly populated manufacturing region around Barmen and Elberfeld. Before the construction of reservoirs on its tributaries, the stream had a very irregular discharge, varying between 0.05 and 90 sec-ft. per sq. mile of drainage area. Flood damage was frequent and considerable, and the numerous water-power plants suffered greatly from low water.

After long deliberation, an association for the construction of reservoirs in the drainage area of the Wupper was formed under a special Prussian act. This association has built three reservoirs on tributaries of the Wupper, for the control of floods and the increase of low-water flow. All water users below these dams must pay an annual assessment to the association.

A third association, of similar character, has constructed six reservoirs in the Görlitzer Neisse, near Reichenberg, in Bohemia. This stream rises in Northern Bohemia and flows northward for 124 miles, emptying into the Oder River about 15 miles below Crossen, in Prussia. Its valley receives a heavy precipitation in its upper portion (13.5 in. in 24 hours having been recorded at some points) and has been repeatedly devastated by floods; therefore, after the great flood of 1888, an association was formed to plan and carry out the con-

Mr. Grant.

struction of protection and regulation works, consisting of widening and straightening the channel and raising and protecting the banks. The estimated cost of these improvements was so heavy, and their probable effectiveness in a great flood so doubtful, however, that practically nothing was done by the association, the actual work confining itself to repairing damages and building the bank protections most urgently needed by the individual property owners.

In July, 1897, this part of Europe was visited again by devastating floods, which revived public interest in flood relief to such an extent that a convention, in which all the neighboring cities and towns were represented, was held in Reichenberg in the fall of that year. At this meeting it was decided to investigate the feasibility of constructing reservoirs for flood control. In January, 1901, the preliminary studies were sufficiently complete to establish the general plans, which contemplated the construction of six reservoirs in the neighborhood of Reichenberg, controlling the run-off from about 29 sq. miles, and in critical flood time holding back about 3 530 sec-ft. of damaging flood discharge.

The result of the investigations gained the association many new supporters, and assured the sympathy of the population of the entire valley of the Neisse with the project. In fact, one of the most noteworthy features of this undertaking is the widespread interest it aroused in the surrounding country and the universal financial support it received. Although all the reservoirs are located in Bohemia, the benefits, both in flood control and increase of low-water flow, are felt by the Saxon and Prussian interests along its lower course, and these two countries, together with various cities, communities, and private interests, co-operated with Bohemia in their construction. The total cost of the work was $1 320 000, and the following contributions show the extent of the co-operation:

Bohemian Government	$660 000
Prussian Government	38 400
Prussian Province of Silesia	9 600
Prussian County of Ober-Lausitz	14 400
City of Görlitz (Prussia)	14 400
Saxon Government	24 000
Combination of Saxon and Prussian water interests	72 000

It is also of special interest that the users of water for power development from three of the reservoirs pay $12 per h.p., and from the other three reservoirs, $28 per h.p. per year. Three of the dams for these German reservoirs are shown by Figs. 3, 4, and 5.

As an instance of what such co-operation might accomplish in the United States, the conditions in the Beaver Valley in Western

FIG. 3.—DAM BUILT BY ASSOCIATION FOR IMPROVING LOW-WATER FLOW OF RUHR RIVER, GERMANY.

FIG. 4.—DAM BUILT BY ASSOCIATION FOR CONTROLLING FLOODS AND INCREASING LOW-WATER FLOW OF WUPPER RIVER, GERMANY.

FIG. 5.—DAM BUILT BY ASSOCIATION FOR CONTROLLING FLOODS AND INCREASING LOW-WATER FLOW AT REICHENBERG, BOHEMIA.

Pennsylvania may be mentioned. This stream drains about 3 040 sq. miles, and empties into the Ohio from the north about 25 miles below Pittsburgh. It is extensively used as a source of domestic and industrial supply, as it flows through a thickly-populated manufacturing district. It is also used considerably for power. On its upper waters there is an ideal reservoir site where a low earthen dam would create a reservoir of large capacity, overflowing a large tract of useless swamp land. This site has already been studied as the source of feed-water for the proposed Lake Erie and Ohio River Canal. It has also just been carefully surveyed and mapped by the State Water Supply Commission, under a special appropriation by the Legislature, for the purpose of determining the possibilities and best use of the site. Here is an ideal condition for a *Beavertalsperrenverein*, which could be made up of the water users in the Beaver Valley and the Canal Company, with the possible addition of the communities along French Creek, a large northern tributary of the Allegheny, because of the flood control that would be afforded by a second reservoir proposed by the Canal Company on the north branch of this creek, which would impound the flood-waters of that stream and deliver them through a canal into the reservoir on the Beaver River head-waters. Mr. Grant.

Another example of what might be done by such co-ordination of interests is afforded by the Youghiogheny River, a stream rising in Northern West Virginia, and entering the Monongahela 15 miles above Pittsburgh. This stream is used extensively as a source of industrial and domestic supply, and has several favorable sites for water-power development. The Flood Commission of Pittsburgh proposes to store part of its flood run-off for the control of floods and for the improvement of the low-water flow, this stream being one of the chief offenders in Pittsburgh floods. The United States Government proposes to slack-water the lower 19 miles, to provide navigation up to West Newton, although a study of the low-water flow indicates that a pool-full stage could not be maintained without the assistance of additional water from storage reservoirs during dry weather. The co-operation of all these interests in the construction of storage reservoirs for the regulation of the flow of this river would unquestionably be of great benefit to all concerned. It would make feasible the development of a large quantity of water power which cannot be developed economically if the entire cost of the storage works must be borne by the water-power interests.

A third example may be found in Eastern Pennsylvania, where a large water-power project in operation on the lower Susquehanna River could greatly increase its capacity if the low-water flow were increased by storage reservoirs on the upper waters. The value of such increased flow to this one power plant would not pay for the cost of constructing such reservoirs; but if other plants, made feasible

Mr. Grant. by the increased low-water flow, were constructed, and contributed to the cost of the storage works, and if co-operation were also obtained from the communities, counties, railroads, and other interests damaged by floods, such a broad treatment of the river would undoubtedly become feasible.

Mr. Hopson. E. G. HOPSON, M. AM. SOC. C. E. (by letter).—This paper deals with more advanced topics, in connection with the control of National and State waters, than the average man is qualified to follow closely or to endorse in their entirety. Mr. Lewis does not write on these matters as a novice or a mere theorist, but as a responsible State official who has administered successfully the regulation of State waters for many years.

It is generally admitted, by those qualified to judge, that the water laws of Oregon are among the most carefully devised and effective of any in force in the United States. They contain certain admitted defects, more particularly in connection with the control of water-power, which may be expected to be eliminated during the next few years, as experience ripens; but the general provisions governing diversions, application to beneficial use, and appurtenancy to lands, are generally beyond serious criticism, except in details.

It is premature, of course, to claim too much for the Oregon system of water titles and control, their application being as yet quite young. Their ultimate value and success depend almost wholly on the capacity and integrity of the officials whom the State may appoint. Very few officials have had better experience than Mr. Lewis in water-right matters, or have devoted more energy and care to the numerous complex problems that are continually arising therefrom. He has been both an appointed and popularly elected State officer, having especial jurisdiction over the interests and prerogatives of the State in its control of State waters. All his official associations and connections necessarily have tended to emphasize in his mind the doctrine of State control of water. Therefore it is especially significant when a man of this type comes forward to affirm the importance and necessity of radical augmentation of Federal power in the control of public waters.

The Oregon Water Laws, like similar laws in other States, affirm the ownership by the State of all streams within the State, and establish rules governing their use; but an administrative State officer in charge of the practical application of these rules finds himself faced with apparently insoluble inconsistencies. Taking the State of Oregon as typical, there are the following complications: First, the National forest reservations, mainly occupying the great mountain ranges, in which most of the sources of the rivers lie, are under the exclusive and permanent administration and ownership of the United States. The appropriations and uses of water in these reserves, from every practical

standpoint, rest wholly with the United States, and not with the State, notwithstanding the doctrine of State control of all waters within the State. It will be readily understood by engineers that the Federal control of storage and diversions within these reservations necessarily conflicts with and renders partly non-effective any system of State control lower on the streams. Mr. Hopson.

Then again, there are the various reservations of reservoir sites and power sites under the Reclamation Act and for the conservation of water-power. These continually run counter to the obvious intent of the administration of the State laws controlling water use, because a State permit to use water for irrigation or power is useless in a large proportion of cases without the utilization of the sites embraced in the reservations.

Then, again, there are the indefinite rights of the Indian reservations, which in many cases are claimed to be superior to rights granted under the State laws to white settlers. These offer a complication not so serious as some, but certainly embarrassing.

Next there are interstate streams, which meander to and fro across the borders of the State, and on which adverse appropriations are made, first in one State and then in another, both being under absolutely independent State jurisdictions.

Then there are the navigable waters, under an indefinite control by the National Government. It is evident to any thinking person that control of the navigability of a stream necessarily implies some measure of control of the feeders of that stream. If the Government is to spend millions to deepen channels, build locks, dams, and other improvements, and be responsible for the maintenance of deep water for navigation, it is evident that it cannot permit private parties at their pleasure, even under State permits, to make diversions adverse to navigation interests. Hitherto, this question has not assumed the pressing importance that it will in years to come, because the population of the Western States and its utilization of water are still comparatively small; already, however, at certain points, there are unmistakable indications of a clash between the opposing interests of navigation and State-regulated appropriations. On one important California river, navigation is being seriously threatened by such diversions, and there is no body, either Federal or State, which has power to make an expert decision on the merits of the case in the public interest. In the meantime, important private interests are being permitted to grow up, with the sanction of the State and under the eyes of the Federal officials having charge of navigation, which inevitably must result in serious complications and losses in the future, but which both State and Federal officials are powerless to prevent.

The greater part of Oregon is within the water-shed of two great navigable rivers, the Columbia and the Willamette. On both these

Mr. Hopson. streams the Government is expending large sums of money in navigation improvements. The Willamette is an intra-state river; the Columbia carries drainage from all the Northwestern States, as well as from Canada. The summer navigation of both may be impaired to a marked degree when the various diversions believed to be feasible and desirable have been completed.

Serious differences of opinion are also arising from time to time over the uses to which inland interstate navigable bodies of water should be put, whether to be used for reservoirs, drained and reclaimed, or continued as mere navigable lakes. At present special Congressional action is necessary in each case, and is an uncertain and unsatisfactory recourse.

It is probable that in the majority of cases public interests will be best served by giving preference to diversions for beneficial use over use for navigation. The point of interest is that each case be considered on its merits at the proper time, and a definite policy be laid down by some competent authority, which obviously cannot be a creation of the State.

Mr. Cory. H. T. Cory, M. Am. Soc. C. E. (by letter).—This paper is much more than timely, and is exceedingly interesting, because, in the Western States particularly, the water laws are of vital importance, not only to very many engineers and individual owners, but to the general public. That there could prevail, in the United States, at the present time, such absurd conditions as exist in California and other Western States, is impossible to grasp fully until one comes into direct contact therewith. The notable exceptions are Wyoming and Oregon; and it seems probable that within a very few years most of the really Western States, if not all, will have improved matters greatly. Two years ago the California Legislature created a State Board of Water Control and a State Conservation Commission, and one year later changed the former to the State Water Commission. At the same time, and after the passage of an amendment to the State Constitution, it made a Public Utility Commission of the State Railroad Commission. As one result of the work and experiences of these various commissions, California will doubtless fall in line, within the next three months, with what is hoped will be the latest word in water-right legislation.

The final draft of the bill which will thus be presented to the Legislature by the administration in January, 1913, has not been made public. It is certain, however, that it will follow closely the Wyoming and Oregon precedents in general, that is, declare all water within the State to be the property of the public; distinguish clearly between the right to water and the right to use water; make beneficial use the basic principle—priority, purpose, period, place, and quantity; provide for determination and certification of existing vested interests,

and sane supervision, control, and certification of appropriations in the future. Due to the experience of the Railroad Commission, the provisions for reviewing the acts of that body, as well as numerous other features of the Public Utilities Bill, will no doubt be adopted almost *verbatim* for governing the work of the Water Commission. Mr. Cory.

The more important of these are as follows: A commission of five appointed by the Governor, and not elected or constituted *ex-officio;* five-year appointments, with provision for recall by two-thirds vote of the members of each branch of the Legislature; provision for investigation or hearing by any one commissioner and making every finding or decision of such single commissioner, when approved by the Commission, binding; power to determine existing rights and limit them to reasonable needs; power to order improvements for preventing water waste; power to subpœna and compel attendance of witnesses and take depositions; provision that all official documents and orders filed, when certified by a commissioner or the secretary under seal, shall be evidence in like manner as originals, and may be recorded; provision that no cause of action shall accrue in any Court unless application shall have been made to the Commission for a re-hearing, prior to the effective date of orders or decision; orders of Commission must be obeyed pending re-hearing, except as Commission may direct by order; power to modify orders after re-hearing; and, finally, that only the State Supreme Court may review any finding, time of appeal limited to thirty days after rendering of decision on re-hearing, but no new or additional evidence may be introduced in the Supreme Court, and the cause must be heard on the record of the Commission as certified by it. The review is limited to determination of whether the Commission has regularly pursued its authority, including a determination of whether the order or decision under review violates any constitutional right of the appellant—in other words, the findings and conclusions of the Commission on questions of fact are final and not subject to review, such questions of fact including ultimate facts.

Further, in the Railroad Commission Act, in the absence of a definite order by the Supreme Court, the Commission's order or decision is operative, pending final decision; and, if the Court stays or suspends the operation of all or any part of the Commission's order, such stay or suspension must contain a specific finding, based on evidence submitted to the Court and identified by reference thereto, that great or irreparable damage would otherwise result to the petitioner, and specify the nature of such damage, and require filing of a suspending bond before the Court's order becomes effective.

Lastly, it is provided that all actions and proceedings under that act shall be heard and determined in preference to all civil business, except election causes, irrespective of position on the calendar.

The Railroad Commission has, and the Water Commission doubt-

Mr. Cory.

less will have, the right and the duty to intervene in any civil action wherein the interests of the Commonwealth may, in its opinion, be concerned, and also initiate proceedings without being petitioned so to do.

It is provided that if any portion of the act be held to be unconstitutional for any reason, the validity of the remaining portions shall not be affected; and it is stated that:

"The Legislature hereby declares that it would have passed this act, and each section, subsection, sentence, clause, and phrase thereof, irrespective of the fact that any one or more sections, subsections, sentences, clauses, or phrases be declared unconstitutional."

The provision for making the Water Commission's decisions or orders binding, with appeal permitted only to the Supreme Court on exclusively legal features, is, in the writer's opinion, a very fundamental and far-reaching improvement over the procedure in Oregon or Wyoming. Several of the other features mentioned are distinct improvements, which though relatively minor, are nevertheless important.

The author's suggestion of equally stringent and positive National water laws and control, rather naturally, though quite unnecessarily, leads him to take up and discuss the water-power policy of the United States, which is practically synonymous with conservation, as politically understood. It seems to the writer that a National Water Commission, related to State Water Commissions in almost identically the same way as the Interstate Commerce Commission (in transportation matters) is related to the State Railroad Commissions, could be arranged, and fill the need exactly. General objections to "Bureaus in Washington" certainly do not apply to the Interstate Commerce Commission, and would have no weight with any other National commission clothed with powers like the California or Oregon Water Commissions or many, and especially the California, Public Utility Commissions. On the other hand, public sentiment, very effective control and regulation of public utilities, and conservation of the natural resources for the public by State authorities—especially in the "Progressive West"—have developed to such a point that it is beginning to be safe for the National authorities to begin to release their powers gradually to those of the individual States.

The essential thing is "Conservation", and whenever it can certainly be obtained by State authorities—and not an instant before—the National Government should relieve itself of the responsibility, because more flexibility and better adaptation of control to local conditions must result. The time is not yet ripe, and never may be, with water-power and forests, for example, but it is with some other things; and the civic awakening of the American public in very recent years is one of the most striking and significant phenomena of the present time.

Mr. Cory.

The author's suggestion as to the National Government developing power and supplying it at cost is exceedingly interesting, particularly because it was made at all. By virtue of their relationships, the members of this Society are probably—next to bankers and a few other types—the most politically conservative people in the Commonwealth. That a member should, in a paper before this Society, frankly and nonchalantly advocate, not only public but National ownership and operation of such a public utility as electric power, seems to the writer most significant of the rapid changes in progress throughout American society.

The writer feels strongly that such a thing would be unwise, and believes, with Mr. Dillman, that effective regulation, with a reasonable premium on able management, is preferable to public ownership, and would result in lower cost to the consumer; but, while that may be true in general, it is not always the case, and irrigation and the Reclamation Service is at least one notable exception. In opposing an idea nothing is truly gained by refusing to acknowledge antagonistic facts and arguments—usually, the effect is exactly the opposite.

The writer believes the conditions affecting the wisdom of Governmental construction and operation of power and irrigation projects in the West are fundamentally different. Power installations are almost invariably put in by well-managed corporations, and the markets are in large part now supplied by private aggregations of capital, and the effect on these by the Government supplying additional energy at cost, would be serious and really unjust. The U. S. Reclamation Service, on the other hand, always deals with projects which are entirely self-contained, and so do not affect the value of other privately or mutually controlled works, even if in the immediate vicinity. Furthermore, due to chaotic and most unwise laws, no well-managed private capital would deal with the irrigation situations comprehensively or wisely. Private irrigation projects have with very rare exceptions fared so disastrously throughout almost the entire West that it is almost impossible to secure capital for such work. Indeed, that is one of the chief reasons for improved State and National water-right laws discussed in this paper.

The Reclamation Service has since its beginning expended about $75 000 000 in irrigation construction, and is now working at the rate of about $1 000 000 monthly. During the past season (1912) it was ready to supply water for about 1 200 000 acres out of 3 000 000 acres for which the works are being constructed. The cost per acre ranges from $22 to, in one instance, $95, with an average of between $50 and $60. In few, if any, instances has any portion of such cost been paid as yet by the land owners, yet the selling price of land under the various projects—with the Government charges yet to be paid—has invariably increased, in some instances by more than $150 per acre. The works installed have uniformly been strictly first class, often monu-

Mr. Cory

mental, sometimes possibly uneconomically so. In any event, the curse of Western irrigation—flimsy construction—has been avoided.

In short, the Reclamation Service has been doing a grand work, and if its operations were a measure of what might be expected of Government ownership as a whole, the proponents of such a policy would have a very strong, if not convincing, case. Its publicity department has been very efficient, but, on the other hand, it has gotten its result at a marvelously small outlay, and, even so, the people, for whom the primary purpose is supplying homes, are coming to the various projects all too slowly. This is almost entirely because the "back to the land" cry is a thing in which many join but few practice. The majority of the people, like the writer, prefer to live in the city.

The Reclamation Service has made not a few mistakes—it would be miraculous if it had not, considering the magnitude of its operations—and even many of its supporters feel that a frank admission of them would have made its position, among those whose opinions are worth while, stronger than it is. Indeed, the writer has urged that comprehensive and detailed papers, with complete cost data, be presented to this Society on each of the projects, preferably all at one time, to make a volume of *Transactions,* or a series of volumes, similar to those describing the new Pennsylvania Terminal in New York City. Opportunity to discuss matters would relieve the minds and hearts of those who feel that criticism is due, and, besides, the results of engineering experience of a Government department should be published in detail for the benefit of the Profession generally, and not kept within the confines of that bureau's staff. It is earnestly hoped that this suggestion will be followed.

Nevertheless, based on a fairly complete knowledge of only the Salt River, Yuma, and Orland Projects of the Service, and the observation and study of data examined during eight years with the Harriman Lines in California, Arizona, and Mexico—six years as a maintenance and operation official, with unusual opportunities to observe—the writer is convinced that, in these three projects at least, the Reclamation Service gets more actual work for a dollar than do the Harriman Lines. Such a statement, of course, is a judgment reached in a general way, because the character of the work done by the two organizations is so fundamentally different as not to permit of analytical detailed comparison item by item. Nevertheless, the writer feels very positive in this judgment and could cite very many instances, some minor and some fundamental, in support, though naturally many of the data at hand bearing on the matter could not properly be given out. Such a result is due to the fact that National politics has been eliminated from the Service, but still affects the Harriman Lines somewhat; that the Director of the Service has more authority and freedom in using his individual judgment than even Mr. Lovett of the railroads has, let

alone the local presidents; that the head officials, and consequently the general ideas of management of these railroads, have been changed, and the Director of the Service has not; that there is much less internal politics in the Service; and the Service organization and work, as yet at least, has not brought about the sharply drawn lines of cleavage between various departments and the leveling routine of "common standard" methods, channels of communication, limitations, prerogatives, etc., of the railroad. Mr. Cory.

The writer firmly believes that effective regulation of public utilities is greatly to be preferred to public ownership in general, and one important reason is the inefficiency of unwieldly organizations. The Reclamation Service is one of the smallest departments of the Government, and its efficiency is less than if it were smaller. A Government power service would be considerably larger, to develop any considerable percentage of unutilized water-powers, and immensely larger than any private corporation would ever be.

O. C. MERRILL, ASSOC. M. AM. SOC. C. E. (by letter).—There are certain fundamental questions in connection with water rights, the determination of which is necessary before a definite and consistent policy can be adopted or executed. Some of these questions have been brought to an apparently satisfactory solution in one or more of the Western States, and a more or less standard practice has arisen concerning them. Most of the so-called "arid" and "semi-arid" States, following the early lead of Wyoming, have provided means for the determination and adjudication of old water rights, for acquiring new rights, and for distributing the decreed water among the users. The most notable exception in this respect is California. One need not go far to find the explanation. Except for certain recent attempts, of somewhat doubtful value, to alter the statutory law of appropriation, California is still struggling along under a statute and a practice devised for and applicable to only pioneer conditions. Along with this has gone a line of decisions by the Courts constantly tending to saddle more firmly upon the State the outworn and inapplicable doctrine of riparian rights. Mr. Merrill.

It is true that the strict common law rule has been modified to the extent of recognizing the co-relative rights of riparian proprietors to the use of the waters of a stream, even to depletion. The Courts have also recognized rights acquired by direct appropriation, if at the time of the appropriation the lands below the point of diversion and riparian to the stream were in public ownership, a condition that at the present time is so nearly non-existent as to be negligible. The theory has been that at one time both lands and water rights were in public ownership; that the Government provided a procedure for the appropriation of the lands, and acquiesced in the appropriation

Mr. Merrill.

of the water apart from the lands; and that, whenever riparian lands were appropriated under the public land laws, the full riparian right to the water immediately and automatically attached to the land, subject only to two limitations: first, the superior rights of prior appropriations of water; and, second, the co-relative rights of all other riparian proprietors. Priority of right to the use of water was made to depend on priority of time of appropriation, whether such appropriation was of water directly, or of land carrying with it a riparian right.

The only fully recognized water right by appropriation is one from a stream on which there are no private riparian lands at the time of the appropriation. When once a piece of riparian land has passed into private ownership, thereafter no right to divert water above such riparian land for use on non-riparian land can be acquired, except upon the acquiescence or neglect of the riparian owner—that is, by right of prescription. No right to divert water below riparian land can be secure against the possibility of complete depletion of the stream by upper riparian proprietors. This is the "California doctrine of appropriation." Moreover, even this is complicated by the existence of water rights in connection with the old Spanish land grants—rights derived neither by statutory appropriation nor under the common law, but in accordance with the civil law of the Spanish colonists.

The situation that exists is not one of mere academic interest; it has very practical consequences. Relying on the rulings of the Courts, certain landed interests in the San Joaquin Valley, for example, appear to have made a business of levying tribute on all appropriators of water from streams tributary to the San Joaquin River, regardless of whether the intended use had any effect at all on the amount of water which would reach the riparian lands. The writer has been informed of instances in which hundreds of thousands of dollars were paid to secure freedom from attack in the Courts, although the water was merely taken out of the stream, carried a short distance in cement-lined conduits and then returned to the stream. If the diversion had any effect upon the flow, it increased it by reducing evaporation and seepage losses between the points of intake and discharge. Even though the purpose of the appropriation be one that will not use up the water, as power development, a mere appropriator has so little standing before the Courts that it is deemed wiser to pay the tribute before litigation than to risk the payment of a higher tribute plus costs of suit after litigation. Riparian owners could hardly have been put into a better position had they been granted letters of marque against all appropriators.

Bad as the present situation is, the outlook for the future is still worse, unless the practice is changed. The prosperity of the State depends on its agricultural development. This will be accomplished in large part by breaking up the old Spanish grants and other large

land holdings—which have hitherto been devoted to stock grazing or grain growing—into small farms under intensive cultivation. The riparian right attaches to only such lands as border on a stream through a single continuous ownership. Riparian owners may prevent by injunction the diversion of waters to non-riparian lands. The breaking up of the large holdings means, therefore, the severance of large areas of land from any water right at all, and the concentration of water rights through riparian ownership into those lands, constantly decreasing in area, which border immediately on the streams—a menacing situation if left uncontrolled. Mr. Merrill.

The writer would like to be able to agree with Mr. Lewis that the case of Kansas *vs.* Colorado settled the question of riparian rights or established a precedent that the States will follow, but, in view of the decision of the Supreme Court of California on January 2d, 1909, in the case of Miller and Lux *vs.* Madera Canal and Irrigation Company (99 Pac., 502), he is constrained to believe that, as far as his State is concerned, the probability of relief from present conditions, or of being able to work out a rational solution of the water right problem, is becoming constantly more remote. The Court in this case said:

"The doctrine that a riparian owner is limited to a reasonable use of the water applies only as between different riparian proprietors. As against an appropriator who seeks to divert water to non-riparian land, the riparian owner is entitled to restrain any diversion which will deprive him of the customary flow of water which is or may be beneficial to his land. He is not limited by any measure of reasonableness."

It might very well be advisable to grant a certain amount of priority in time to the owners of riparian land, as such land, from its natural position, is likely to be more readily irrigable; but it is a violation of the common equities and of good public policy to allow riparian land owners to put to uneconomical use or to waste completely for an indefinite period one of a State's greatest resources, on the plea that sometime, somehow, they may find use for it. The riparian user of water should be restricted to precisely the same degree and measure of beneficial use as any other user. He should be given a certain time, under a statute of limitations, within which to make beneficial application of water to his land. After the expiration of that time, he should have only the standing of an appropriator in acquiring any additional rights to the use of water.

What is true of California is true to a greater or less degree of a considerable group of Western States, the so-called "semi-arid" States. In Washington, the Dakotas, Kansas, Nebraska, and probably in Montana and Oklahoma, the California doctrine of modified riparian rights has received the sanction of the Courts. Except in those apparently rare instances where appropriations were made when the

Mr. Merrill.

banks of the entire stream were in public ownership, the only secure right other than a riparian right is one obtained by prescription—by open and notorious adverse user against the rights of the riparian claimant and without objection from him for the period prescribed by the statute of limitations. In any event, this is concluded to be the only form of secure title that a non-riparian owner can acquire in California, regardless of the fact that the State statutes are silent in respect to any other right than that acquired by appropriation.

Until this fundamental question concerning the acquisition of rights to the use of water is settled, either completely for or completely against riparian ownership, or in such a way as to make in all cases, riparian or otherwise, beneficial use within a reasonable time the basis of right to the use of water; unless the "dog-in-the-manger" attitude which the doctrine of riparian rights, modified or unmodified, upholds, is definitely and completely repudiated, no hope of building up an enduring policy with respect to the public control of water resources, or of securing a complete utilization of them, or of giving definite title to them, can prove anything but illusory. What possibility is there, for example, of making any final adjudication of water rights on a stream where some users claim by appropriation, others by prescription, and others by virtue of the riparian situation of their lands? The quantity of riparian lands is constantly changing. Each riparian owner has as good a right as every other. An adjudication of such rights made to-day is inapplicable to-morrow if any of the conditions as to the volume of stream flow or amount of riparian land has changed. No effective policy could be established concerning the acquisition of new rights, for such rights would be automatically acquired in certain cases by the acquisition of title to the land, in other cases they would be obtained by prescription due solely to the negligence or lack of interest of lower riparian owners, and in other cases by purchase or condemnation. Real appropriation, the securing from the State of a clear title to the use of a definite quantity of water, cannot exist in such a situation. Similarly, but little force can attach to any scheme for an administrative control of the distribution of water. No user, save he who has acquired a prescriptive right, has any claim to the use of a definite quantity of water, or a quantity sufficient for a definite area. Everything depends on the co-relative rights of the other riparian owners under the conditions of the moment. In a country dependent on irrigation, the doctrine of riparian rights leads to nothing but unending confusion. If the Courts of Oregon have allowed that State to join the roll of those which have repudiated such a doctrine, then Oregon is to be congratulated.

Even if this first problem, the right of use, should be solved satisfactorily, there will still remain certain other fundamental issues, some of which have been met in several States, but others of which, as

far as the writer can learn, have not been met in any State. Without attempting to name the States which have taken action or the means which have been used in the solution of certain of these problems, the writer will merely outline what seems to him to be the fundamental questions involved in the administration of water rights in those States which have not deprived themselves of the power to name the conditions on which water rights may be acquired and retained. Mr. Merrill

Before a thorough-going public policy can be developed for the administration of public waters, it is first necessary to determine what is the underlying purpose to be accomplished, and then to provide the means for its accomplishment. The underlying purpose should be to encourage the settlement of lands, the development of agriculture, and the building of homes and communities—the promotion of the general welfare of the citizens as a whole, rather than the special profit of certain individuals. To accomplish this purpose, it is necessary to consider carefully what character of right should be granted under varying circumstances, where or in whom the ultimate ownership of such right should vest, and what limitations, if any, should be made, and what conditions imposed upon the grant.

The purpose expressed above, however often lost sight of, has actuated the disposition of the agricultural lands of the public domain. These lands have been given to those who would cultivate them and who desired to make homes on them. It has been deemed contrary to a wise public policy to allow the title to large bodies of public land to pass to one owner. The limit has been placed at that amount which an individual owner could reasonably be expected to improve and cultivate. To have given more would have resulted in withholding the excess land from use or, if the patentee sold it, in increasing the cost to the purchaser and user over what the latter might have acquired it for first hand had the excess area been left open to entry. In securing patent to public land, the individual must act for himself. He cannot obtain title as a member of an association or of a corporation. Although details differ, the same general practice of encouraging individual enterprises and of preventing speculation and non-use has also been applied to the disposition of public mineral and timber lands. Recently, however, it has come to be realized that, although this principle applies to the disposition of agricultural lands and certain kinds of mineral lands, there are other kinds of mineral lands to develop which with reasonable economy is far beyond the reach of ordinary individual enterprise, and that a new public policy and a new method of disposition must be provided for them.

In granting title to the use of public waters to the extent of beneficial use, the practice of water appropriations has followed, in general outline, the practice in respect to the appropriations of agricultural land; but in making little or no distinction between the

Mr. Merrill.

appropriator and the actual user, the general practice has been quite different. To accomplish the purpose which was expressed above, the title to water rights should vest in the ultimate user. The character of right which the appropriator should be allowed to acquire should depend on whether the right applied for is to be used by the applicant himself for his own purpose, on his own property, and only indirectly for profit, or whether it is to be used by the applicant directly for profit in the delivery and sale of water or in supplying the public with some commodity or service which will be derived from or be dependent on the use of the water appropriated.

When water is appropriated by individuals, by mutual associations, or by municipal corporations for irrigation purposes on their own lands, where any profit which may be derived from the undertaking will be indirect through the products of the soil, or where these same classes of users have appropriated water for their own domestic purposes, the character of the right granted to the actual users should be that of ownership limited by two conditions: (1) that the water shall be applied to a beneficial use without unnecessary waste; and (2) that the water shall be appurtenant to the land or the locality for which it is appropriated.

The principle underlying the disposition of public agricultural lands will apply also to the use of water for manufacturing purposes or for power, if such use is confined to localized industries and to power developments comparable in extent with the agricultural operations of the homesteader; but, to give title of ownership to the use of water for manufacturing or for power in operations of the magnitude which customarily obtain, would be at variance with the general principle which has been recognized in the disposition of the public lands. Such uses should rather be treated in accordance with the special policy proposed for disposition of extensive areas of mineral lands. The title which the appropriator may acquire for power or manufacturing purposes, in any event for such of them as comprehend quasi-public uses, should be something less than ownership. Some such lesser title should also be granted the appropriator for irrigation or for domestic use when the appropriator is not the user but is engaged in a business which takes on a quasi-public character.

The primary object in the administration of water rights for irrigation, namely, to encourage the settlement of lands, the development of agriculture, and the building of homes and communities, will best be promoted if the water rights are in all instances made appurtenant to the land on which the water is used. Whether the appropriation is made by a mutual association, by an irrigation district, or by a person or corporation engaged in the business of delivering water to the land, the water right should be an appurtenance of the land irrigated, and the actual owners of the water right should be the land owners

themselves. Appropriators of water for sale should not be given a water right equivalent to ownership, but only a right of agency—a license to act in behalf of those who are the real owners until such time as they may desire to assume complete control. Mr. Merrill.

Similar considerations hold with respect to the appropriation of water for domestic uses. Such water rights also should be appurtenant to the lands or the localities served, such as the homestead of the individual appropriator, the district embraced by a mutual association or other organization, or to the territory included within the boundaries of a municipal corporation; and the actual owners of the right should be the users themselves. It is manifest that, in general, the right cannot be made appurtenant to specific parcels of land or other property, and that the ownership cannot be individual, as with irrigation water rights. Either the individuals must act through organizations, such as municipal corporations, or must receive the service through the agency of persons or corporations who will make the appropriations and perform the service. If the second alternative is adopted, the appropriators should be allowed to acquire from the State only the necessary right of agency—a mere license to act in behalf of the users until such times as the users may desire to act for themselves—while the real ownership should remain in perpetuity in the community served.

From the point of view of a public administrative policy, one of the most important uses of water is for the development of power. In the form of electric energy, this use extends over wider areas, reaches a larger population, and finds a more diversified application than any other use of water. Moreover, on account of the magnitude of the undertaking and the character of the services performed, organizations which handle it are almost invariably corporate, and the business itself, with few and minor exceptions, assumes a quasi-public and monopolistic character. Clearly, this use of water cannot, in general, be made appurtenant to any specific parcels of land or to any definite locality, because the use may go beyond even the boundaries of the State. Nevertheless, the appropriator, because of the quasi-public character of his business, acts only as the agent of the public which he serves. This agency should be recognized in the grant, and the appropriator should be given only a license or lease, leaving the real ownership in that widest public which is represented by the State itself.

With a complete title, or even one limited to beneficial use, the appropriator will invariably capitalize the right to its full commercial value, if no more, regardless of whether he paid for the right or received it gratis. It is not likely that any Court will refuse to allow full value for a water right of such character in any proceeding respecting the valuation of the properties of the appropriator. If so

Mr. Merrill.

valued, then the appropriator would be allowed to earn an income thereon, and that portion of the public served would be called on to pay it in the form of rates. Furthermore, if it should become desirable for the public to purchase the properties of such appropriator, it would be necessary to pay, in addition to the value of all other properties, the full market value of the water right which the public once owned but gave away.

Every person or corporation engaged in a business of this character should be allowed to earn a fair, even liberal, return on the capital actually and legitimately invested, but no such person or corporation should be allowed to acquire property gratis from the public and afterward charge rates and earn an income on it. Such a situation can be avoided in part by retaining title to water rights and by giving the appropriator only a license or lease. It can be avoided wholly only by reserving in addition the right to cancel such license at any time by paying full value for all the physical property of the licensee. If the purchase is made before the licensee has had a reasonable time within which to realize the expected profit from his undertaking, a bonus in the form of a certain percentage of the value of the physical property, varying inversely as the time which the license has run, should, in the writer's opinion, be also paid. It is believed that the investment of the licensee would be fully protected if, in the place of intangible values, a bonus of three-fourths of 1% of the appraised valuation of the real property should be paid for each year less than fifty years that the license has been in force. Such a license would be in effect an indeterminate franchise—the form which best protects the interests both of the public and of the investor.

If water-right applicants are given licenses for fixed terms without the reserved right of purchase, all such licenses or grants will, as any other unexpired franchise, have a value in proportion to the time that the license has to run, unless the license is granted on the express condition that no value shall at any time be assigned to or claimed for it, or the rights granted under it, in respect to any valuation of the properties of the licensee for the purpose either of rate making or of sale.

The appropriators of water for distribution and sale, whether for irrigation or for domestic use, and the appropriators of water for power purposes are on a common footing. Each will be engaged for profit in a business which is quasi-public; each will use in his business partly his own property and partly the property of the public; each, in his use of the public property, should be considered as the agent of the public. This relation between the quasi-public appropriator and the public can be fully maintained only by:

(1) Making water rights for irrigation purposes appurtenant to the lands to be irrigated;

(2) Making water rights for domestic purposes appurtenant to the lands or communities served; Mr. Merrill.

(3) Retaining in general public ownership water rights for power purposes;

(4) Granting licenses terminable by purchase to quasi-public appropriators of water, whether the use be for power purposes or for purposes of sale and delivery of water to others for domestic supply or for irrigation;

(5) Granting such licenses only upon condition that they shall not be capitalized for any purpose.

To accomplish the objects and to carry out the principles named above has been the chief purpose of the Federal Government in its administration of water-power sites on the public lands. The use of the public land for water-power development, both within and without the National forests, is open to all applicants who can give any assurance of a purpose actually to develop the sites. Mere speculation in power sites has been discouraged, and properly so. Only one who has been personally in touch with the situation can realize the extent of pure speculation in water-power rights. Such speculation is no assistance toward actual devolpment; it is rather a hindrance. No sooner is it learned that a municipality or an operating company is planning to make developments, than water-right locators and right-of-way applicants immediately appear, trying to forestall the municipality or corporation and hold them up for a price. The Oro Electric Corporation, of California, has recently been working up plans for additional generating stations to be located on streams within the Plumas National Forest. Within a few days after the facts became known, applications for the use of the site were filed in the District Office of the Forest Service at San Francisco for the sole purpose of securing a prior right in order to demand from the corporation a price for withdrawing. The attempts were not successful. This, however, illustrates what has come to be an established industry in some of the Western States. It is much more successful with relation to water rights than to rights-of-way across the public lands. It is the duty of any administration, State or National, to check such practices. Whatever price the speculator may secure is so much more to be added to the capital of the operating company, and the public pays interest on it forever. Just why this indirect method of getting money out of the public pocket finds so many ardent defenders it is hard to say. The ultimate effect is no different than if it were taken from the public treasury. One method adds to direct, the other to indirect, taxes; but in either case the public pays the bill.

WILLIAM G. DAVIES, ASSOC. M. AM. SOC. C. E. (by letter).—It is particularly pleasing to note the general optimism in regard to public rights, and especially Mr. Johnston's view that: Mr. Davies.

Mr. Davies. "Because the States have been slow in asserting the doctrine of public rights in property which is essentially of a public character, we need not fear that the public has lost title in any way."

We are impatient at the lagging of water legislation so far behind physical development and need. At times it does us good to curb our impatience and note conditions in other countries.

While France was a Roman province, it had the Roman water laws. Under the Merovingian kings, property was held under a different tenure, and all rights of ownership in watercourses and waters were vested in the rulers themselves. In feudal times the watercourses came largely under the feudal lords, but control was constantly disputed by the king.

Upon the decline of feudalism and the beginning of modern history, about 1500, Roman law was largely restored. Modern history in France began then with navigable and raftable streams as public domain, and smaller streams entirely under the control and virtual ownership of riparian owners.

From this position, of almost complete ownership and control by riparian owners, the centuries have seen them gradually lose control. They no longer have much, if any, ownership of the stream-bed, until dry; they have largely lost their rights to the water, no longer having the right of ownership, this being now the possession of the Nation, but having only a right to use the water, which right cannot be forfeited by non-use.

In the United States—California for example:

True riparian rights doctrine—the right of a riparian owner to have the waters of a stream pass his property "undefiled in quality and undiminished in quantity"—has fallen. We now have the modified riparian rights; and we well know, from the history of France, Italy, and Spain, and from the strong present tendency to minimize individual rights and magnify public rights, that this modification will be a continued process, and we will end with riparian rights being nothing at all, or, at most, but a shadow of their former selves. Even now, in California, leading attorneys declare the best water right to be one acquired by prescription—adverse use.

Mr. A. E. Chandler points out* that, based on the Court decision of Anaheim Union Water Company *vs.* Fuller (150 Cal., 331), riparian rights attach to only the least parcel of land abutting on a stream, and that, if an owner of a tract of riparian land subdivides and sells part of his land, those portions not contiguous to the stream lose their riparian rights unless the conveyance declares the contrary, and that the land thus severed can never again regain the riparian rights by any reconveyance.

* "Elements of Western Water Law," published December, 1912.

Mr. Davies.

Now we have the right of "reasonable use"; but when we have a water right based on modified riparian rights and "reasonable use", there is but little difference in net results, so far as the irrigator is concerned, between this and appropriation and reasonable use. The principal difference is that, under the Oregon administrative system, the water right is readily determinable, ownership being practically as easy to determine as land ownership, whereas, under the riparian rights system, the holder is never free from the worry and expense of a lawsuit about his title to water. Some authorities have pointed out that passing a law annulling riparian rights existing before the passage of the act is unconstitutional. Nevertheless, the passage of an act annulling riparian rights not asserted at the time of passage of the act would be of use, as it would influence Courts in the constant minimizing of riparian rights.

This process took centuries in France, and it is not yet complete. Are we doomed to spend an equal time? No; for, besides the fact that the world moves faster now, we have rapid hydro-electric development as a stimulant for rapid legal development.

When a water right is for an individual irrigator or for water-power for a single grist mill, it is of much less general public importance than when it is for development of power for a public utility electric power company with a network of lines covering some great district. The economic interest of the public in a river is vastly increased by hydro-electric plants of large public utility companies. This being so, it will inevitably and necessarily follow that public rights on that river will increase and individual rights adverse to the general public good will decrease; and this is as it should be. On every hand we see the disposition to enlarge or define more clearly and defend public and community rights and minimize individual rights.

Mr. Justice Cooley, in defining a public use, as the term is applied in the law of eminent domain, said:

"The reason of the case and the settled practice of every government must be our guide in determining what is or is not to be regarded as a public use, and it can only be considered such where the government is supplying its own needs or is furnishing facilities for its citizens in regard to those matters of public necessity, convenience or welfare which, on account of their peculiar character and the difficulty of making provision for them otherwise, are proper, useful and needful for the government to regulate."

From this definition a public use depends on times and conditions. A private property to-day may become a public necessity to-morrow. A stream of interest to but a small group of irrigators to-day may speedily become of very great interest to a whole valley using electric power.

In California the electric power development has been rapid, the merging of power companies rapid, and, in consequence, a conservation

Mr. Davies.

commission was appointed to report to the 1913 Legislature. It has done a very great deal of work in preparing reports. Because of the arousing and focusing of attention, the chance of getting some good water laws enacted is much better than for many years past, when irrigation interests alone were at stake.

This same general condition, however, prevails throughout the Nation. The Eastern States were not at all interested in irrigation, and, before hydro-electric power development began, they could get along very well with their old laws based on riparian rights doctrine. The arid States felt the pinch of need, and so kept constantly changing their water laws. The two portions of the Nation—the humid and the arid—were getting more and more dissimilar in their water laws; but, now that hydro-electric development is growing so rapidly, there once more appears a reason and a basis for fairly similar water laws. This is no doubt the thing that must be seized on when we urge that there should be essential uniformity of water laws among the States and abrogation of riparian rights.

There is an instance of such rapid economic change and consequent rapid legal growth in Switzerland. In that country each of the twenty-five cantons had always exercised the fullest authority over unnavigable streams within its borders. This worked very well until the development of water power on a large scale began. Then the necessity for change of laws became apparent to many. In 1891 the Swiss Society "Frie Land" issued a petition demanding the insertion of the following clause in the Federal Constitution:

"All the water powers of Switzerland not yet utilized are the property of the Confederation. A federal law shall regulate all that concerns the application of this resource and the distribution of the net benefit produced by it."

In 1895, after a thorough investigation, the Federal Assembly rejected the proposition and approved the following resolutions, which sound amusingly familiar in America:

"1. The great majority of Cantons which possess and exercise the right of sovereignty over their watercourses and which often derive direct income therefrom are not disposed to renounce that right of sovereignty.

"2. In general, the public interest in the matter is safeguarded by the Cantons according to the importance of each case.

"3. The transfer to the Confederation of the right of sovereignty and of administration over watercourses would not afford any advantage to the country and would not present any source of new revenue, either to the Confederation or to the Cantons.

"4. The possibility of availing itself of the water powers in the future could very easily be reserved to the nation by careful legislation.

"5. In general, the Cantonal authorities are better able than the Federal Government to see to the development and utilization of water

powers, both from an economic point of view and from that of public and industrial interests. Mr. Davies.

"6. The importance, sometimes limited, of the object in question and the securing of a rational use of the various falls, which is often difficult, require the co-operation of the Cantonal authorities specially qualified to protect the development of the local trades and industries of the Cantons."

In the years following 1895, hydro-electric development went on apace and public opinion kept an equal stride, so that in October, 1908, by a popular vote of almost 6 to 1, the people completely reversed the former decision and adopted the following amendment:

"The Federal Congress shall have supervision over the development of water power.

"The Federal Congress shall make provision for the disposition of water-right concessions, shall prescribe the terms thereof, and shall regulate the transmission and distribution of electrical energy so far as may be necessary to protect public interests and to provide for the proper development of such resources.

"All water rights to which the terms of the federal law do not extend shall be under the jurisdiction of the Cantons, which shall dispose of the concessions, regulate the same, and impose taxes and fees for their use, but such regulation taxes and fees shall not be so severe as to prevent or inhibit the development of water powers.

"The National Government shall regulate and dispose of concessions for powers located on inter-cantonal and national boundary streams, and shall determine the taxes and fees to be imposed thereon, after hearings have been granted to the Cantons interested, but such taxes and fees shall be collected by the Cantons.

"No power development in a stream located within the Union shall be transmitted to a foreign country without the consent of the Federal Council.

"The Provisions of the Federal law shall apply to water rights concessions already existing, except in cases specifically exempted therefrom by law."

Now, to come down to the present and to America: Public opinion in America is by no means ready for any such Federal law as that just quoted from Switzerland. The growth and change of public opinion here will not take the centuries it took in France for the modification of riparian rights, nor yet will it be so rapid as to take only thirteen years, as in Switzerland, for the great legal change noted. A few days ago Secretary of the Interior Fisher, in his Annual Report to President Taft, urged a "definite and comprehensive water-power policy for streams on the public domain and navigable streams not on the public domain." While good, it is not comprehensive enough, no doubt intentionally so, as it does not provide for water rights for other things than water power, nor specifically for water rights on interstate streams.

Mr. Davies.

The question is: What is the limit of Federal or State legislation now practicable or now probably possible?

Fourteen years ago,* it was stated that:

"An adequate remedy [for difficulties on interstate streams] through national legislation, it is to be feared, is out of the question * * * Any general legislation by the National Congress relative to water rights would mean an upheaval too great and too far-reaching to be practical. It would mean that a number of the States would have to make changes, not only in their laws, but in their constitutions, and would overturn the long line of established practice and decisions of the courts in dealing with this question.

"The waters of natural streams within the boundaries of the several States in the irrigated regions being, by virtue of constitutional provision, by the abandonment of control by the General Government, or by usage or the decisions of courts, the sole property and under exclusive control of these States, it is clear that reform of evils which exist by reason of defective legislation in these States, or by reason of lack of all legislation, can only be effected by proper legislation on the part of the legislative branch of the governments of these States. It is clear, too, that reform can not be effected unless the several States, in forming new legislation or correcting that which already exists, take into consideration the rights of the citizens of neighboring States as well as the rights of their own people."

A convention to consider uniform laws was urged. Several conventions under various auspices have been held. The U. S. Reclamation Service has worked out an outline form of law for adoption in the arid States. There has been a great growth in uniformity, and but little, if any, growth in diversity of water laws.

In the fourteen years since the foregoing opinion was written, there have been three great events: First, rapid development of hydroelectric plants, intensifying the need of better water laws and nationalizing the problem. Second, a great increase in the interest taken by the Federal Government in the use of water in both irrigation and power development, and a relative growth in the legal powers and claims of the Federal Government as compared with that of State Governments. So great has been this change of thought that in the opinion of Mr. Morris Bien, of the U. S. Reclamation Service, "It is difficult to find any possible grounds for the theory of State control, as to non-navigable streams within the State, which are not tributary to a navigable stream." Third, a great growth in public opinion to the effect that a much greater number of our difficulties of all kinds should be settled by administrative processes than by appeal to Courts.

The writer proposes the following as a compromise measure, but one which accomplishes the object of limiting water rights on inter-

* *Bulletin No. 70*, Bureau of Irrigation Investigation, U. S. Department of Agriculture, entitled, "Water-Rights Problems of Bear River" (an interstate stream), published under the direction of Elwood Mead, M. Am. Soc. C. E.

state streams in accordance with beneficial use, and making the water right appurtenant to land rather than personal property. Mr. Davies.

Pass a Federal law with provision as follows:

Provide for a permanent bureau for interstate streams and lakes; that this bureau shall have no jurisdiction except on interstate waters (and possibly on navigable rivers and on non-navigable streams on the public domain); that this bureau shall make surveys for each interstate stream, determining areas of land irrigated, area irrigable, size of ditches, points of diversion, volume of water used, discharge of stream, storage sites, power sites, dates of appropriation and use, etc.; that this bureau shall prepare a table describing land irrigated, giving date of priority, maximum amount of water allowed for irrigation of each tract, nature of use, allowable dates of use per annum, as does the State Engineer of Oregon on an intra-state stream, but ignoring State lines; that the division of water is to be based on beneficial use and the greatest good to the greatest number; that no lawsuit involving interstate right to use water on a stream may be begun in a Court until the bureau has made its survey and table of priorities, and then only on questions of law, not of fact.

There is undoubtedly much greater hope of passing such a law as this than one under which the Federal Government would take control of all streams.

Mr. Chandler states* that decisions on interstate waters to date have been mostly on small streams. In Bean *vs.* Morris, the U. S. Supreme Court, May 29th, 1911 (221 U. S., 485), said, concerning the waters of Sage Creek, an interstate stream:

"We believe that it always was assumed, in absence of legislation to the contrary, that the states were willing to ignore boundaries, and allowed the same rights to be acquired from outside the states that could be acquired from within. * * * The doctrine of appropriation has prevailed in these regions [Montana and Wyoming] probably from the first moment that they knew of any law and has continued since they became territory of the United States. * * * Before the State lines were drawn, of course, the principle prevailed between the lands that were destined to be thus artificially divided. * * * The only reasonable presumption is that the states, upon their incorporation, continued the system that had prevailed theretofore, and made no changes other than those necessarily implied or expressed."

In a case between riparian owners in California and appropriators in Nevada on West Carson River, the Court did not attempt to ascertain individual priorities, but attempted an equitable adjustment between those in one State as a whole and those in the other State as a whole.

* "Elements of Western Water Law."

Mr. Davies. These decisions being so fair, the question arises, "Why substitute an administrative body for a Court in dealing with interstate streams?" And the answer must be: "For the sake of efficiency."

Mr. Freeman. W. B. FREEMAN, ASSOC. M. AM. SOC. C. E. (by letter).—This valuable paper and the discussions thereon have been particularly interesting to the writer, because, for a number of years, he has been working in Wyoming, Colorado, and New Mexico, and has been intimately connected with matters pertaining to water rights and the distribution of the flow of the rivers of those States. At present there is no question of more vital public importance in the United States than the equitable distribution of the waters of interstate streams, involving a definition of the relation of the States to each other and to the Federal Government.

The Oregon law, as outlined by Mr. Lewis, is an excellent one. The fact that it is working well is rather strong evidence of its merit; and it is gratifying to know that there is a successful code of water laws in actual use, for there have been many defects in all previous ones, including that of Wyoming (which, heretofore, has been regarded as the model), and, in many States, the laws—or lack of laws—in existence have been utterly ineffective and confusing. The writer believes it to be desirable that all States—at least the irrigation States—should proceed immediately to adopt new laws, fairly uniform in character, with the Oregon law as a standard; then, as Mr. Lewis clearly demonstrates, the matter will be practically taken out of the Courts, where only litigation and confusion has been the rule, and put in the hands of a Board of Control capable of determining, classifying, and indexing every right in existence. In that way it will be possible to know the quantity of water available in each stream system, for future appropriations, and the conditions under which such water is available, without detriment to prior beneficial uses. That depends, also, of course, on the variation of stream flow from one season to the next; but, with discharge data available, an expert board is surely able to make a better division of waters than the Courts.

Oregon Laws.—In the discussion, several suggestions have been made for the improvement of the Oregon law. One, which is very good, is that the unit of measurement be defined more clearly. For instance, instead of stating that the maximum use is 1 sec-ft. for 80 acres, it would be much more definite to state that not more than 2½ or 3 acre-ft. per season can be used for each acre irrigated, and it would also be well to define the maximum flow allowed in the ditches under each right. In that way much trouble would be avoided in the division of water between storage and direct users, and there would be no question as to the extent of each right, regardless of the length of the irrigation season.

Mr. Freeman.

Another writer suggests that the rights and duties of the State Engineer be defined more specifically in certain matters, such as his authority to grant additional rights on a stream until its flow and the characteristics thereof are well known from a record extending over a number of years. It is quite necessary that general rules be laid down for his guidance, but it would seem to be impracticable to make laws relating to minute details in matters of this kind (nearly as much so as to attempt the regulation of precipitation and run-off by statute), and a great deal must necessarily be left to the discretion of the State Engineer and the Board of Control. They, however, should be given special authority for non-approval of filings and applications pertaining to wildcat projects, or schemes of which the merit is doubtful.

On the whole, it seems that the Oregon law needs very little improvement, and, with slight modifications, there is no reason that it should not be as applicable in the humid as in the arid or irrigation States. In fact, many of the Eastern States have already discovered the benefits to be derived from irrigation, and, if one is to believe the reports of the Department of Agriculture, the practice may be extended to every part of the Union. The present uses of water in the Eastern States, where it is returned to the stream largely diminished in quantity, do not really differ materially from use for irrigation, and, of course, power use in both localities is identical. The difficulties in regard to the adoption of uniform laws seem to exist largely in the minds of those who have been educated to riparian doctrines and can conceive of use on no other basis.

Interstate Streams.—It is very evident that there is need for immediate and comprehensive legislation regarding the division of interstate waters. The present system, whereby the Courts, at intervals of a number of years, render decisions in specific cases, some of which are contradictory in character and not one of which has yet clearly outlined the relation of the States, is utterly without efficiency, and the result is that matters are constantly becoming more complicated as the appropriations continue to increase. Congress, which had the power to create an Interstate Commerce Commission, has certainly some power to legislate without fear of being overruled by the Courts in a matter which the Courts themselves have apparently been unable to decide in a satisfactory manner.

The case of Kansas *vs.* Colorado is the one most usually referred to in discussions on this subject, and the decision itself and the parts thereof have been given a thousand and one interpretations, many of them diametrically opposite, by the adherents of various sides of the question. The people in Colorado, for instance, are generally of the opinion—by virtue of the fact that the State Constitution makes the State the owner of all waters within its boundaries—that it is the privilege of the citizens of the State to divert every drop of water, if they

Mr. Freeman.

wish, from streams flowing into neighboring States, regardless of prior appropriations in those States; and they constantly refer to the result of this suit and a decision which they believe virtually sustains their contention. It is rather hard for one who is impartial, and has been trained in the doctrine of priority and beneficial use, to conceive that any Court of Justice should support such a theory, and there is serious doubt whether such was the intent of the Supreme Court. However, it is largely on that idea that the Colorado interests expect to win the case of Wyoming *vs.* Colorado, now before the U. S. Supreme Court.

Mr. Lewis demonstrates that the Kansas-Colorado decision practically asserted that the "doctrine of riparian rights, * * * is not the law, and, therefore, never has been the law" even of interstate waters. Mr. Knowles, in his discussion, shows just as clearly that the "principle of equal rights, which is the basis of riparian rights," was followed. The writer, however, believes that the learned judges, although following the language of riparian rights—because, from education and precedent, they knew no other—actually had in mind the doctrine of prior appropriation and beneficial use. In fact, it is difficult to imagine, from the conditions surrounding the case and the evidence introduced, how riparian issues could be considered; therefore, the arguments advanced by Mr. Lewis are perhaps well grounded. The whole matter, however, shows very plainly how unsatisfactory and confusing is the present method of administration by injunction and Court decisions, and that effective remedies are necessary.

The Government and the States.—Another issue to be decided is the relation of the various Federal bureaus to the States, in the administration and use of streams, intra-state and interstate. Several who have discussed this paper have taken advantage of the occasion to attack the Reclamation Service and its work, and Federal policies in general, relating to irrigation and the conservation of natural resources. This is hardly pertinent to the question; neither is it the writer's intention to defend the bureaus thus attacked. The Reclamation Service, regardless of its unpopularity in some quarters, has done a great work and has given a tremendous impetus to irrigation development, and the Conservation movement, which seems to be a good one, has been handicapped by insufficient Congressional legislation and because the powers and duties of the officials in charge have not been defined.

The present methods of administration of the Reclamation Service and other bureaus, and the grievances resulting, are traceable directly to the chaotic state of affairs resulting from a system based on government by injunction and the determination and adjudication of water rights by the Courts. In the absence of definite limitations of their powers, it was necessary for these bureaus to define their own, and it is safe to say that many which they have assumed are not constitutional

Mr. Freeman.

It is pointed out by one writer that the Federal Government recognizes the sovereignty of the States in matters pertaining to the use of water for irrigation purposes because the Reclamation Service files its applications for water rights in the offices of the State Engineers and in accordance with the regulations of the State where the project is located. This is hardly consistent with the fact that this Service has made filings in a number of instances for all the unappropriated waters of a stream, a right which an ordinary appropriator might find it difficult to sustain. Nor does it seem entirely fair, as has been done in the case of the Rio Grande, a stream rising in Southern Colorado and flowing into New Mexico and Texas, that the Reclamation Service, not only assumed the right, some ten years ago, to file on all the unappropriated waters of the stream and its tributaries north of Elephant Butte for the irrigation of land in Southern New Mexico, Texas, and old Mexico, but has been able to maintain it by rulings of the Secretary of the Interior, and thereby prevent further development in Southern Colorado and Northern New Mexico; whereas it is questionable whether the Reclamation project will be completed, for any considerable percentage of the ultimate acreage, within fifteen years of the time that the filings were first made. That proposition and the policy involved certainly seem to be at least as unfair and as much open to criticism as the one advanced by Colorado of the right of its citizens to use every drop of water within the State. It seems easily possible to improve on both of these rather arbitrary viewpoints or methods of procedure, to the end that justice be done to every one.

Administrative Control.—The foregoing illustration is given without prejudice, either to the rights of a State or a Federal bureau, but as an example of the results of the present system. Such a condition could hardly have existed if there had been a State and National system of administrative control, as suggested by Mr. Lewis, with the authority of the Commission of Control clearly defined; and, in the light of all the experience obtained, there seems to be no reason that such a Commission should not be able to operate expeditiously and successfully. It certainly should be more efficient in securing results than the workings of the present system would ever lead one to hope for.

The personnel would probably consist largely of technical experts in matters of this kind, and provision would no doubt be made that States involved in a particular controversy be given ample representation by their own authorities to act in conjunction with this Commission in the settlement thereof. When the number of interstate streams in the United States is considered, or even those in the irrigation States, and the number of appropriations on each stream along its course, it would seem that there will be sufficient work to occupy the attention of such a Commission for a long time.

Mr. Freeman.

The writer sees no more equitable principle to follow, in the adjudication of a stream from source to mouth, than the doctrine of priority and beneficial use, regardless of State lines, there being a clear definition of domestic and other preferred uses, and the fact also being remembered that there will be a certain return flow to the stream from the upper users. All this will undoubtedly require a great deal of study and expert investigation, but it seems inevitable that such adjudications must be made eventually, and the sooner it is done the more advantageous it will be. Experience does not lead to the belief that much relief can be expected if the Courts continue to adjust these matters.

The first move would seem to be the adoption by the States of uniform laws, similar in character to those in Oregon. As soon afterward as possible there should be a complete determination and adjudication of all intra-state water rights, with their priorities, by the State Engineer and the Board of Control of each State. Such a movement in the States would no doubt accelerate the creation of a National Commission, which, when formed, would have the benefit of all data as to water rights of the various States, and this would expedite the complete adjudication of the interstate streams and the settlement of controversies relating thereto. The writer believes that engineers will agree that results of that kind are necessary and desirable, whether or not they agree on the method of procedure suggested. It seems certain that the Engineering Profession must have much to do with the final determination of these matters, and the more they are decided on their merits as technical rather than legal questions, the more satisfactorily and expeditiously can they be handled.

Mr. Lewis.

JOHN H. LEWIS, ASSOC. M. AM. SOC. C. E. (by letter).—The foregoing discussion has greatly strengthened the writer's conviction that it is the duty of the Engineering Profession to lead in the reform of State and National water laws. There is no profession which is better qualified to judge as to what the laws relating to water ought to be, and no organization better fitted than the American Society of Civil Engineers to carry on a persistent educational campaign to secure the ultimate enactment of such laws. Much of Oregon's success in the administration of her water laws is due to the pioneer work along this line in Wyoming. However, on one or two points, in his admirable discussion of the principles of law, it is believed that Mr. Johnston, former State Engineer of Wyoming, is in error.

He says that "The States have not properly administered the smaller streams which they own." From this it is assumed that Mr. Johnston means to say that:

"The waters of all natural streams, springs, lakes, or other collections of still water within the boundaries of the State of Wyoming are * * * the property of the State,"

as provided in Article VIII, Section 1, of the Constitution of Wyoming. This, on its face, looks like an irrevocable grant by Congress of all waters within its borders to the State of Wyoming, and that the United States, or any adjoining State, can have no jurisdiction or control over the same. Mr. Lewis.

Later, Mr. Johnston states that principles are of so much more importance than details of law that he does not feel inclined to discuss the question of State or National control.

It seems that this question is fundamental. It is true that the principles of priority and beneficial use, as a basis for water titles, should be understood and adopted by both the States and the Nation, but, until we can decide as to whether this system of water titles should be administered by the States or by the Nation, there is little use discussing details.

It is doubtful if the approval by Congress of a lengthy document containing the words above quoted will ever be construed as a grant of water to a State, as to do so would virtually give to Wyoming the control of all Government land within its borders, as this land is worthless without water. Such construction would be in conflict with Section 3 of the ordinance forming part of the Wyoming Constitution, providing that the State disclaims all right and title to the unappropriated public lands lying within its boundaries.

Few, if any other, States have such positive declarations as to State ownership of water. Whatever the law in the Eastern States, there must be some unappropriated waters in most streams subject to public control under any law that may be enacted at this time. It is important that the public ascertain and determine the location and extent of these public waters so that flood-water reservoirs may be constructed for the preservation of life and property during periods of excess run-off, and for the benefit of navigation, power, irrigation, and domestic supplies during the low-water period. To do this we must have some sort of an interstate or Federal administrative system, corresponding in character to that found desirable within the State for such work. The riparian owner cannot insist that those destructive floods continue to flow uninterrupted as in the past. The right to the use of all water in every part of the United States which has been put to beneficial use can in general be considered as vested. In some parts of the East, the riparian owner has perhaps some rights in the ordinary or low-water flow of the stream, notwithstanding the fact that he has not put the waters to beneficial use. The public is entitled to know the extent of all vested rights, of whatever nature, and to have provided by law some orderly method of acquiring rights in such unappropriated water, so that development can keep pace with modern demands. Knowing the extent of such rights, they can be pur-

Mr. Lewis.

chased or condemned, and their value to the owner will be increased accordingly.

If we had not discussed the relative merits of county control and State control in Oregon, we would still be attempting to administer streams through a cumbersome system of county control. It is high time that all who are thinking along conservation lines get down to a discussion of the fundamental questions on which any constructive legislation must be built, that is, the proper jurisdiction for administrative purposes.

Mr. Knowles states that "There may be a question, also, as to whether the law has become sufficiently determined to justify the creation of an administrative commission," also, "If it be true that the law for all cases has not been determined, it would appear almost certain that any important contest between States, before an administrative board, would be appealed to the Supreme Court, until the universal law had become established, and a Commission might therefore be of no value at present."

We have practically no interstate or National law relating to the administration or distribution of streams. How, then, can the law ever become settled by judicial interpretation? In the absence of such statutory laws, the Courts, as new cases arise, must practically legislate on the point at issue in order to decide the matter. If Mr. Knowles expects to await the building up of a Federal administrative system by this slow and expensive system of Court legislation, then we may as well abandon the whole subject of constructive legislation. Many lawyers take this view of the question, as the chaotic condition of State and National laws is desired by a certain class of powerful corporations seeking the monopolistic control of water without use, and because litigation of this character extends over many years, and is therefore highly profitable to the legal profession.

Appeals from any administrative board established by Congress to regulate streams are certain to be carried to the highest Courts. The quicker such appeals are taken, the better. If the law is defective, it can be amended, and we will be on the high road to a solution of these many important problems. If it is upheld, such point will probably never be carried again to the Courts. A few such cases will settle all doubtful points, and the administrative board will proceed with its work, speedily and economically, and with great benefit, through the higher development and use of our natural resources.

With reference to the Oregon system of water titles, Judge Bean, of the United States District Court for Oregon, said, in a recent case (Silvies River case, 199 Fed., 495):

"I am impressed with the soundness of the view that a proceeding for the adjudication and determination of the rights to the use of the waters within the state, instituted and conducted as provided in the

legislative act of 1909, is in effect a proceeding on behalf of the state through an administrative or executive board to have judicially settled in an economical and practical way, the rights of various claimants to the use of the waters of a stream or source of supply, and thus avoid the uncertainty as to water titles and the long and vexatious controversies concerning the same which have heretofore greatly retarded the material development of the state." Mr. Lewis.

The statement by Mr. Dillman concerning two strong corporations on a stream in California which "shut out the small fry" by protracted litigation over water and then withdrew the suit and divided the water between themselves, is a good example of the kind of justice some States mete out to their citizens. By arguing the question of States' rights or Federal rights thus delaying action, we will soon find "the small fry" getting the same kind of justice meted out to them in the Federal Courts through litigation over interstate rights, irrespective of the fact that in some States good water codes may be in effect.

In the above-mentioned case, construing the Oregon administrative code, one of California's most powerful corporations was shut out of the Federal Court and was compelled to submit to the administrative officers of the State. The same tactics had been pursued for years on Silvies River, in Oregon, where litigation has been in progress for so many years that most of the "small fry" were about ready to sell out for little or nothing and leave the country. They now have some chance to have their cases tried without ruinous expense, and once for all time, which is the important point.

Mr. Dillman wishes to be delivered from any more Government Bureaus, but if only a Government Bureau can protect "the small fry," then by all means let us have another bureau. California, however, needs a State Water Bureau worse than any other State in the Union, and the lack of such bureau is probably due to the presence of such powerful companies having control of great quantities of water under lax laws which do not require beneficial use as the basis of the right.

The writer is glad to note the admission by Mr. Sheley that the attempt to adjudicate water rights in Utah through proceedings in the Courts has been found to be impractical. This is the history in every State where an earnest attempt thus to adjudicate water rights has been made, and is the reason why many States are now turning over all water matters to administrative boards having only subordinate judicial powers.

Mr. Knowles believes that, by applying the "rule of reason" to the two conflicting doctrines of riparian rights and appropriations and use, both can be merged into one and the conflicting laws of adjoining States be thus brought into harmony. This plan has been attempted for years in California. It has resulted in the most confused jumble

Mr. Lewis.

of impractical laws to be found in any State in the Union. What the law is in that State no one can tell without examining thousands of pages of conflicting Court decisions, and then no two investigators of the law can agree exactly as to what the law really is. The rule of reason applied by one judge will differ from that applied by another. In those large interstate or National problems like the control of the Mississippi or Ohio Rivers, where millions of dollars of the peoples' money must be invested, we must have some absolutely definite legislation before such work is undertaken. Such works should endure for all time, and the necessary title to water should not be left to the reason or logic of any judge, however learned.

In his discussion, Mr. Knowles has attempted to point out certain errors in law made in the paper. As Mr. Johnston says, "Principles are of so much more importance than details of law," and the writer believes it is almost a waste of time for the engineer to discuss such detailed matters. Therefore, no attempt will be made to point out what are believed to be errors in his reasoning.

We must recognize the fact that we have at the present time no interstate or National administrative laws relating to the diversion and use of streams. It should be the province of the engineer to ascertain what the law ought to be. When this has been accomplished, and such law is framed in harmony with the laws of Nature and in conformity with good engineering and business practice, then legal experts should be called in to advise what changes are necessary to conform with good legal practice. Some of the best lawyers are always found on the side of reform to promote the public good. Owing to the present confusion of water laws, it will doubtless be found that almost any law for the highest public good can be sustained in the Courts. We are certain, however, that every section of such law which conflicts in any way with vested property rights will be pointed out by the lawyers in Congress, and most fully corrected before any such legislation will be enacted. However, it is believed that Congress will welcome suggestions from the Engineering Profession as to what the law ought to be, in order to stimulate the development of vast engineering enterprises.

Divided Control.

Since writing the paper, the Department of the Interior, of the United States, has issued regulations concerning rights of way through the public lands and reservations of the United States * * * for Power Purposes, approved August 24th, 1912. These regulations apply to Interior Department lands, and are much the same as those adopted by the Agricultural Department for lands within the National Forests. They are based on the theory of land control, impose certain limitations on the use of water, and amount to the same thing as the United States controlling the water. Permits are revocable at will by

the Secretary, and terminate in fifty years unless renewed under certain conditions. Mr. Lewis.

These regulations have confirmed the writer's opinion that the United States controls not only the public lands in the Western States, but also the water flowing over the same, and that the State exercises almost no control whatever over such waters, except by virtue of these regulations which require compliance with State laws. When such lands pass into private ownership and water is appropriated, then such water to that extent is subject to State regulation.

The Acts of Congress of 1866 and 1877 are believed by many to be an irrevocable grant of water to the States, but this, apparently, is not the case.

Concerning this question of State control of waters on Federal lands, the Supreme Court of the United States held, in the case of the United States *vs.* Rio Grande Dam and Irrigation Company (174 U. S., 690-703), that:

"Although this power of changing the common law rules as to streams within its domain undoubtedly belongs to each state, yet two limitations must be recognized: (1) That in the absence of specific authority from Congress, a state cannot by its legislation destroy the right of the United States, as the owner of lands bordering on a stream, to the continued flow of its waters; so far at least as may be necessary for the beneficial use of the Government property; (2) That it is limited by the superior power of the general Government to secure the uninterrupted navigability of all navigable streams within the limits of the United States."

"In other words, the Court holds that the jurisdiction of the United States over the natural watercourses upon the public domain" is superior and paramount to the jurisdiction of any State; and that all needed measures may be taken by the Government to preserve the watercourses of the country for "at least" the two purposes named above "even against the action of any state," in authorizing, under its laws, appropriations to be made. The Court, especially in the Kansas-Colorado and Rio Grande cases, clearly intimates, to say the least, that the Government might also make other claims to the water than for its use for irrigation, or as a riparian owner. Whether it will do so, time alone will tell.*

"The Government is still the owner of the surplus of the waters flowing upon the public domain, or rather the owner of all the waters flowing thereon, remaining after deducting the rights to the use of the same which have vested and accrued in some legal way to individuals and companies. * * * It therefore follows as the result of the ownership by the United States of the waters flowing on the public domain, that any dedication by a State of all the waters flowing within its boundaries to the State or to the public, amounts to but little, in the

* Kinney, in his recent work on Irrigation Law, p. 1096.

Mr. Lewis.

face of any claim which might be made by the Government, at least to all the surplus, or unused waters within the State."*

Kinney states, further, that Congress, if it had seen fit, could have laid claim to the necessary surplus water for projects constructed under the Reclamation Act, by "virtue of the fact that title to the surplus waters flowing over the public domain is in the Government," and not under the State laws, as was provided in Section 8 of such Act. Much confusion within the States may result eventually where Congress has reserved water for Indian reservations, which, after many years, has never been used by the Indians, but, in the meantime, has been used by others below.

It appears, therefore, from these authorities and from the wording of the Acts in question, that Congress, if it saw fit, could repeal at any time existing laws relating to water and adopt some new law for all surplus and unappropriated waters on the public domain. In such an emergency, we would have divided control within the Western States to such an extent as to make any control impracticable except through the closest co-operation.

Mr. Cory states that it is beginning to be safe for the National authorities to start gradually releasing their water powers to the individual States, and that National ownership and operation of such a public utility as electric power would be unwise.

The writer will attempt to show that in some cases the first proposition is unwise, and that the second proposition is the only logical plan for the development, distribution, and use of water power in the Western States.

Transfer to States.

Owing to the conservation sentiment in the Eastern States, it is believed to be very unlikely that the United States will ever turn over to the States, for administrative purposes, the control of public lands now withdrawn for power purposes. We cannot await the settlement of this complicated political issue before undertaking some of the large enterprises in the West, which per unit cost are far cheaper to construct than many of the small projects now being undertaken by private capital, or by the public under the Reclamation Act, or Carey Act, without co-operation with all other interests in the field. To illustrate the point, one large irrigation project and one large power project in Oregon will be described, and an attempt made to show that immediate construction is what is wanted, leaving to the future the settlement of the question of State or Federal control of streams.

Deschutes Irrigation Project.

On the Deschutes River, at Benham Falls, 181 miles measured along the stream from its junction with the Columbia River at Oregon, a

* Kinney, on Irrigation, Second Edition, p. 692.

75-ft. dam will back the water up for more than 20 miles, flooding 25 000 acres, and will store 700 000 acre-ft. of water. The remainder of the 1 053 000 acre-ft. of water which passes this point annually can be diverted from this stream in the vicinity of the Town of Bend, without storage, for irrigation during the summer, and will supply about 100 000 acres of land. The stored water will irrigate about 210 000 acres in addition. The entire stream, at Benham Falls, will thus supply 310 000 acres, which is equivalent to a strip of land 1 mile wide and 484 miles in length. It has been roughly estimated that the cost of construction will be about $30 per acre. Mr. Lewis.

Incidental to this development, an enormous amount of summer power will be produced, for, in the 37 miles between the dam site and the last diversion dam for irrigation purposes, there is a total fall of 1 300 ft. During the height of the irrigation season, about 5 000 sec-ft. of water will be available for power development in the upper portion of this stretch. As the different diversion dams for irrigation are passed, smaller quantities of water will be available for power until the last diversion at Cline Falls is reached, where about 1 500 sec-ft. will be diverted for the lower districts to be irrigated.

During the winter, when the reservoir is filling, the power possibilities along 70 miles of the stream channel, having a total fall of 2 600 ft., will be destroyed, but this is not a serious loss, as the seepage water below the reservoir can be carried through the lower irrigation canal to a vertical drop about 800 ft. in total height, where more winter power can probably be developed than can be used for many years to come in that section. Near the lower end of this district which it is proposed to irrigate, the stream enters a deep rock-walled cañon from which it is impossible to divert water. Some of the largest tributaries enter just below the section to be irrigated, so that, with full storage at Benham Falls, about 4 500 sec-ft. can be depended on at the mouth of the stream, provided 80 000 acre-ft. can be stored on Crooked River, one of the upper tributaries, to piece out the low-water flow. There is a fall of 1 400 ft. in 111 miles of this lower river, below the mouth of the Metolius River, its principal tributary. On this latter stream there is a fall of about 2 600 ft. in 70 miles. Practically all of this enormous fall can be utilized. The flow of the stream is most peculiarly uniform, due to the light porous pumice stone formation which covers the entire upper drainage of the Deschutes and its principal tributaries to a considerable depth.

These enormous power and irrigation possibilities are so interrelated that the United States could not surrender the power sites without jeopardizing its land and irrigation rights. The United States owns about one-half the irrigable land in this district, and has withdrawn enough land along the stream practically to control the power situation. So enormous are the power possibilities that ultimately

Mr. Lewis.

much of the Government land along the Columbia River and other streams, both in Oregon and Washington, within economical pumping range, will ultimately be reclaimed by power from the Deschutes River.

To settle finally all the complicated State and National questions, so as to permit the logical development of this stream for the greatest good to the greatest number, would require many years. In the mean time, the railroad which is now constructed up the Deschutes River to the Town of Bend, will have been constructed southward through the proposed reservoir site where its right of way is now partly cleared. Also, numerous power plants will have been constructed along the main stream immediately below the proposed dam site, thus preventing the storing of the winter flow. These and other like complications, if not prevented, will accumulate to such an extent that in a few years this magnificent project will be too much encumbered to undertake; but all such difficulties can be prevented without in any way retarding present development, if such private development is forced to conform to some public plan for the stream as a whole.

The development of much of the water power on the Lower Deschutes River has been greatly complicated by the recent building of a railroad along either bank of the stream so near the water surface that the construction of dams to an economical height is made impossible without moving the grades. These roads were forced to elevate their tracks around the proposed power sites of two private companies, also one site selected by the U. S. Reclamation Service. With but little, if any, extra cost, these roads could have been constructed at a uniform height of 100 ft., or more, above the bed of the stream. The water power, however, belonged to the public, and we have been so busily engaged in disputing the right of the State or the Nation to control that, in this instance, much power has been almost completely destroyed through public neglect. The same will occur with respect to the irrigation and power possibilities of the upper valley, where only 65 000 acres are now under irrigation, and where there is a possibility of irrigating 500 000 acres if the water is put to use in accordance with a comprehensive preconceived plan.

The State has a large measure of control over the waters of this stream, and the United States, through its National Forest Reservations, Indian Agencies, and water-power withdrawals, exercises a very large control over such stream through the control of land rights. Therefore, the public interest could be well protected if the State and the Nation could unite in some workable plan for the greatest good.

Co-operation.

On February 21st, 1913, the Legislature of the State of Oregon appropriated $50 000 for co-operation with the U. S. Reclamation Service in the preparation of a comprehensive plan for the Deschutes

River Basin, and the Secretary of the Interior has agreed to allot a like sum for such work, which is to be carried out jointly. Mr. Lewis.

The State law authorizes the withdrawal of all necessary water rights for the protection of the project. On the completion of the plans, any part or all of the project can be turned over to private capital for construction, on payment of the full cost of preparing such plans, the money to go into a revolving fund for the promotion of other projects; provided that no such project, or any part thereof, shall be turned over to private capital except on full hearing of all interested parties, and proper assurance that public interest will be safeguarded.

Anticipating difficulty in securing private capital to carry out so large an undertaking, the Legislature has recently submitted a constitutional amendment for the vote of the people, authorizing the issuance of State bonds to the extent of 2% of the assessed valuation of the State for the construction of irrigation and power projects, and for clearing and developing the cut-over timber land of the State.

In case it is found necessary for the public to undertake the development of its own resources, it is being strongly urged that the State co-operate with the Nation, rather than attempt a new organization. It is believed that the people will not vote millions of dollars for development projects without tying up to some stable, experienced organization which has actually made a success in this important work. The few mistakes of such service only serve to strengthen the arguments for co-operation, as these mistakes are not likely to be repeated. In this way the difficult question of politics and patronage can be overcome. It is believed that the United States can be prevailed on to co-operate with the State, dollar for dollar, as $20 000 000 has already been voted by Congress for irrigation in the West, without any offer of co-operation on the part of the States most vitally interested.

It thus appears that the policy most likely to secure immediate development is that of co-operation between the State and Nation, leaving to the future the discussion of States' Rights and Federal Rights. If we should take the position, advocated by Mr. Cory, of demanding the turning over by the United States to the States, of its various resources in the West, we might never attain that end. If we did, we would then be many years behind the times, as each State would have to organize a complicated technical bureau to handle the work, and would inevitably repeat many of the mistakes of the United States, if not do far worse.

In a very brief campaign, we have actually attained in Oregon co-operation with the United States. Furthermore, the people are in entire sympathy with a comprehensive development programme, as the Legislature has just appropriated $450 000 to complete one unit of the big Deschutes scheme, where the State has made a failure in

Mr. Lewis.

the reclamation of 27 000 acres from Tumalo Creek, under the provisions of the Carey Act. Water rights to about 20 000 acres of land had been sold where the supply was barely sufficient for about 3 000 acres.

Power Development by the Public.

Each house of the Oregon Legislature has passed a somewhat different bill appropriating $25 000 for the thorough investigation of the Columbia River Power Project, near The Dalles, as outlined by the State Engineer in his Fourth Biennial Report. It is believed that an agreement will be reached within the next few days and the investigation authorized. It is the purpose of this bill to make diamond-drill borings, prepare detailed plans, specifications, and estimates of cost for a 536 000-h.p. project, and to estimate the cost of transmission of this power to various points in Oregon and Washington; also to estimate the cost of distributing such power from sub-stations in the cities to individual consumers. To show the saving which would result, estimates are to be furnished giving the cost of producing power from other sources than water. This work is to be carried out jointly by the States of Oregon and Washington, and the United States, if cooperation can be had from such sources. A joint legislative commission from both States, headed by the respective Governors, has examined the project and recommended the plan. In order to show why private capital cannot undertake the construction of this project, and why it is necessary for the public to promote it, and perhaps eventually construct it, a brief description of the entire plan is presented.

Columbia Power Project—Summary.

Installed Machine Capacity: 536 000 h.p. with 300 000 h.p. of 12-month power and 236 000 h.p. of 8-month power.

Location: At Big Eddy, 3 miles above The Dalles, 90 miles east of Portland, the metropolis of Oregon, and 200 miles from the mouth of the Columbia, and the Pacific Ocean.

Market: 240 000 h.p. for fertilizer works, the remainder for the iron and steel industry, wood distillation plants, aluminum, carborundum, carbide, alkali works, electro-chemical industries, woolen mills, pulp and paper mills, light, heat, and power in wholesale blocks to encourage new industries, and without competition in retail business of local power companies.

Dam: Present channel of Columbia to be closed by a dam, 300 ft. long, approximately 180 ft. high above foundations, and new channel excavated in solid rock 1 400 ft. wide, and water surface regulated by removable dam, sections 100 ft. long, 60 ft. high. Location, 1½ miles above power-house.

Mr. Lewis.

Power-House: Oregon or Washington side. Planned for Washington side, at Big Eddy; 1 200 ft. long, about 200 ft. high above foundations, contains 21 turbines, supplied by canal, 300 ft. wide, with 20 ft. depth of excavation, 1½ miles long from pool above dam.

Head of Water: One-half height of Niagara Falls (73 ft. at low water; approximately 42 ft. at high water). Natural fall at low water in river 11 ft., with fluctuation of 90 ft. at proposed dam site.

Water Available: Minimum, 50 000 sec-ft., maximum, 1 390 000 sec-ft., mean flow, 235 000 sec-ft. Drainage area at The Dalles, 236 800 sq. miles. Stream flow record for 33 years available.

Turbines: Runner 16 ft. in diameter, shaft of steel 30 in. in diameter, 60 ft. long, supporting generator on top approximately 36 ft. in diameter, maximum capacity, 32 000 h.p., all at 80 rev. per min. on one oil bearing. Maximum water capacity of each, 5 000 sec-ft.

Cost: $23 076 000, or $77 per h.p. for 300 000 h.p. Cost of low-tension power station, $6.90 per h.p. per annum. Cost of power by steam from waste sawdust, about 0.5 to 0.7 cents per kw-hr., or from $33 to $46 per horse-power-year. Minimum price at Niagara for large blocks, $9.00, average about $15.00.

Transportation: Competing transcontinental railways at power-house, with navigable water from same to Pacific Ocean, and for many miles inland.

Raw Products: Abundant and accessible for many different industries. Air, 20 000 000 tons of nitrogen above 1 sq. mile of the earth's surface, or enough to supply fertilizer for the world for 50 years. Timber, iron ore, lime, salt, and other products accessible because of rail and water transportation.

Market for Manufactured Products: The World; as the power plant is at the gateway to an inland empire, with water outlet to the Pacific. With public docks at Portland, and the Panama Canal completed, shipping facilities will be available for industries seeking world markets.

Low water in the Columbia River invariably occurs during the winter, and floods during the summer. These floods are caused by the melting of snow in the high mountains at the head of the stream.

Fig. 6 shows the total power available in the Columbia during an average year. It is based on approximately maximum head conditions, and made up from records of the last 10 years, with an assumed turbine efficiency of 80%, a generator efficiency of 93%, and on the

Mr. Lewis.

assumption that sufficient turbines are installed to use all the water at all stages.

The curve, B_1 B_2 B_3, in this diagram shows the power which could be delivered to the switch-board by twenty hydraulic units, assuming the generator large enough to transform the power without overheating.

The line, *DD*, is the normal rated generator capacity, 400 000 kw., or 536 000 h.p. The lower of the three lines at any point is the maximum power output of the station. Thus it will be seen that at low-water periods the flow of the river limits the station capacity (A_1 O and R A_2); at intermediate discharge, the generator capacity limits (O P and Q R); and at high-water periods the turbine capacity is the controlling feature (P B_2 Q). The resulting minimum capacity is represented by the shaded line. The line, *CC*, is the adopted minimum station capacity of 300 000 e.h.p., or represents the line of perennial power, sometimes called "primary power," or that which is deliverable with reasonable certainty under all conditions.

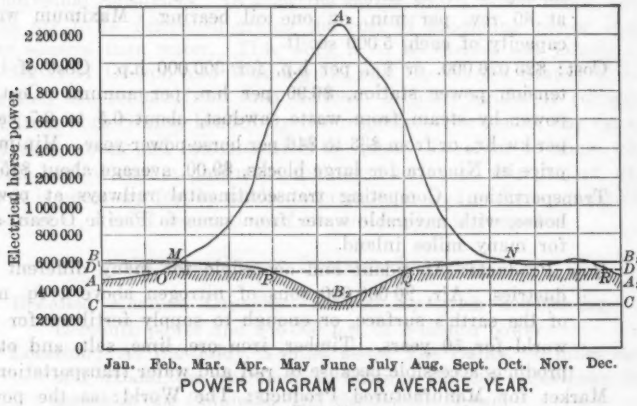

FIG. 6.

The shaded line, at nearly all places, is far above this line, *CC*, indicating that much surplus power would be available at certain seasons of the year if customers could be found whose operations could be temporarily suspended during floods and during extreme low water.

Thus it will be seen that, during practically all of February, March, April, August, September, October, November, and December, or 8 months of the average year, a total of 536 000 e.h.p., or 236 000 e.h.p. of surplus or secondary power, could have been delivered to the switch-board without any additional capital investment.

During the summer irrigation season of nearly 5 months, as much as 500 000 h.p. in addition could be developed at an initial cost of

about $44 per h.p. and furnished at about $4.50 per horse-power-season. This power could be transmitted along the river for pumping to arid lands in both Oregon and Washington. It is this power that the United States should be interested in; and this is the reason that the Reclamation Service should co-operate in the investigations. (The writer has been assisted in working out the technical details of this project by Messrs. L. F. Harza and V. H. Heineking.) Mr. Lewis.

The proposed dam will flood about 6½ miles of the navigation canal which is now being constructed by the United States at a cost of several million dollars. The lower 1½ miles, containing three locks, will be utilized in connection with the proposed power project, the boats entering the stream immediately above the dam and proceeding up the wide open river. At low stages, 10 ft. of water will be found above Celilo Falls. Owing to this saving in construction cost, the ease with which boats can go up the wide river, in place of the long, narrow, shallow canal, it is believed the United States should not only co-operate in the investigation of the project, but also in its construction.

When this navigation canal was projected there was no prospective market for 536 000 h.p. To-day it is believed that the entire quantity could be disposed of within a short time after the completion of the plant, and to new industries not now located in the Northwest. The construction of this project would mean the investment of perhaps $100 000 000 of new capital in this district, besides affording profitable employment to thousands of laborers, and add greatly to the taxable wealth of the State.

This statement relative to market is based on correspondence with large power users in different parts of the world. The representative of certain foreign capital has examined all power possibilities on the Pacific Coast, including this one. After going over the proposed project, as briefly outlined above, he agreed to recommend to his company the purchase of 240 000 h.p. at $9 per horse-power-year, delivered at the low-tension bus-bars of the generating station, putting up a $200 000 surety bond, provided the State would contract for 40 years, the power to be used in making fertilizer from the air.

This sale alone, amounting to $2 160 000 per annum, would fully finance the entire project for the development of 536 000 h.p., paying interest, depreciation, operating and maintenance expenses, carefully estimated at $2 068 000. It is probably true that some of the remaining power could be disposed of at from $30 to $50 per horse-power-year to the railway lines in this vicinity, but only a very limited market could be found at such figures. This one plant could supply a city thirteen times the size of Portland to-day, or one of nearly 3 000 000 inhabitants. Forty years hence the population of Portland may reach this figure.

Mr. Lewis.

NECESSITY FOR CO-OPERATION.

One-half the bed of the stream, and of the water, is subject to the control of either State, and the United States controls all matters relating to navigation.

Private capital would have extreme difficulty in negotiating with these three agencies, and would run considerable risk through subsequent legislation detrimental to their interests.

The Oregon Legislature recently came within a few votes of imposing a heavy annual license tax for regulation purposes on all vested water-power companies, and the Washington Legislature has now under consideration a bill providing for the forfeiture of water rights in that State if electricity from a plant now under construction is transmitted across the river for sale in Oregon.

Oregon now limits franchises to the use of water for power purposes to 40 years, and imposes an annual tax of from 25 cents to $2 per horse-power-year, depending on the percentage of power appropriated which is put to beneficial use. Partly for this reason, power plants prefer to locate just over the line in Washington. The United States would probably insist on some different franchise limitation, and the payment of heavy charges to the Federal treasury for revenue or for the improvement of the stream. The State charges alone, or the annual payments to the Federal treasury, would defeat this project, as there is even yet no market for this power except at extremely low prices.

The limit for fertilizer works is, perhaps, $9 or $10; for iron and steel works, $7; for aluminum, alkali, carborundum, and carbide works, $10; and cost or less for heating purposes. Much power could be used in heating retorts for the distillation of waste wood products, in each cord of which, as stated on reliable authority, there is $18.40 in value, as follows:

4 gal. of turpentine, at, say, 30 cents	$1.20
85 lb. of calcium acetate, at 12 cents	1.70
2 gal. of alcohol, at 50 cents	1.00
40 gal. of tar	8.50
1 000 lb. of charcoal	6.00
	$18.40

The utilization of this waste wood would thus greatly stimulate the development of our already extensive lumber business, and the making of pig iron in the electric furnace would afford a market for the charcoal thus produced.

Pig iron is now being produced successfully at Heroult, Shasta County, Cal., where a plant has been in operation for the past six years. It is stated on good authority that the experimental stage of

this industry is definitely past, and the recent enlargement of the plant appears to confirm this fact. Mr. Lewis.

Electrical metallurgists, such as Heroult, are now very confident that, when the new method is installed on a large scale, it will be feasible to attain a yield of 12 kg. of pig iron per horse-power-day. Under such conditions, current at $9 per horse-power-year could compete with $4 coke.

At such rates there could be but little if any profit for private capital in the electrical end of the business, and few enterprises which have but recently passed the experimental stage can afford to risk $23 000 000 in a power plant in order to get a small block of cheap power. The present retail power rates in this vicinity vary from $74 to $460 per horse-power-year, and thousands of horse-power in the State can be developed and delivered to consumers in reasonable quantities at perhaps $15 to $25 per horse-power-year. With the opening of the Panama Canal, it is believed that the development and sale of power by the public at little, if any, profit, will do far more to stimulate industry and promote the peace and general prosperity and welfare of the people in the Western States than can ever be accomplished through irrigation, and that, without such public development and distribution of power, this development will be forever denied to this section of the United States.

For the same reason, therefore, that the United States was compelled to go into the irrigation business in order to dispose of its arid lands, and for the same reason that the State is now planning to cooperate with the United States in the irrigation and colonization of both public and private lands, so the State and Nation must go into the power business if its untold wealth of water-power resources is ever to be put to use. In Oregon, more than 3 000 000 h.p. is going to waste in the streams, to produce which in steam engines would consume $144 000 000 worth of coal annually. This economic waste is enormous. Why should Oregon impose heavy taxes on power development and the companies pass this on to the people, thus maintaining power prices the same as in coal-producing regions, when, by basing the price on cost of construction, power could be sold at such low rates as to give the western section a tremendous advantage over the eastern section which has enjoyed for years an unfair economic advantage over the Northwest in having cheap coal?

The capital now invested in the exploitation of the natural fertilizer deposits in Chili is $136 000 000. It would require a capital investment of $860 000 000 to assure the production of an equal quantity of artificial fertilizer from the air by means of the electric furnace, assuming that cheap power were available.* It is proposed that Oregon

* Special Agents Series No. 62, p. 76, U. S. Dept. of Commerce and Labor.

Mr. Lewis.

adjust her laws so as to compete with the world in attracting these new industries.

It makes little difference whether the State or the Nation backs the bonds for irrigation works, as long as such works are built speedily and economically, and the lands are colonized so that the money is returned with interest. Likewise, it makes little difference who owns the land or the water at feasible power sites, so long as these sites are developed economically and the power put to use. Co-operation for the speedy construction of these projects should be the aim of all, leaving the control to the State or the Nation in proportion to the funds advanced. It is a waste of time to talk about State or National control at this stage. These matters will all be adjusted later.

TERRITORY AFFECTED BY COLUMBIA AND MISSISSIPPI RIVER POWER PROJECTS.

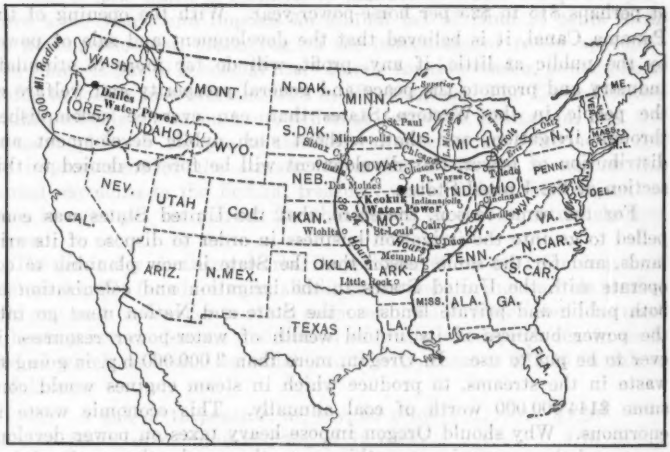

FIG. 7.

ADVANTAGES IN CO-OPERATION.

There are many advantages in co-operation. From Fig. 6 it will be noticed that approximately 2 000 000 h.p. can be developed in the Columbia near The Dalles, during June of each year. When the Columbia River is at low stage, almost all the other rivers in the Northwest are at high stage. Power from this plant could be transmitted, from 300 to 400 miles, at prevailing commercial rates, if no other cheap power were available. From Fig. 7 it will be observed that the entire Northwest falls within a radius of 300 miles from The Dalles. The demand for power in this territory varies from hour to hour, and from season to season, with as great fluctuation as stream

flow. By having all plants in this section tied into one system, supplying all consumers, a tremendous economic advantage will result. No individual State can ever accomplish such a comprehensive scheme, nor could the United States acting alone. Any independent action, by either State or Nation, will result in endless complications, such as are already beginning to be felt in the Northwest through the divergent laws and interests of different States. Mr. Lewis.

Private capital is aware of the economies attained by consolidation, but the people favoring public ownership and control are many years behind the times. Each town is attempting to supply its own citizens for special uses. As a result, from two to four times the necessary machine capacity must be installed to carry peak loads, and the plant is practically idle for a large part of the time each day. The cities, perhaps, can take care of local distribution, but the States and the Nation should take care of the generation and transmission of power.

The information on Fig. 7, relative to the Mississippi plant at Keokuk, was furnished by the Keokuk Industrial Association, and is intended to show the very great territory affected by cheap power. According to this authority the 200 000 h.p. to be developed at the Keokuk plant will cost $125 per h.p., in comparison with $77 estimated for the Columbia River plant. The difference in cost prices at which power could be sold from these plants will, for some products, more than equal the freight rate from Portland to Chicago.

In the Eastern States, where water power is somewhat limited, and where all the people cannot enjoy equal advantages from the distribution of power at low prices, it may be found to be better policy to impose annual charges on water-power companies, so as to offset the special privilege enjoyed by such companies in competition with power produced from coal, the revenue thus secured going to reduce the general burden of taxation. On thorough consideration, the water powers in all sections of the United States may be found to be ample, so that the same policy could be adopted for the Nation as a whole, using Government coal burned at the mine to supply cheap power to those sections unfavorably located with respect to cheap water power.

The present era of unregulated competition must come to an end in the near future. In its place we will have a National water-power trust, in either private or public control. A water-power expert who is familiar with hydro-electric power conditions throughout the world recently expressed surprise at the extensive development of water power in California and the very limited market. The writer has what is believed to be reliable information to the effect that a 200 000-h.p. plant is now under construction within 200 miles of San Francisco which expects eventually to deliver power in that city at $10 per horse-power-year, or $8 less than can be supplied by its nearest com-

Mr. Lewis.

petitor. The result is inevitable. The water-power trust must purchase this plant, sooner or later, thus adding additional equipment which is not needed at the present time, and the people will have to pay dividends on such "hold-up" prices. Owing to such extravagance, which is forced on the company in control, power rates cannot be greatly reduced to stimulate sales, and the new industries requiring large quantities of cheap power cannot secure a foothold in such State.

Mr. Cory has had wide experience in railway work. He admits the successful handling of reclamation work by the U. S. Reclamation Service, saying that the "Reclamation Service gets more actual work done for a dollar than the Harriman Lines do," in certain cases coming under his observation. He says:

"Such a result is due to the fact that National politics has been eliminated from the Service, but still affects the Harriman Lines somewhat; that the Director of the Service has more authority and freedom in using his individual judgment than even Mr. Lovett of the railroads has, let alone the local presidents; that the head officials, and consequently the general ideas of management of these railroads, have been changed, and the Director of the Service has not; that there is much less internal politics in the Service; and the Service organization and work, as yet at least, has not brought about the sharply drawn lines of cleavage between various departments and the leveling routine of 'common standard' methods, channels of communication, limitations, prerogatives, etc., of the railroad."

The writer has had several years' experience on engineering work for the Harriman system, has served in the U. S. Reclamation Service for about the same length of time, and for the past eight years has had charge of water right and irrigation matters for the State of Oregon. He is thoroughly conversant with the value of system, and of thoroughness in the perfecting of a large organization for a complicated technical work. He is also aware of the instability of the average legislature, and its lack of respect for stability and permanence in organization. Often the person seeking a job has more influence with the State Legislature, through influential members, than a responsible State officer elected by the people and under bond to perform his duty. There is no opportunity in State work for a young person to enter the service as a life occupation. Merit is not, and cannot be, rewarded under such an unstable system with frequent changes. Where work is intrusted to a board, and new officers are elected every few years, a conscientious officer is likely to see years of patient work along some definite policy destroyed by the adoption of some new and antagonistic course of action which the inexperienced majority honestly believes to be the best, at least the best for personal political reasons. Salaries are never equitably adjusted.

Mr. Lewis.

State Work.

With this experience in private and public work, the writer had come to the same conclusion as Mr. Cory with respect to the success of Government irrigation. The criticisms offered by the general public are usually of a minor nature, and little is ever heard of real engineering mistakes. The present difficulty of the Service in colonizing its lands can easily be overcome through co-operation on the part of the States which are most vitally interested. This is the weakest part of the Reclamation Act.

Believing that it is preferable to expand an existing organization which has already made a success of its work, than to create a new and independent organization to work in a complicated field without harmonious relations with the larger organization, the writer is now urging co-operation between the State and Nation in the construction of both irrigation and power projects.

By having a local man representing each State, in active co-operation with the Federal Bureau, many of the objections now urged against the Washington Department will soon be overcome. It will be far easier to overcome these minor objections in administration than to create a new bureau. Stability of organization, and the following out of a fixed policy through many years until the funds advanced are actually returned with interest is essential to development on a large scale. If the States put up one-half the money for such work, closer scrutiny of all expenditures will be had, and funds will not be invested in particular projects for political reasons only.

It would thus appear from the very close relation between irrigation and water power, from the very wide range over which electric power can be transmitted, and from the innumerable legal and practical complications, that it is extremely unlikely that the United States will ever turn over to the individual States her undeveloped water powers; also, it is believed that such action would lead to far more confusion than the policy of co-operation for the immediate development of both power and irrigation possibilities without regard to State lines.

Conclusion.

In closing this discussion on the question of State and National water laws, the writer wishes to urge on all engineers the importance of studying the question from the standpoint of what the laws ought to be, to stimulate investments in works for the utilization of water. The lawyer is paid to protect private rights, and to ascertain what the law is. His experience and training totally unfit him for the important duty of framing constructive water legislation. Engineers, perhaps, are more responsible for the present chaotic condition of water laws than the members of any other profession.

Mr. Lewis.

The present law is very unsatisfactory, from the standpoint of the investor. There must be some Governmental agency to which he can go to ascertain what the law is, how much water in any stream is already vested, the extent of surplus water belonging to the public, and what procedure must be followed in establishing a definite right to such surplus. He must also have assurance that when his money is invested, the State or the Nation will protect him in his right, and not leave him to wage an unequal fight in the Courts, with perhaps a great Commonwealth of the Union or with one of the National bureaus interested in the stream.

If it is proper at this time, and it is within the province and scope of the work of the Society, the writer would like to suggest that, as soon as convenient, the President of the American Society of Civil Engineers be authorized and directed to appoint a commission of engineers to draft a law dealing with interstate and National problems relating to water, and to publish such draft as soon as possible for comment and criticism. At the close of such discussion, perhaps the same commission should be called on to reconsider such proposed law in the light of any criticisms offered, and present the same at some appropriate time for adoption by the Society. Such bill could then be forwarded to Congress and might serve as the foundation for needed constructive water legislation.

A programme of this nature would greatly stimulate research and study along this line, promote discussion, and serve to educate the public as to the necessity for reform in both State and National water laws.

Paper No. 1257

PREVENTION OF MOSQUITO BREEDING.*

By Spencer Miller, M. Am. Soc. C. E.

With Discussion by Messrs. Harold Farnsworth Gray, J. J. Rosenthal, E. P. Felt, Ralph H. Hunt, Robert A. Rutherfurd, Kenneth Allen, W. E. Britton, Thomas H. Means, and Spencer Miller.

In order to promote the health and comfort of the public, mosquito breeding must be prevented as far as practicable in many parts of the United States.

Mosquitoes breed in standing or quiescent water. In the summer of 1910, a pest of common house mosquitoes invaded a city. These mosquitoes bred chiefly in the water standing in the sewer catch-basins during the summer drought. During periods of dry weather, these catch-basins are now regularly oiled, and the mosquito pest has been largely reduced. When these basins are flushed by heavy rain-storms, mosquitoes are not produced for about 10 days. Can a practical type of sewer catch-basin be constructed so that it will not breed mosquitoes?

Sewer manholes provided with a pail suspended just beneath the manhole covers have been found to be extensive breeding places for mosquitoes. Can this pail be eliminated, or if not, can it be made to drain off the water?

Engineers who direct the construction of great railroad fills across salt-marsh areas frequently neglect to provide for the adequate drainage of these marshes. The culverts which are provided are almost invariably placed too high to drain the lands sufficiently to pre-

* Presented at the meeting of December 18th, 1912.

vent the breeding of salt-marsh mosquitoes. The latter lay their eggs in mud, and they are hatched as soon as the mud is well flooded. Six broods of these mosquitoes (within the vicinity of New York) occur each season. Each square foot of salt marsh may breed 5 000 mosquitoes in a single brood. An acre of land contains 4 840 sq. yd.; thus, 1 sq. ft. of salt-marsh breeding area will furnish one mosquito for every square yard in an acre of land. Surely 5 000 mosquitoes to an acre must be regarded as a "pest." A square mile contains 640 acres. A pool on the salt marshes, about 25 ft. square, may supply a pest of mosquitoes for 1 sq. mile of territory; 100 000 people could live on 1 sq. mile of land. Such a pool, therefore, could breed mosquitoes enough to torment 100 000 people for six periods during a season; and, furthermore, as mosquitoes may live two weeks, these 100 000 people may be tormented for one-half the summer season. When so great a pest may proceed from so small a source, is it not the duty of engineers employed in railroad work to give full consideration to drainage facilities for the salt marshes which are being crossed?

In other ways, also, the work of engineers may be directly associated with the prevention of mosquito breeding. It was established in the City of New Orleans that the yellow fever mosquito bred most prolifically in elevated water tanks and water barrels. By the introduction of a central water supply system, these water tanks and water barrels were eliminated, and the mosquito pest was thereby largely reduced.

Cesspools are prolific breeders of the common house mosquito. The introduction of a sewer system and the filling up of these cesspools have been known to reduce largely the mosquito pest.

City engineers can order dirt taken from roads in grading to be dumped in low spots where water stagnates.

The civil engineer has an opportunity to serve his fellow men and do a vast amount of good work in the prevention of mosquito breeding, if he acquires the knowledge now available on their breeding habits.

It is not intended in this paper to review the work which has been accomplished by entomologists during the last few years. A number of pamphlets, devoted exclusively to the subject, have been published by the Department of Agriculture, and are obtainable for the asking.

Reports by State Entomologists are also frequently obtainable. Dr. L. O. Howard, Chief Entomologist of the Department of Agriculture, has published an extremely valuable book on the subject, which is obtainable from publishing houses. The late Dr. John B. Smith, State Entomologist of New Jersey, prepared a most elaborate review on the mosquitoes bred in the State of New Jersey, which, if not out of print, is obtainable by application to Dr. Lipman, Director of the State Experiment Station, New Brunswick, N. J. Dr. Ephraim P. Felt, State Entomologist of New York, has prepared a review on the mosquitoes of New York State, which is intended for free distribution. There are numerous other books on the same subject, many of which are printed abroad.

The writer quotes herewith in full the "Mosquito Brief," prepared, a few years ago, by the American Mosquito Extermination Society, with the aid and endorsement of the members of the Advisory Board of Entomologists. This Brief may be regarded as the A-B-C of the whole problem of mosquito prevention, and is authoritative.

"MOSQUITO BRIEF.

"1.—There are over 100 species of Mosquitoes in the United States.

"2.—Mosquitoes breed only in water. They may breed in any kind of quiet water unstocked with destroying fish.

"3.—Mosquitoes generally require from one to three weeks to develop from eggs to winged insects in warm weather, longer in cold weather. Some female mosquitoes three days old lay eggs, the average is greater. Some species lay as many as three or four hundred eggs at once, some lay them singly. Mosquitoes may live several months (as shown by hibernation and otherwise), but probably few live over a month.

"4.—Mosquitoes do not breed in grass, but rank growths of weeds or grass may conceal small breeding puddles, and form a favorite harboring place for adults. The Pitcher Plant holds sufficient water to breed a rare and small species.

"5.—Different species of mosquitoes have as well defined habits as different kinds of birds, flies, etc. Some are Domestic, some Wild, some Migratory.

"6.—Most Domestic Mosquitoes breed in fresh water, fly short distances and habitually enter houses.

"7.—Most Migratory Mosquitoes breed in salt and brackish marsh areas, fly long distances. They are not conveyers of malaria.

"8.—Rigid tests, both direct and eliminative, have proved that certain species of mosquitoes are the only known natural means of

transmitting malaria and yellow fever. Some other diseases are known to be conveyed by mosquitoes.

"9.—Of the domestic varieties, the dangerous malarial mosquitoes (several species of the genus Anopheles) are among the most generally distributed. They seem never to travel far, only a few hundred yards.

"10.—A most common and dangerous domestic mosquito in the South and the tropics is Stegomyia fasciata, which is the natural conveyer of yellow fever.

"11.—Mosquitoes are known to bite more than once, as can be seen by observation and is proved by the transmission of disease from an infected person to a new subject.

"12.—Mosquitoes are a needless and dangerous pest. Their propagation can be largely prevented by such methods as drainage or filling of wet areas, removal, emptying or screening of water receptacles, spraying standing water with oil where other remedies are impracticable. Attention should be paid to cisterns, house-vases, cesspools, road basins, sewers, watering troughs, roof gutters, old tin cans, holes in trees, marshes, swamps and puddles. As malarial mosquitoes may be bred in clear springs, the edges of such places should be kept clean, and they should be stocked with small fish. The breeding and protection of insectivorous birds such as swallows and martins, should be encouraged. Thorough screening of houses and cisterns is necessary to prevent the spread of malaria or yellow fever. The continued breeding of any kind of mosquitoes with the attendant menace to public health and to the life and comfort of man and beast is therefore the result of ignorance or neglect."

The writer's own observations, which cover the past eleven years, have seemed to establish the fact that the most troublesome varieties of mosquitoes are those bred in man-made water holders. Common house mosquitoes habitually enter houses and are busy all night singing and stinging. When these mosquitoes are ready to lay their eggs, they leave the house for the nearest spot where standing water is to be found. They lay their eggs in rain-water barrels (man-made water holders); in cesspools (made by man); in rain-water gutters which are not kept clean; in fire-pails; in pools formed in excavations, cellars, trenches, etc. These man-made water holders are prolific breeders chiefly because they breed nothing else. Natural pools which hold water for a greater part of the season frequently contain water beetles and other creatures which devour the mosquito larvæ, and thus prevent their development into winged insects.

Another fact established by the writer's observations is that it pays to eliminate breeding places throughout small areas, and that the

greater the area thoroughly controlled the better will be the results. For example, he observed one section where no mosquitoes were seen for two weeks, while people living less than 400 ft. therefrom were suffering severely from the pest. An examination showed that, where the mosquitoes were troublesome, they were breeding extensively in two water barrels.

Another example which came under his observation, was that of a municipality, 2 miles square, which was known to be thoroughly controlled, but was found to suffer considerably from common house mosquitoes which were breeding extensively beyond its borders.

Because of these experiences, he believes that the unit of operation against mosquito breeding should be enlarged. The county becomes a proper sized unit; furthermore, all counties throughout a State should work in unison in order to accomplish the best results. A law passed by the State Legislature of New Jersey during the session of 1912 is printed herewith. It provides for the appointment of commissioners by the Supreme Court Judge of each county throughout the State. It also provides for raising, by taxation, the funds needed to carry on the work of mosquito prevention.

"CHAPTER 104.

"An Act for the establishment of county mosquito extermination commissions and to define their powers and duties.

"BE IT ENACTED *by the Senate and General Assembly of the State of New Jersey:*

"1. In any county of this State it shall be the duty of the justice of the Supreme Court presiding over the courts of said county to appoint six persons, three of whom must be persons who are or have been members or employes of boards of health. A board of commissioners to be known as 'The County Mosquito Extermination Commission,' inserting the name of the county in and for which the commissioners are appointed. The commissioners first appointed under the provisions of this act in any county shall hold office respectively for the term of one, two, and three years, as indicated and fixed in the order of appointment, and all such commissioners, after the first appointment, shall be so appointed for the full term of three years; vacancies in the said commission occurring by resignation or otherwise shall be filled by such justice, and the persons appointed to fill such vacancies shall be appointed for the unexpired term only; such persons so appointed, when duly qualified, constituting such commission and their successors are hereby created a body politic, with

Judge of Supreme Court to appoint commission.

Official name.

Terms.

Vacancies.

power to sue and be sued, to use a common seal and make by-laws;
Expenses paid. the members of any such commission shall serve without compensation, except that the necessary expenses of each commissioner for actual attendance on meetings of said commission shall be allowed and paid.
Oath. No persons employed by the said commission shall be a member thereof; before entering upon the duties of his office each commissioner shall take and subscribe an oath or affirmation before the clerk of the county in and for which he is appointed to faithfully and impartially perform the duties of his office, which oath or affirmation shall be filed with the clerk of the county wherein the commission
Organization. of which he is a member is appointed; every such commission shall annually choose from among its members a president and treasurer, and appoint a clerk or secretary and such other officers and employes as it may deem necessary to carry out the purposes of this act; it may also determine the duties and compensation of such employes,
Office. and make all rules and regulations respecting the same. It shall be the duty of the board of chosen freeholders in each county to provide such commission with a suitable office where its maps, plans, documents, records, and accounts shall be kept, subject to public inspection at such times and under such reasonable regulations as the commission may determine.

Duty of director of experiment station. "2. The director of the State Experiment Station shall be a member *ex-officio* of each commission and shall co-operate with them for the effective carrying out of their plans and work. The said director shall serve without compensation, except that the necessary expenses actually incurred by him in the attendance on meetings of said commissions shall be allowed and paid. He shall furnish the said commissions with such surveys, maps, information, and advice as they may require for the prosecution of their work, or, as in his opinion, will be of advantage in connection therewith.

Powers. "3. Every such commission shall have the power to eliminate all breeding places of mosquitoes within the county wherein it is appointed, and to do and perform all acts and to carry out all plans which in their opinion and judgment may be necessary or proper for the elimination of breeding places of mosquitoes, or which will tend to exterminate mosquitoes within said county.

Annual estimate. "4. Said commission shall, on or before the first day of April in each and every year, file with the director of the State Experiment Station a detailed estimate of the moneys required for the ensuing year, and a plan of the work to be done and the methods to be employed. The said director shall have the power to approve, modify or alter the said estimates, plans and methods, and the estimate, plan and method finally approved by him shall be by him forwarded to the board of chosen freeholders in each county on or before the first day of May following its receipt.

"5. It shall be the duty of the board of chosen freeholders of each county, or other body having control of the finances thereof, to include the amount of money approved by the director of the State Experiment Station, annually in the tax levy; *provided, however,* that in no year shall the amount so raised exceed the amount hereinafter specified, to wit, in counties where the assessed valuations are not more than twenty-five million dollars, a sum not greater than one mill on every dollar of assessed valuations; in counties where the assessed valuations are not more than fifty million dollars a sum not more than one-half of one mill on every dollar of assessed valuations; in counties in which the assessed valuations are in excess of fifty million dollars a sum not more than one-quarter of one mill on every dollar of assessed valuations. Appropriation. Proviso; amount raised annually.

"6. The moneys so raised, or so much thereof as may be required, shall be paid from time to time to the said mosquito commission on the requisition of said commission, duly signed and approved by the president and secretary thereof. Payments.

"7. It shall be the duty of each commission annually, on or before the first day of November in each year, to submit to the director of the State Experiment Station and to the board of chosen freeholders in their respective counties a report setting forth the amount of moneys expended during the previous year, the methods employed, the work accomplished and any other information which in their judgment may seem pertinent. Annual report.

"8. Nothing in this act shall be construed to alter, amend, modify or repeal the provisions of chapter 134 of the laws of 1906, or alter, amend, modify or repeal any act now existing conferring upon State or local boards of health any powers or duties in connection with the extermination of mosquitoes in said State, but shall be construed to be supplementary thereto. Act considered supplementary.

"9. This act shall take effect immediately.

"Approved March 21, 1912."

The Essex County, New Jersey, Mosquito Extermination Commission was organized in March, 1912, and under this law obtained $75 000 from the Board of County Freeholders to carry out the work in the county during 12 months ending May 1st, 1913. There are about 600 000 people in Essex County, and this tax amounts to 12½ cents per inhabitant per annum. The work accomplished during 1912 has been extraordinary; on every side the same story is heard: "We have never known a year when we have seen so few mosquitoes. We might almost say we have hardly seen one in our house this year."

The organization of this Commission is as follows:

1.—Six Commissioners serving without salary.

2.—One Chief Inspector, salary, $1 800 per annum.

3.—One Secretary, salary, $1 200 per annum.

4.—One Assistant Chief Inspector, $1 500 per annum.

5.—Three Deputy Chief Inspectors (who must qualify as engineers), salary, $1 200 per annum.

6.—Forty-five Inspectors at $3 per day.

7.—Thirty to forty Laborers at $2 per day.

8.—Stenographer and Clerk, salary, $600 per annum.

Each inspector patrols a distinct district, making his rounds once in every 10 days. In certain sections of the City of Newark, a day's work for an inspector is from 100 to 300 houses; a day's work for an inspector in the outlying districts is far less. All breeding places which cannot be eliminated at once are recorded on maps made by the Deputy Chief Inspectors.

In closing, the writer wishes to emphasize:

1.—That all standing water does not breed mosquitoes, and great economy can be effected in the cost of drainage and oiling if each pool of standing water is carefully examined for mosquito larvæ before any work is expended thereon.

2.—That we will never be relieved of the work of mosquito prevention. The fight will be continuous, and any slackening of vigilance on the part of the organization will invite the immediate reappearance of the pest.

DISCUSSION

HAROLD FARNSWORTH GRAY, JUN. AM. SOC. C. E. (by letter).— Within the short space of this paper, the author has compressed considerable information on the subject of mosquito control. It is hoped that the paper will call to the attention of engineers the fact that, in many instances of design and construction, there are details which, if overlooked, may be the cause of considerable annoyance on account of mosquito breeding. Mr. Gray.

The writer gains the impression, on reading this paper, that Mr. Miller's experience with the mosquito problem has been obtained largely in New Jersey and contiguous territory, where it is more a problem of nuisance than of health. Considered on a National scale, however, mosquito control is primarily a problem of health, and is rural rather than urban. In general, it becomes an urban problem only when there is a lax administration of the municipal departments of health and public works.

The author's observations on cesspools as breeding places of mosquitoes have been confirmed by the writer in many cases. A particular illustration of this point came to his attention two summers ago, in a town of about 5 000 population. At that time a sewer system was being constructed, and completion was expected in September. On that assumption, the residents did not keep their cesspools in proper repair, in view of the expected expense of sewer connections in the near future, and a large number of cesspools were in very bad condition. In June a pest of mosquitoes resulted, and it required nearly a month of continuous work to get the situation in hand. Under ordinary conditions, however, cesspools, properly constructed and cared for, do not breed mosquitoes. It is also significant that the Anopheline (malaria-transmitting) mosquitoes do not breed in cesspools, except in rare instances.

Mr. Miller has failed to mention street gutters as sources of mosquitoes. This is a common condition in California, on streets with practically no grade, especially if the gutters are fouled with rubbish. The regular use of a broom would abate the nuisance.

Railroad construction very often diverts or obstructs the natural drainage of the region through which the line passes. The Southern Pacific Railroad through Placer County, in California, furnishes numerous examples. Between Auburn and Roseville on this line the region is intensely malarial, and the railroad contributes a large number of breeding places. The difficulty has been caused by the lack of sufficient culverts, or by culverts improperly placed, and could have been obviated at slight cost at the time of construction. A portion of this line has been greatly improved, partly by ditching and partly by

Mr. Gray.

filling on the higher side of the embankments. The writer would call to the attention of engineers the fact that it is not the collection of water in considerable volume and depth behind embankments which is responsible for mosquito breeding. This might occur if no culverts at all were placed under a high fill. It is the small, shallow pools which breed the Anophelines, and, to prevent such slight accumulations, water culverts must be placed more carefully than has been the custom.

A matter not mentioned by the author, and probably the most important in engineering interest, is the eradication of mosquitoes and malaria on irrigation projects. In California, this problem is decidedly prevalent, practically no project in the Sacramento-San Joaquin Valley being exempt. The establishment of irrigation has often been marked either by the introduction, or the noticeable increase, of malaria. Irrigation projects are financed and executed as commercial propositions, and anything that affects unfavorably the sale of such lands means a financial loss in two ways, first, the selling value of the land may depreciate, second, the sales may be retarded, tying up capital for a longer period than anticipated. Malaria is a very potent factor in depreciating the value, and retarding the sale, of land. In regions which are potentially malarial, the engineers in charge of irrigation projects should investigate carefully the possibilities of mosquito breeding, and at the time of construction make such provisions as are necessary to prevent the accumulation of stagnant water. The writer hopes that members of this Society who have had to cope with such conditions will add their data to the discussion of this paper.

It may be stated, as a general proposition, that it is the misuse of irrigation water, or defective irrigation systems, and not irrigation in itself, that is responsible for mosquito breeding and malaria on irrigated lands. The writer need not call to the attention of this Society the fact that irrigation unaccompanied by such drainage as is necessary to remove promptly all excess water is bad engineering and agricultural practice, as well as unhealthful. In California, attention to this matter is apparently seldom given. There are a number of cases on record where whole districts have been ruined by irrigation in which there was no provision for drainage, and in certain large areas the ground-water has been raised to an alarming extent. Under such conditions, mosquitoes and malaria become an important factor in retarding commercial and agricultural development.

In the writer's opinion, the solution of the mosquito problem on irrigated projects lies in the following measures:

(1) Improvement, not obstruction, of the natural drainage courses;
(2) Adequate artificial drainage;
(3) Prevention of seepage from ditches, with its resulting collection of water in adjoining low areas;

(4) Proper leveling or surfacing of the land, to eliminate small low areas; Mr. Gray.

(5) Maintenance of canals, ditches, and drains free from obstructions to flow;

(6) Strict regulation of the use of water, to avoid excessive use and waste;

(7) The occasional use of oil or larvicides on isolated collections of stagnant water which are too small or temporary to require drainage.

With the author's selection of the county as a proper unit of mosquito control operations the writer heartily concurs, but with the condition that the field of the county's operations shall not include incorporated cities. The city problem, as far as local breeding is concerned, is best handled by the city health department. The advisability of a special county mosquito extermination commission is questionable. The writer does not deny that in New Jersey, where the mosquito problem is largely due to salt marshes, a special commission may be advantageous; but the average mosquito problem is very directly one of public health, and, therefore, should be a part of the work of the county health office. The writer is convinced that, as a general rule, the appointment of special commissions is an unnecessary multiplication of executive bodies in the county government. It may be objected that the average county health department is inefficient, and that it does not argue well for the success of anti-mosquito measures to trust them to such a department. This may be granted, but, on the other hand, it may be argued that no department of county government, on the average, is remarkable for its intelligence and efficiency, that there is no assurance that a special commission will show greater efficiency than the existing component parts of the county government, and that the increase of executive bodies under such conditions can only result in duplication of functions and still greater inefficiency. Efficiency in government is to be obtained by concentration, not dispersion, of functions and authority.

In California, in spite of a crying need for anti-mosquito work over a very large area, practically nothing has been done by the county governments. The only attempt in this direction, so far as the writer is aware, has been the passage of an ordinance by the Board of Supervisors of Tehama County. This ordinance was constructed by the writer, and was designed as a club in the hands of a certain irrigation company which is trying, with fair success, to eliminate malaria on its project. The county officials have provided no funds for the enforcement of this ordinance, although the economic loss to this county from malaria is certainly not less than $100 000 annually. The expenditure of $5 000 annually by the county for the administration of anti-

Mr. Gray.

mosquito work (the cost of drainage to fall on the owner of the land benefited) would make it possible practically to wipe out this economic loss in 5 years, with a net economic saving in this period of about $330 000.

With the author's statement, that "The civil engineer has an opportunity to serve his fellow men and do a vast amount of good work in the prevention of mosquito breeding, if he acquires the knowledge now available on their breeding habits," the writer can agree only within certain limits. He believes that engineers, simply as engineers, are not qualified to undertake in an executive capacity the direction of anti-mosquito measures of magnitude, as such work, for highly successful prosecution, requires marked abilities as an educator and publicist, as well as a unique combination of thorough knowledge as to engineering, parasitology, hygiene, vital statistics, law, and government. The remarkable abilities of Sir Ronald Ross illustrate the point in question. At the same time, engineers can render distinct and valuable service by making certain that the works they design and construct do not become, through mosquito breeding, a menace to the health and comfort of the people.

Mr. Rosenthal.

J. J. ROSENTHAL, ASSOC. M. AM. SOC. C. E. (by letter).—The writer is deeply interested in this paper, as he has experienced much unpleasantness from this pest on Corregidor Island, Philippines, a military post about 3 miles square. The houses are screened, but only by using mosquito nets on the beds can one insure any sort of protection from these insects at night.

About four years ago, before active construction was commenced, and when there were fewer inhabitants, there was no trouble from mosquitoes. The rains, producing pools in natural depressions, were as heavy then as now, so that the influx of the pest must have been due to the numerous uncovered wooden water tanks and barrels introduced by the U. S. Engineers and the Quartermaster's Department, wherever work was going on. An effort is now being made to eliminate the insects by destroying all unnecessary water receptacles and building reinforced concrete covered reservoirs with screens over all openings.

The Island of Caballo, about half the area of Corregidor, and only ½ mile south of it, offers a pleasing contrast. At this place, when construction was begun by the U. S. Engineers, all water receptacles were kept covered, and care was taken to prevent the accumulation of any stagnant water, hence the mosquito has not yet found a home there.

In Manila the pest still breeds heavily, due, in part, to the uncleanliness of the natives and to inadequate sewerage and water connections, especially in the localities where the nipa (palm-leaf) and bamboo huts still abound.

E. P. Felt, Esq.* (by letter).—The studies and observations on mosquitoes in various localities in the State by the writer's department, convince him that the engineer may play a very important part in the control of mosquito breeding, because so much of it is purely local. He is thoroughly convinced, for instance, that the incidental pool, roadside or other, is a more important factor in the production of mosquitoes than the larger bodies of water so frequently viewed with distrust by the general public. The engineer has much to say as to methods, in all undertakings where his services are necessary, and it frequently happens that very little or no additional expense is required to eliminate small collections of water, sometimes ignored by members of that Profession. Mr. Felt.

The writer is particularly interested in Mr. Miller's reference to sewer catch-basins and the possibility of eliminating mosquito breeding in such places. It has occurred to him that, if no better method could be devised, it would be comparatively easy to suspend over the collection of water in the catch-basin, a small container filled with petroleum or other oil and adjusted in such a way as to drip slowly for an extended period. This device, in a modified form, has been used most successfully in certain tropical regions where thorough drainage was impractical. The same idea could be applied to cesspools, and also to cisterns, if the water from the latter was taken from below the surface.

The writer heartily endorses the idea of extending mosquito control over considerable areas. There is more or less migration or drifting of these annoying forms, and, the more extended the work, the better will be the results as a whole. The communities along shore lines, particularly in regions of extensive marshes, are more interested than those farther inland, which may be rarely annoyed by migratory forms, such as the banded salt-marsh mosquito. While it would be desirable to have the unit for mosquito control coincident with county lines, under conditions such as mentioned above, it would seem probable that greater efficacy would be secured by the co-operation of townships or communities suffering from similar conditions. It is difficult, for example, for inland residents to appreciate the desirability of large expenditures for the control of marsh forms practically unknown in their own locality.

Ralph H. Hunt, M. D.†—The speaker is sure that no one is more fit or better equipped to speak with authority on this subject than Mr. Miller, for in New Jersey he is called the "father" of mosquito extermination and prevention of mosquito breeding, in that he was the first to make of it a live issue and bring to the notice of the Dr. Hunt.

* State Entomologist, Albany, N. Y.

† President, Essex County Mosquito Extermination Commission.

Dr. Hunt.

people the fact that the mosquito could be placed under control and rendered less of a nuisance.

Mosquito work began some years ago, under the efforts of an English Army surgeon, Sir Ronald Ross, who demonstrated that only through the mosquito, in this case a variety of *Anopheles*, could malaria be carried from man to man, and that it was the only known carrier of the infection. Previous to that time it had been supposed that malaria was caused by a miasma or by something in the atmosphere, the idea of the disease being very indefinite until, through the investigations of Italian observers, the organism was discovered in the blood of the human being. Shortly after that Sir Ronald Ross demonstrated conclusively that the mosquito was the carrier of malaria. This was the first thing that brought to the attention of the people the necessity of getting the mosquito pest under control. It is seen, therefore, that in those days it was purely a health problem.

Later, the United States Army surgeons in Havana, Cuba—three of a commission of four sacrificing their lives in the investigation—demonstrated the fact that a certain variety of mosquito, *Stegomyia fasciata*, was the carrier of yellow fever. That was proven beyond a doubt; and two things stand out in scientific medicine and health problems to-day, namely, that if there were no mosquitoes, there would be no malaria and no yellow fever.

The malaria problem would be done away with entirely by the extermination of the variety of *Anopheles* which carries the disease; but, the habits of that mosquito being more difficult to control, it has been less controlled, even where it is a menace, than the yellow fever mosquito in yellow fever countries.

The control of the yellow fever mosquito is comparatively easy, owing to its habits of breeding. It seems that it breeds only in barrels and other small receptacles around houses. One has only to prevent water from standing in these receptacles in order to get rid of the yellow fever mosquito. A complete demonstration of the efficiency of work of that sort has been given in Havana, Cuba, a place formerly pestered with yellow fever but to-day absolutely free from the disease. Yellow fever formerly was a positive menace, and retarded the industrial development of the city; to-day there is no more quarantining of the port, and no more shutting up of business.

We know that the Isthmian Canal could probably never have been completed had not this scientific question been met prior to commencing the mechanical work. In the Canal Zone to-day there is no yellow fever, and mosquito control alone has accomplished this wonderful result.

Referring to the speaker's section of the country, namely, Essex County, New Jersey, which place has been pestered from the time it was first colonized, in early days, to the beginning of the present season,

we have reports from Colonial times stating that it was almost impossible to live in certain parts of this section of the country on account of the mosquito pest. The Essex County Mosquito Extermination Commission holds that it has faced a difficult problem and has worked it out to a practical solution for the first time, as far as the speaker knows, in the history of the country. Dr. Hunt.

In previous years local boards of health had attempted to control the mosquito, and through them a desultory movement began. Mr. Miller, who was in this work at its inception, states that it began about eleven years ago, and the speaker assumes that that was about the time when the first practical work was attempted by local boards of health with respect to mosquito control. Up to 1912, it was found that such a method was impractical. The local boards of health could not obtain, or would not spend, the money, and even those that did make an effort to do their share in the extermination of the mosquito, suffered greatly from the inroads of mosquitoes which were bred by their neighbors.

This led to an attempt to formulate a law by which to get control of the whole problem, and be sure that, if there were six little towns or villages in the county, instead of having two do the work and suffer from the lack of work on the part of the other four, some arrangement could be brought about whereby all six municipalities would do enough work to control it. That led to the passing of the present county law, by which, as Mr. Miller has stated, county commissions are established. Each commission is given funds in accordance with the law, rated by the taxable valuations of the county. The commission formulates its plans, states the amount of money which it will need for the season's work, and sets forth the need of the work to be done. This is forwarded to the Director of the State Experiment Station, and his "O. K." makes it mandatory on the board of freeholders to furnish the money on the request of the commission. The commission is appointed by the chief justice of the county. This relieves the situation and takes the question out of politics. The commission serves without pay, and, up to the present time, this system, as it is being tried in Essex County, has been found to be admirably adapted to the problem.

The Essex County Commission has met with much criticism, but in spite of that it has gone ahead with the work. The members have felt that they know the problem, know the mosquito, and know how it breeds; they know how it can be controlled, and they have men willing to put in the time and do the work, and, under the new law, they have the money.

The law was framed so that the appropriation was not available until a certain proportion of the county had been flooded with mosquitoes which bred on the salt marshes, but, after that, the work was

Dr. Hunt.

carried out as thoroughly as possible. As a result, both the local papers and the general sentiment of the communities were unanimous in the opinion that they had never known a season when mosquitoes were so few in Essex County as the one just past. Weather conditions may have been favorable for the Commission during 1912, but it is known that wherever mosquitoes have been found heretofore they were found to be breeding during the past summer, but there were enough men to control the situation. It seems almost useless to continue the discussion of the paper, because the speaker's work and that of Mr. Miller naturally have been on parallel lines; his plans are the speaker's plans on this subject, and the results are the same.

To reiterate: There is in Essex County, as Mr. Gray has stated, not only the salt-marsh mosquito, but the house mosquito, the *Culex pipien,* which has proven a greater nuisance than either of the salt marsh varieties. The *Culex cantator* and *Culex solicitans* breed only in salt water. These mosquitoes have been found in Morristown, Summit, and Bernardsville, and also at points from 20 to 25 miles from the nearest salt marsh. It is apparent, therefore, that these varieties are migratory, and are capable of flying 25 miles. They are most prolific, and can be controlled only by ditching the salt marshes. The salt marshes on the Hudson County Meadows and on the Union County Meadows are being ditched thoroughly, and it is hoped and believed that the salt-marsh mosquito can be eliminated from Essex County and from New Jersey, if this work is continued in its present form.

The *Culex pipien* is a small mosquito which breeds in fresh water, and the dirtier the water, the better it likes it. It breeds in brooks, in old tin cans, in pools, and in any place where there is water. It requires a house-to-house inspection for its control. It is a continuous nuisance, and to eliminate it each inspector must visit and revisit every house in his district. Essex County was divided into as many districts as seemed wise, and an inspector was placed over each one and made directly responsible to his chief, and the chief to the Commission.

The above-mentioned mosquitoes are practically the only three varieties which are found in Essex County. We know where they breed; we know how they breed; and we know how to beat them; and, if the money is still forthcoming in future years, we believe it to be inevitable that the mosquito must go.

All will acknowledge the fact that it would be a wonderful thing for New Jersey or for any community to rid itself of mosquitoes. One can hardly estimate just what it means in real estate values alone. It is within the experience of everybody who lives in New Jersey that men who have gone there to occupy property and to make it a permanent home, have suffered from this little pest, the *Culex*

pipien, and the salt-marsh mosquitoes, and have gone away and refused to invest in property in that State. Therefore, in Essex County, it is considered a good investment to devote $75 000 toward the extermination of the mosquito and set it against the depreciation in real estate and the actual discomfort which comes from the pest. Dr. Hunt.

The speaker is a practicing physician, and during 1912 has been somewhat interested in the amount of malaria in the county. He thinks that the mosquito problem is more of a nuisance than a health proposition; not that we do not have malaria in New Jersey, for we do have it, but it is a negligible quantity, and we would not feel justified in spending any such sum of money to get rid of what little malaria there is in the county. In doing away with this nuisance, however, we will destroy the *Anopheles* mosquito, which is the carrier of malaria.

The speaker is very glad that Mr. Miller has written this paper, and feels that everywhere we go we should preach this gospel. If intelligent men could be interested in the subject, another step in the fight would be won. It is hoped that each engineer will do all he can in his community to create an interest in this work and aid it in every possible way.

The mosquito acts as an intermediate host. The malarial organism goes through an entirely different stage in the mosquito from what it does in the body of man. This is also true in yellow fever, as far as is known. It cannot be traced in yellow fever, because the organism has not yet been determined, but in the case of malaria the organism has been traced in all its stages from man to mosquito and from mosquito back to man.

ROBERT A. RUTHERFURD, ESQ.—In Connecticut, a number of people interested in the mosquito question, including the speaker, are trying to obtain some legislation, based on the effective New Jersey law, but modified to suit the different political and physical conditions. Mr. Rutherfurd.

The people are bothered to a great extent with salt-marsh mosquitoes which can be eliminated by drainage of the salt marshes. One of the proposed bills places the entire direction and execution of the marsh drainage part in the hands of the Director of the State Agricultural Experiment Station. Another bill deals with the breeding of fresh-water mosquitoes, and empowers boards of health to remove them like any other nuisance.

From all the preliminary missionary work that has been done, it looks as if favorable results would be obtained from the efforts which are being made at Hartford.

The proposed bill putting the marsh drainage work, etc., in the hands of the Director of the State Agricultural Experiment Station calls for an appropriation of $200 000, and gives power to investigate,

Mr. Rutherfurd. inspect, and survey all suspected breeding marsh areas, and also gives him authority to hire engineers, etc., to survey and map such areas, and to estimate and inspect such work as required. The engineers should have a knowledge of mosquito breeding marshes.

Some private anti-mosquito work in several of the small towns has given very good results, particularly the ditching of salt marshes; and, of course, as Mr. Miller states, that has to be maintained from year to year, and kept in proper shape, or the mosquitoes go back and make worse breeding places than ever.

Mr. Allen. KENNETH ALLEN, M. AM. SOC. C. E.—Reference has been made to the breeding of mosquitoes in catch-basins. These basins may be very prolific sources of such pests in our cities, and very little has been done to prevent them from becoming breeding places. When in Washington, in September, 1912, the speaker was interested to see that active preventive measures were being taken to that end, under the direction of Asa E. Phillips, M. Am. Soc. C. E., Superintendent of the Sewer Department. The catch-basins, of which there are more than 5 000, are flushed regularly, once a fortnight, and are given a dose of about a cupful of oil during the breeding season. The cost of each application is about 6 cents per basin. The catch-basins are cleaned once in 4 weeks throughout the year, the flushing being merely to remove the stagnant water.

Cesspools also afford favorable conditions for mosquito breeding, and it will be interesting to note what change may be observed in a city like Baltimore, where 100 000 cesspools are being abandoned on the introduction of sewerage, and where, in certain localities, this insect has been a serious nuisance.

The dissemination of disease by mosquitoes has been suspected for many years, although the conclusive proof is recent. Dr. Howard A. Kelly, of Baltimore, in a paper before the Johns Hopkins Medical Society, mentions some native writings of the Sixth Century, discovered by the Governor of Ceylon about ten years ago, in which insects are mentioned as carriers of disease, and certain kinds of mosquitoes which cause malaria are described.

In 1848 Dr. Josiah C. Nott, of Mobile, Ala., expressed the opinion that yellow fever was transmitted by insects, but it was not until 1886 that the disease was charged to the *Stegomyia fasciata* by a Scotchman then living in Havana—Dr. Carlos J. Finlay; and then some 14 years elapsed before this was demonstrated to be a fact by Dr. Walter Reed, U. S. A., and his colleagues. Referring to this, Dr. Kelly says:

"One thing must strike every reader of Reed's experimental work—that it is based on nothing which was not easily within the scope of scientific investigation at any time within the last 200 years. Their success rested upon inductive reasoning, accuracy of observation, and

perseverance, and thus affords an added illustration of the old lesson that the simple solution is the product of the master mind." Mr. Allen.

W. E. Britton, Esq.* (by letter).—The writer has been much interested in this paper and realizes that the civil engineer has a great opportunity for effective work in mosquito elimination. Especially is this true in regard to construction work, where some of the very worst breeding places have been formed by carelessly intercepting the natural drainage in the building of railroads and highways across marsh lands. Mr. Britton.

The subject of mosquito control naturally falls into two subdivisions: (1), Salt-marsh or migratory species; and (2), Malarial, rain-barrel, and other local species.

The control of the first species requires a large initial expenditure for drainage. As salt-marsh mosquitoes migrate, often flying many miles, not only the area where they breed, but all the adjacent towns are affected. Local effort, therefore, is not satisfactory unless universal co-operation is established. This is difficult. It seems to be a wise provision, therefore, that such work be managed by the State, as is done in New Jersey. After the drains have been cut, a small sum must be expended annually for maintenance, and the writer believes that this may be safely imposed on the towns, possibly with a provision that the State may do the work in case the towns fail. It must be done some way.

The second subdivision deals more particularly with a local nuisance, and more properly belongs to the province of the health officer. If the laws are insufficient, more authority should be given to the health officer and more funds provided in order to enable him to cope with the situation.

The control of the rain-barrel and malarial and other non-migratory species may best be effected by frequent inspections of premises, at the expense of the town or city, and by orders issued by local authorities, the cost of the treatment to be borne either by the property owner, or by the municipality or town. State supervision or interference is hardly necessary.

Whether or not county mosquito commissions are desirable will depend on conditions existing in the different States. In Connecticut, for instance, there are county public health associations composed of the town, city, and borough health officers and a few citizens prominently interested in matters of public health. Such organizations at their meetings discuss these problems and adopt general policies; and each individual health officer will solve his local difficulties with a stronger courage if he knows that the organization is back of his efforts.

* State Entomologist, New Haven, Conn.

Mr. Britton. In mosquito elimination, as in all other questions of great public import, however, a strong public sentiment must be obtained. Thinking people must be awakened. Often laws will help to create that sentiment, but they are of little value unless supported by it. A great educational campaign is needed, and every legitimate means should be adopted to an end which will improve the health, efficiency, comfort, and, ultimately, the financial condition of the people.

Mr. Means. THOMAS H. MEANS, M. AM. SOC. C. E. (by letter).—This is a timely paper and of great value. We have too long considered the mosquito a sort of necessary evil, and it is of great importance to show that it can be prevented, generally at no large expense. The writer well remembers, during boyhood, the old rain barrel, at the corner of the house, filled with wigglers. No one then connected the wiggler with the pest of mosquitoes which bothered them all summer, and, of course, no one had any idea that the chills and fever were in any way connected with the mosquitoes.

In irrigated districts, mosquitoes rapidly become a great nuisance, unless special precautions are taken to eliminate their breeding places. Very little systematic work seems to have been attempted in the matter of mosquito prevention in the West. Few engineers seem to realize how easy it is to lessen the number of mosquitoes to such a degree that they cease to be a pest. It is to be hoped that Mr. Miller's paper will serve to increase the interest in the matter.

Within the last two years the writer has been engaged on a small irrigation project in the Sacramento Valley. Here, as everywhere else, mosquitoes are a nuisance, but here the matter is much complicated by the presence of the species which distributes malaria. The problem of preventing or lessening malaria is vital to the success of the project. During the summer of 1911, the first year of the writer's connection with the enterprise, no attempt was made to control the matter, largely because no one appreciated its importance. Experience during that season, however, showed the absolute necessity of subduing the malaria mosquito. Plans were made and work was commenced in the season of 1912.

The problem was attacked from all sides. An attempt was made to prevent the breeding of mosquitoes, to isolate the human carrier of the disease, and to encourage the people of the community to take good care of their general health by sleeping under screens, by using good drinking water, and by taking quinine as a preventive. There was no measure of the amount of malaria in the community previous to 1912, except the records kept by the school teachers. These showed that for the previous three years about 80% of the children of school age were sick with the disease. In the fall of 1912, after the one season's work, the percentage of children sick with malaria was reduced to about 15. During this year there had been a great influx of

new people, and, had there been no change in the conditions, a much larger percentage of sickness might have been expected, for the disease is always worse in the case of new comers. The writer feels that he has reason to be pleased with the results. Mr. Means.

Whether or not the season was favorable, no one can say; malaria in the country generally seemed to be about as usual in 1912. Very few farmers have much faith in the mosquito theory of malaria, and it was hoped, at least, to establish confidence in the method of handling the matter. There was very little co-operation during the year from the farmers, on account of their scepticism, but it is found that now nearly all of them are satisfied that malaria prevention is possible, that mosquitoes have something to do with its spread, and next year they will give their hearty help, and the work should be more successful.

In laying the plans, attention was directed to drainage, as the first and most important matter. Open drains were made, in order to prevent surface water from standing. Where drainage was not possible, oil was used to prevent mosquito breeding. Two men, equipped with knapsack sprays, made regular trips over the country and sprayed every place where mosquitoes could breed. These trips were made at least every two weeks in the warm weather. The territory covered was about 10 000 acres. During the season, 1 400 gal. of oil were used. The total cost of the work was about $3 500. As there were about 1 200 people in the district patrolled, the cost, if pro rated, would have been about $3 per person, which is trifling when the results are considered. The relief from mosquito bites alone would have been well worth the cost.

It has been stated that mosquitoes travel only short distances. This may be true in an unsettled country, but, where there are many people or animals, they will travel great distances. In the evening every traveler will be followed by a swarm of the insects, and every cow coming from pasture will bring them with her.

It is of importance, therefore, to exercise care in preventing the breeding of mosquitoes, even in remote spots.

Malaria mosquitoes seem to prefer the quieter, warmer spots of water. They do not seem to breed in ditches or streams, but every little puddle will produce great numbers. They are a little slower in development than the common varieties, and do not become abundant until the latter part of the season.

As the result of the season's work, the writer would suggest the following for a community troubled with malaria:

1. Drain all surface water.
2. If drainage is not possible, use oil. The cheaper grades of oil from the refineries, such as stove oil, mixed with crude oil, will an-

Mr. Means. swer very satisfactorily. Use a fine spray, and distribute enough oil to form a thin, but visible, film on the surface of the water.

3. Keep the person, known to have malarial parasites in the blood, isolated if possible. Mosquitoes do not generate malaria, but must get it from the blood of a human being. Insist that all malarial persons sleep under screens. Have every such person undergo a thorough treatment under a good doctor.

4. Encourage the use of good water. Deep wells are generally best. Malaria cannot be transmitted through water, but every condition which tends to run the system down will make a person less resistant to the disease.

5. Screen all houses, and, as a special precaution, screen all sleeping places. Keep indoors as much as possible after night. The malarial mosquito is a nocturnal insect.

6. Take quinine during the season when malaria is prevalent. A doctor's advice should be asked. Take a little quinine, no matter what he advises.

Mr. Miller. SPENCER MILLER, M. AM. SOC. C. E. (by letter).—The writer is much gratified with the reception accorded his paper and the thoughtful discussion it has brought forth. Mr. Gray intimates that the writer's experience with the mosquito problem has been largely obtained in territory where mosquitoes are more of a nuisance than a menace to health. Are not all kinds of mosquitoes a menace to health? Nature provides a period of sleep to maintain health. Mosquitoes which disturb that sleep surely affect one's health; and the greater their number the greater the menace. Recreation in the open air and sunshine maintains health; therefore, a pest of mosquitoes of any variety that drives one indoors is a menace to health.

There are many times more non-malarial than malarial mosquitoes breeding in the State of New Jersey. The malarial mosquito may breed almost anywhere, even in salt marshes, and any campaigning against it must, of necessity, call for the inspection of all quiescent waters. The cost of inspection is the largest part of the cost of extermination. Seeking for malarial mosquito larvæ will lead the inspector to the larvæ of non-malarial mosquitoes. The destruction of non-malarial larvæ adds but a trifle to the expense of a campaign against malaria, and, in the interest of health, such a campaign should be directed against every kind of mosquito.

Mr. Gray states that the problem "becomes an urban problem only when there is a lax administration of the municipal departments of health and public works." In the City of New York, the Department of Health is fully alive to the importance of mosquito prevention. It is lax only because hampered by lack of funds. A large portion of the Borough of Brooklyn is pest-ridden with salt-marsh mosquitoes which

breed in about 9 000 acres of marshes in Jamaica Bay within the limits of the Borough. The Borough authorities have not $10 000 to expend for this purpose at present. It will cost about $60 000 to ditch these marshes alone, and it is estimated that an annual expenditure of about $150 000 per year will be required to relieve properly the Borough of Brooklyn from the mosquito pest. This sum would cost the people residing there less than 10 cents per annum per inhabitant. While salt-marsh mosquitoes probably furnish 75% of the pest in Brooklyn, there are thousands of fresh-water breeding places where the common house mosquitoes breed. These are a greater nuisance individually than the marsh mosquitoes, because they get indoors and sing and bite all night. Mr. Miller.

Mosquito breeding in Prospect Park, Brooklyn, has been known and talked of publicly for the last ten years, yet at the present time the City health authorities have not the funds to prevent it. Citizens of Brooklyn have formed an association and are raising a fund of $60 000 by subscription to start the work.

The writer became interested in forming county mosquito extermination commissions because, after ten years of endeavor, he failed to obtain the co-operation of adjoining communities to do anti-mosquito work effectively.

Mr. Gray concurs in the "selection of the county as a proper unit of mosquito control operations * * * with the condition that the field of the county's operations shall not include incorporated cities."

The Board of Health of Newark, N. J., for five or six years, expended about $5 000 to $7 000 annually. This was about one-sixth of the sum required to do the work effectively within the city limits. After the work was taken over by the County Commission, in the summer of 1912, more than 9 000 breeding places were discovered in the city, entirely outside of salt-marsh areas. Newark has a well-organized and highly intelligent Board of Health, but it was limited financially. Breeding was stopped to a certain extent, but not enough to satisfy the citizens, as will appear from the following editorial comments in Newark papers:

The *Newark Evening Star* on the 15th of July, 1912, said:

"In no previous summer season were Newark and its suburbs so free from the pest as during the present season. Last year in many localities the infliction was unendurable, and the change is most grateful to a large population. The money appropriated for this blessed work is the best public investment ever made by the county. It is being richly repaid in benefits."

On August 17th, the same paper stated: "The mosquito extermination act has been amply justified by results."

Mr. Miller.

The *Newark News*, on July 13th, 1912, said:

"After just two months of activity, backed by an adequate appropriation, it has been demonstrated that the work of the Essex County Mosquito Extermination Commission is accomplishing definite results. * * * After this comparatively short time, results are visible in the lessened number of the pests that find their way into houses and within the confines of screened porches."

On July 24th the *Newark Evening News* stated:

"Sh-h-h!

"Have you noticed it, or are we dreaming! It seems almost too good to be true.

"Has the wily mosquito left us?"

The writer feels that it is necessary to include incorporated cities in connection with county work. A county tax is paid by the taxpayers of the cities as well as the villages. A county commission should expend the money collected by taxation for the benefit of the people who pay it.

Mr. Gray is convinced that "the appointment of special commissions is an unnecessary multiplication of executive bodies in the county government"; and states, further, that "no department of county government, on the average, is remarkable for its intelligence and efficiency"; and "that there is no assurance that a special commission will show greater efficiency than the existing component parts of the county government."

The assurance offered in the New Jersey law, included in the paper, that these commissions shall be intelligent and efficient, is that they shall be appointed by the Supreme Court Judge of each county and shall serve without salary. Mr. Gray states that, in California, there is a crying need of anti-mosquito work, and that practically nothing has been done by the county governments.

He states further: "the county officials have provided no funds * * * although the economic loss to this county [Tehama] from malaria is certainly not less than $100 000 annually." No better argument can possibly be put forth for the necessity of the appointment of specially selected men for carrying out a definite public work.

Mr. Gray says that "highly successful prosecution, requires marked abilities as an educator and publicist, as well as a unique combination of thorough knowledge as to engineering, parasitology, hygiene, vital statistics, law, and government."

The Essex County Mosquito Extermination Commission is composed of: Two doctors, one civil engineer, one retired quartermaster-general, one successful business man, and one grain merchant, all having proven by previous service that they were public-spirited citizens. This Commission has been successful.

Mr. Rosenthal refers to the mosquito pest in the Philippines, which followed the introduction of numerous uncovered wooden water tanks and barrels, "man-made water holders." Mr. Miller.

Mr. Felt speaks with authority when he refers to the incidental pool, roadside or otherwise, as being more prolific in the production of mosquitoes than the larger bodies of water so frequently viewed with distrust by the general public. His suggestion to suspend a small container filled with oil and adjusted so as to drip slowly into a catch-basin has been tried in Newark, N. J. The plan proved effective only when the catch-basins were kept clean. After some days they become partly filled with dirt, and on this the oil may drip and not reach the water; for that reason the plan was abandoned. The catch-basin covers are now removed, and the oil is sprayed all over the surface of the water. What is wanted is a mosquito-proof catch-basin which needs no inspection or oil.

Dr. Hunt views the subject largely from a medical standpoint. The Supreme Court Judge of Essex County was fortunate in having found a man of Dr. Hunt's ability and zeal to serve as a commissioner. Where county commissions are appointed by Supreme Court Judges, the latter would do well to select one or more progressive medical men to serve on the commission, because such men can usually be depended on to be intelligent and unselfish in their desire to relieve the people from the pest.

Mr. Rutherfurd refers to the problem of Connecticut and to a Bill placing the marsh-drainage work and $200 000 in funds in the hands of the Director of the State Agricultural Station. The conditions in Connecticut are peculiar, fully 75% of the population being affected by a mosquito pest breeding along the borders of the State. There is hardly a county which will not be benefited by the elimination of the salt-marsh pest; it is a State nuisance, and a good beginning will be made by the passage of the Bill.

The writer endorses Mr. Britton's suggestion, in which he states that "a great educational campaign is needed." During the season of 1912 the Essex County Mosquito Extermination Commission issued 50 000 cards to be hung in houses. These cards illustrate how mosquitoes breed, and give methods for the prevention of breeding.

The real value of an educational campaign, however, is in moulding public opinion to uphold organized effort for anti-mosquito work. One error frequently made is to expect that people when they know how the mosquito pest can be eliminated, will look after their own premises individually. Experience during ten years has taught the writer that less than 5% of the population will do anything of the sort. No better illustration of that can be found than the fact that the inspectors employed by the Essex County Mosquito Extermination Commission found mosquitoes breeding in the rear of the writer's stables.

Mr. Miller.

In reference to the cost of anti-mosquito work, the following data may serve as a rough basis for making estimates:

1. Port Said, with 50 000 population and compactly built, controls its mosquito pest for 12 cents per inhabitant per annum. Ismailia, an open village, with 10 000 population, expends 50 cents per inhabitant per annum.

2. Klang and Port Swettenham, 5 miles apart, have a combined population of 3 000 and spend $4.72 per inhabitant.

3. Mr. Means, in his discussion, refers to anti-mosquito work in the Sacramento Valley, Cal., in a territory of about 10 000 acres and 1 200 people at $3 per inhabitant per annum. This, however, is only 36 cents per acre per annum.

4. The estimated cost for the Borough of Brooklyn (Kings County), with a population of 1 700 000, is 10 cents per inhabitant per annum.

5. In South Orange, N. J., a suburban community of 5 000 population, the cost of effective work is about 30 cents per inhabitant per annum, or an average of $1.50 per acre per annum.

6. The estimated cost of keeping New Jersey reasonably free from the pest is 29 cents per inhabitant per annum, or an average of 13 cents per acre. This sum is provided for under the New Jersey law quoted in the paper.

7. In Panama, the entire sanitation of the Canal Zone costs approximately $2.43 per inhabitant per annum, and the cost per acre is $1.14. (This is about 1% of the cost of the Canal.) The breeding season is twice as long as that in the latitude of New York or Washington, and probably only one-half of the sum expended was for anti-mosquito work. In order to compare the Panama Canal Zone with New Jersey, these costs must be divided by two, to separate the mosquito work from other sanitary work; and by two again, because the breeding season is twice as long in Panama; and again by two, to compensate for the vast difference in rainfall. The result is 31 cents per inhabitant, or 14 cents per acre per annum.

TRANSACTIONS

Paper No. 1258.

THE THEOREM OF THREE MOMENTS.

By J. P. J. Williams, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Milo S. Ketchum and J. P. J. Williams.

The design of continuous beams, plate-girder draw spans, and swing-bridge trusses is based on the values of reactions and bending moments found by the use of a restricted form of the theorem of three moments, neglecting shear deflection. Theoretically, this usual restricted form applies only to beams built to conform accurately to the supports, which are assumed to be perfectly rigid and without possible settlement, and to beams with constant moments of inertia, and straight over the intermediate support. In practice, these conditions are never completely fulfilled. It is desirable, therefore, to determine the approximate value of the error introduced in such common practice. A complete general form of the theorem of three moments will be derived, and its application to a plate-girder draw span with variable moments of inertia will be made, in order to find the percentage of error introduced by the use of the usual formula. The theoretical maximum limit of the error thus introduced for such a typical case will be shown to be about 16.8% on the side of danger. Several fundamental and general relations for continuous beams will be given as the basis of the derivation, and also a direct derivation of the usual restricted form of the theorem. The subject matter will be divided into sections as follows:

Section 1.—The Continuous Beam.—Definition and Use of the Theorem of Three Moments.

Section 2.—Methods of Derivation.

Section 3.—General Deflection Equations for Curved Beams and Arches.
Section 4.—Application to Fixed-Ended Arches.
Section 5.—Application to Simple Beams.
Section 6.—Fundamental General Relation for Continuous Beams.
Section 7.—General Values of Bending Moments, Shears, and Reactions, for Any Span of a Continuous Beam.
Section 8.—Derivation of the Usual Restricted Form of the Theorem of Three Moments.
Section 9.—Effect of Settlement of Supports.
Section 10.—Derivation of the Complete General Form of the Theorem of Three Moments.
Section 11.—Application to Plate-Girder Draw Span with Variable Moment of Inertia.

Section 1.—The Continuous Beam.—Definition and Use of the Theorem of Three Moments.

The continuous beam resting on n supports, at which positive or negative reactions are developed, presents a problem in which the reactions are statically indeterminate. As n unknown reactions are to be found, and only two fundamental equations of static equilibrium are available, the solution of the problem requires $n - 2$ additional equations. The theorem of three moments, which was developed in its original form by Clapeyron in 1857, makes it possible to write the $n - 2$ equations required, and thus solve the problem. It is based on the relation between the elastic distortion in adjacent spans caused by the bending moments in those spans.

Definition of Theorem.—The theorem of three moments is expressed as an equation giving the algebraic relation which exists between the bending moments at any three consecutive supports of a continuous beam and the loading on the two included spans.

This algebraic relation is thus seen to be independent of the loading on the other spans outside of the two adjacent spans considered. It is directly affected by any movement or settlement of the supports, and the general form contains terms which give the effect of such settlement or of nonconformity to supports before loading. The application of the theorem equation to the $n - 2$ pairs of adjacent spans of a continuous beam with n supports, will give $n - 2$ simultaneous equations in terms of the bending moments at the supports and the load-

ing. The two end bending moments being known, there are only $n - 2$ unknown bending moments, which, therefore, can be found at once either by algebraic solution or by the use of determinants. These bending moments at the supports being known, it is possible to find the reactions, also the shear and the bending moment for any span.

Section 2.—Methods of Derivation.

The theorem of three moments may be derived in either of two ways: First, the general bending-moment equation, $M = E\ I\ \frac{d^2y}{dx^2}$, found by the common theory of flexure, can be used to find the slope, $\frac{dy}{dx}$, at the intermediate support, and the values as found from the equations for the two adjacent spans equated when the beam is straight over the intermediate support. Second, a more general fundamental relation between the end deflections for the two adjacent spans, when the beam is not straight, can be derived from the fact that the angle between the tangents at the intermediate support will remain constant, and this relation may be used in the derivation.

The first method is usually given in textbooks, and results only in the restricted form of the theorem. The second method is used by F. E. Turneaure,* Assoc. M. Am. Soc. C. E., for a straight beam with constant moment of inertia, also by W. H. Burr,† M. Am. Soc. C. E., for the perfectly general case of any curved beam. This second method will be applied here, both for the derivation of the restricted form and for the general form of the theorem. It is based directly on a general formula giving the relative vertical deflection, D_v, of any point due to bending, in terms of the bending moments along the beam. This general deflection formula will now be derived.

Section 3.—General Deflection Equations for Curved Beams and Arches.

Let Fig. 1 represent a perfectly general case of a fixed-ended arch subjected to elastic bending stress throughout its length. By assuming a very short length, $N_1\ N = n$, the value of the bending moment, M, can be considered as practically constant throughout such length and equal to its value at, say, N; also, the summations and co-

* "Modern Framed Structures," Vol. II.

† "Elasticity and Resistance of Materials."

ordinates can be taken from N_1 or N, indiscriminately. The differential amount of the deflection of any other point, O, can then be found by considering the movement of the chord, NO, due to the elastic bending in the short length, $N_1 N = n$. For the total deflection caused by elastic bending in the whole length, $N_1 O$ or NO, the summation of these differential deflections can be made. In this manner the general equations for change in angle, and for horizontal and vertical components of total deflection due to elastic bending, can now be derived.

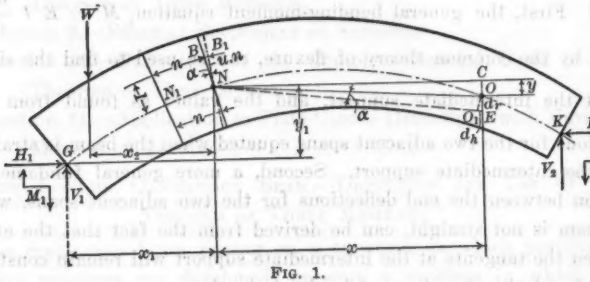

FIG. 1.

Notation.—The notation is indicated by Fig. 1, and also:

n = any small length, $N_1 N$, along neutral axis (theoretically, a differential length; practically, often some convenient length).

M = the general value of the bending moment at any given point, N, considered as an average value for the distance, n, namely, $M = M_1 + V_1 x_1 - H_1 y_1 - \Sigma W x_2$.

α = a small angle in radians between the plane normal section, $N B$, before bending, and its position, $N B_1$, after bending has occurred in the distance, n. The slight effect of variation in distance, $N_1 N$, when the normal planes at N_1 and at N are not parallel, is negligible.

$A = \sum_{O}^{N} \alpha$ = the total angular change = the change in angle between the end tangents at N and O.

d_h and D_h = the differential and total horizontal components of deflection of O, referred to a fixed tangent at N.

d_v and D_v = the corresponding vertical components of deflection of O.

u = the rate of strain at a unit distance from the neutral axis.

f_1 = the intensity of stress at a unit distance from the neutral axis.

E = the coefficient of elasticity.

I = the moment of inertia of the normal section, $N\ B$ = the average for all normal sections in length, n.

Drawing the chord, NO, N is taken as the instantaneous center for the revolution of the point, O, due to bending in the length, n, only, and since no bending occurs yet in the length, NO, the chord remains at a constant angle with the normal plane, NB, and revolves with that plane through the angle, α. OO_1 then represents the deflection of O due to bending in the length, n, and d_h and d_v, the two components of such deflection, are $O_1\ E$ and $O\ E$, respectively.

Now, by the definition of the rate of strain, u:

$$B\ B_1 = un;$$

and, by the common theory of flexure,

$$M = f_1 I = u\ EI. \quad \text{Therefore, } u = \frac{M}{EI} \ldots\ldots\ldots\ldots (1)$$

From the triangle, NBB_1, as α is small:

$$\alpha = \text{tan. } \alpha = u\,n \ldots\ldots\ldots\ldots (2)$$

Therefore, from Equation (1):

$$\alpha = \frac{Mn}{EI} \ldots\ldots\ldots\ldots (3)$$

Then the total summation of these angular changes in length, ON, would be:

$$A = \sum_{o}^{N} \alpha = \sum_{o}^{N} \frac{Mn}{EI} \ldots\ldots\ldots\ldots (4)$$

Considering the similar triangles, $OO_1\ E$ and OCN:

$$\frac{O_1E}{OO_1} = \frac{OC}{ON}; \text{ therefore, } d_h = O_1E = \frac{OO_1\ OC}{ON} = \frac{OO_1}{ON}\ y.$$

$$\text{Also, } \frac{OE}{OO_1} = \frac{NC}{ON}; \text{ therefore, } d_v = OE = \frac{OO_1\ NC}{ON} = \frac{OO_1}{ON}\ x.$$

But $\frac{OO_1}{ON} = \text{tan. } \alpha = \alpha = \frac{Mn}{EI}$, from Equation (3), which, when substituted in the above values for d_h and d_v, will give:

$$d_h = \frac{Mn}{EI}\ y \ldots\ldots\ldots\ldots (5)$$

$$d_v = \frac{Mn}{EI}\ x \ldots\ldots\ldots\ldots (6)$$

The total deflections, D_h and D_v, of the point, O, due to bending in the length, ON, therefore, will be the summation of these elementary deflections, giving:

$$D_h = \sum_O^N \frac{Mn}{EI} y \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

$$D_v = \sum_O^N \frac{Mn}{EI} x \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

It should be clearly understood that the values obtained by making the summations indicated in Equations (4), (7), and (8) will give the resulting effects of bending in the length, ON or ON_1, only. If bending occurs outside the portion, ON or ON_1, considered, it causes a deflection of both O and N or N_1, and affects their relative deflection with respect to each other. Therefore, Equations (7) and (8) give the relative horizontal and vertical deflections of O, with respect to N or N_1, only when the bending does not change the position of the original normal plane of reference at N or N_1. As a tangent to the neutral axis at N or N_1 is perpendicular to such normal plane, it follows that both tangent and normal plane at the end, N or N_1, of the section considered must remain fixed if such equations are to give relative total deflections.

The origin for the co-ordinates, x and y, is at O, the point for which the deflection is being found. It is evident that this is really a moving point, as it is being deflected, but the relative amount of such deflection is insignificant in comparison with the values of x and y.

Section 4.—Application to Fixed-Ended Arches.

Perhaps the most important application of General Equations (4), (7), and (8), is to the case of the fixed-ended concrete or reinforced concrete arch, which is statically indeterminate to the third degree, there being six unknowns and only three fundamental equations of equilibrium, $\Sigma H = 0$, $\Sigma V = 0$, and $\Sigma M = 0$. Such an arch is assumed to have fixed end tangents and to sustain no relative deflections, either horizontal or vertical, between the ends, that is, the abutments are assumed to be absolutely rigid at G and K, Fig. 1. Such assumptions would make the values of Equations (4), (7), and (8), each equal to zero, when the summations are made for the total length,

G to K, giving the following three fundamental equations for elastic equilibrium, which make the problem determinate:

From Equation (4), $$\sum_G^K \frac{Mn}{EI} = 0 \quad \ldots\ldots\ldots\ldots (9)$$

From Equation (7), $$\sum_G^K \frac{Mn}{EI} y = 0 \quad \ldots\ldots\ldots (10)$$

From Equation (8), $$\sum_G^K \frac{Mn}{EI} x = 0 \quad \ldots\ldots\ldots (11)$$

It should be noted that these equations are based on deflections due to bending only, and do not account for the effect of direct thrust, shear, or temperature changes.

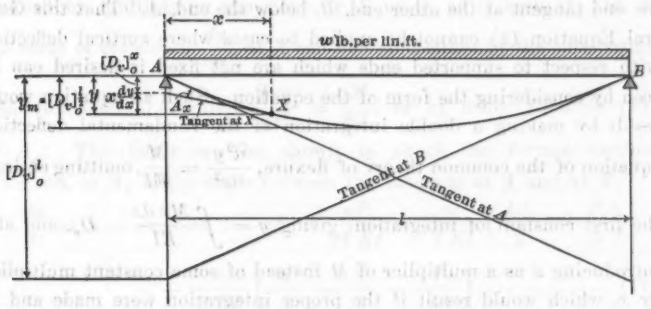

FIG. 2.

SECTION 5.—APPLICATION TO SIMPLE BEAMS.

In order to illustrate the use of Equation (8), giving the relative vertical deflection, D_v, before applying it to the case of the continuous beam, consider the simple beam uniformly loaded, as in Fig. 2. E and I will be assumed as constant and $n = dx$. Then Equation (8) becomes $D_v = \frac{1}{EI}\int_0^x Mx\,dx$, in general for the length, AX. The general value of M, for uniform load, w, per foot, is:

$$M = \frac{w}{2}\, x\,(l - x).$$

Therefore, $$[D_v]_0^x = \frac{w}{2\,EI}\int_0^x (l-x)\,x^2\,dx = \frac{w}{2\,EI}\left[\frac{lx^3}{3} - \frac{x^4}{4}\right] \ldots (12)$$

If the integration is made for the half length, the maximum deflection, y_m, is obtained:

$$[D_v]_0^{\frac{l}{2}} = y_m = \frac{w}{2\,EI}\left[\frac{l^4}{24} - \frac{l^4}{64}\right]$$

or,

$$y_m = \frac{5\,wl^4}{384\,EI} \qquad (13)$$

If the integration is made for the whole length:

$$[D_v]_0^l = \frac{w}{2\,EI}\left[\frac{l^4}{3} - \frac{l^4}{4}\right] = \frac{wl^4}{24\,EI} \qquad (14)$$

It is thus evident that the expression for D_v, when integrated for the total length, l, of a simple span, will not give zero (the relative deflection of the ends), but the value of the vertical movement of the end tangent at the other end, B, below the end, A. That this General Equation (8) cannot be applied to cases where vertical deflection with respect to supported ends which are not fixed is desired can be seen by considering the form of the equation. Such an equation would result by making a double integration of the fundamental deflection equation of the common theory of flexure, $\frac{d^2y}{dx^2} = \frac{M}{EI}$, omitting entirely the first constant of integration, giving $y = \int \frac{Mx\,dx}{EI} = D_v$, and also introducing x as a multiplier of M instead of some constant multiplied by x, which would result if the proper integration were made and M contained terms in x.

The second constant of integration which would now be introduced in either case is always zero, as $y = 0$ when $x = 0$. The first constant of integration is really the value of the slope, $\frac{dy}{dx}$, of the end tangent at the origin, A.

From Equation (14) it is seen that the end tangent at B has a slope, $\frac{wl^4}{24\,EI} \div l = \frac{wl^3}{24\,EI}$. This value can be checked by the ordinary equations of deflection for such a beam, found by integrating the fundamental equation, $\frac{d^2y}{dx^2} = \frac{M}{EI}$, and will be the first constant of integration. It can also be checked by using Equation (4) for change in angle, A, because, for small angles, tan. $A = A$. In general, when $n = dx$ and $E\,I$ is constant, Equation (4) gives:

$$A_x = \int_0^x \frac{M dx}{EI} = \frac{w}{2\,EI}\int_0^x (l - x)\, x dx = \frac{w}{2\,EI}\left[\frac{lx^2}{2} - \frac{x^3}{3}\right] \ldots\ldots (15)$$

The slope of the end tangent at B with respect to the horizontal tangent at the center is then found by integrating from 0 to $\frac{l}{2}$, that is let $x = \frac{l}{2}$ in Equation (15),

$$A = \frac{dy}{dx} = \frac{w}{2\,EI}\left[\frac{l^3}{8} - \frac{l^3}{24}\right] = \frac{wl^3}{24\,EI} \ldots\ldots\ldots (16)$$

The total deflection, y, at any point, x, is not given by the D_v Equation (12), but can be found by adding to $\left[D_v\right]_0^x$ the quantity obtained by multiplying the slope at X by x, as is seen in Fig. 2. The value of the slope, $\frac{dy}{dx}$, at X can be found either by the integration of the fundamental equation, $\frac{d^2y}{dx^2} = \frac{M}{EI}$, or by using Equation (15) for A_x. The latter can be shown to check the former method as follows, as A_x is the angle between the tangents at A and at X:

$$\frac{dy}{dx} \text{ at } X = \text{slope at } A - A_x = \frac{wl^3}{24\,EI} - \frac{w}{2\,EI}\left(\frac{lx^2}{2} - \frac{x^3}{3}\right)$$

$$= -\frac{w}{2\,EI}\left[\frac{lx^2}{2} - \frac{x^3}{3} - \frac{l^3}{12}\right] \ldots\ldots\ldots\ldots (17)$$

Equation (17) checks the value obtained by general integration, but with opposite sign.

The total deflection, y (using Equations (12) and (17)), therefore, is:

$$y = \left[D_v\right]_0^x + x\left(\frac{dy}{dx} \text{ at } X\right) = \frac{w}{2\,EI}\left[\frac{lx^3}{3} - \frac{x^4}{4} - \frac{lx^3}{2} + \frac{x^4}{3} + \frac{l^3 x}{12}\right]$$

Therefore, $y = -\frac{w}{24\,EI}\left[2\,lx^3 - x^4 - l^3 x\right] \ldots\ldots\ldots\ldots (18)$

Equation (18) checks the value obtained by general integration, but with opposite sign.

It should be explained that the difference in sign is due to the fact that the D_v Equation gives positive values for deflection when the

positive bending moment occurs, while, in the notation for deflection by the general integration of $\frac{d^2 y}{dx^2} = \frac{M}{EI}$, the deflection is downward or negative for the positive bending moment.

It is also important to observe that the origin for x in the D_v Equation is at the deflecting point, the result being positive if that point has deflected upward with respect to the tangent at the other end of the section considered. No constants of integration are introduced in the foregoing, as they are zero.

Whenever concentrated loads occur, it is necessary to make separate integrations for each segment of the beam, because the law of variation of the bending moment with x will change at each load.

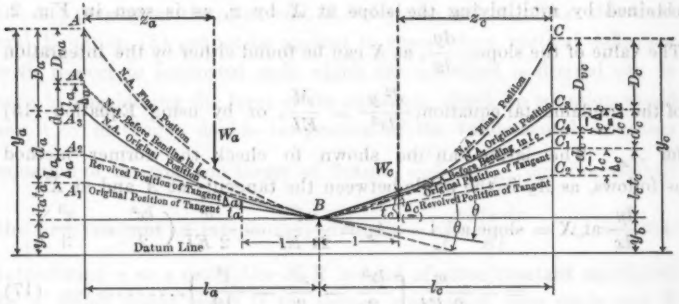

FIG. 3.

The deflection, $y_m - y$, at any point, X, cannot be obtained from the integrated value for D_v in Equation (12), because the origin for x is not at X. The bending moment, M, must first be written in terms of x_1 (say) with X as the origin, and the integration made by the General Equation, $D_v = \int \frac{Mx\,dx}{EI}$. If, however, the bending moment, M, is constant in the section considered, as, for instance, in the case of a simple beam loaded with two symmetrical concentrated loads, the deflection between the center and the load on either side can be obtained by Equation (12), because M has the same value regardless of the origin used.

SECTION 6.—FUNDAMENTAL GENERAL RELATION FOR CONTINUOUS BEAMS.

Consider two adjacent spans, l_a and l_c, of any continuous beam with a curved neutral axis (N. A. Fig. 3) resting only on the interme-

diate support, B, before the application of loads. Neglecting the effect of deflection due to shear, a fundamental equation based on the fact that the tangents to the neutral axes at B, for the two adjacent spans, remain at a constant fixed angle with each other, may be derived as follows:

Let t_a = the tangent of the angle between the original position of the tangent at B for the span, l_a, and the horizontal.

Δ_a = the change in t_a due to the rotation of the tangent at B.

D_a = the vertical distance from the original position of the neutral axis to the support, A, + if upward.

d_a = the vertical distance at A between the original tangent and the original neutral axis.

D_{va} = the total vertical deflection of the neutral axis at A due to bending in the span, l_a, only, that is,

$$D_{va} = \sum_A^B \frac{Mnx}{EI}.$$

t_c, Δ_c, D_c, d_c, D_{vc} = the corresponding quantities for the span, l_c, as shown.

y_a, y_b, and y_c = the elevations of the supports, A, B, and C.

The vertical movement, D_a, at A, between the original and final positions of the neutral axis, is seen to be composed of two parts: First, the movement, $A_3\ A_4$, due to the rotation of the tangent at B; and second, the movement or deflection, $A_4\ A$, due to the bending in the span, l_a, with respect to the tangent at B. This rotation of the tangent at B would certainly occur in the general case. The bending deflection for the span, l_a, only, is not equal to the total movement, D_a, except for the special case of symmetry about B such that no movement of the tangents at that point would take place.

From a consideration of Fig. 3, it is seen that the vertical movement at A between the original and final positions of the tangent is $A_1\ A_2 = l_a\ \Delta_a$; and the corresponding movement of the neutral axis vertically at A is $A_3\ A_4$, and also $= l_a\ \Delta_a$, because d_a remains practically constant. The bending deflection, $D_{va} = A_4\ A$, in the span, l_a, is the other portion of the movement, $A_3\ A$, of the neutral axis to bring it to the support at A. This deflection, by Equation (8), is:

$$D_{va} = \sum_A^B \frac{Mnx}{EI}.$$

If the $+ M$ terms are greater than the $- M$ terms, D_{va} is $+$ or upward, as shown. Note that the origin is at A.

As θ is constant:

$$\Delta_a = -\Delta_c \quad \ldots\ldots (19)$$

and, from Fig. 3,

$$D_{va} = D_a - l_a \Delta_a \quad \ldots\ldots (20)$$

Also,

$$D_{vc} = D_c - l_c \Delta_c = D_c + l_c \Delta_a \quad \ldots\ldots (21)$$

Solve Equations (20) and (21) for Δ_a, and equate:

$$\Delta_a = \frac{D_a - D_{va}}{l_a} = \frac{D_{vc} - D_c}{l_c}$$

whence,

$$\frac{D_a}{l_a} + \frac{D_c}{l_c} = \frac{D_{va}}{l_a} + \frac{D_{vc}}{l_c} \quad \ldots\ldots (22)$$

Substituting the values of D_{va} and D_{vc}:

$$\frac{D_a}{l_a} + \frac{D_c}{l_c} = \frac{\sum_A^B \frac{Mnx}{EI}}{l_a} + \frac{\sum_C^B \frac{Mnx}{EI}}{l_c} \quad \ldots\ldots (23)$$

Equation (23) is the fundamental and perfectly general equation by which the theorem of three moments can be developed by determining values for the summations indicated in the second member. As a check on Equations (22) and (23), consider the usual case of a horizontal beam resting on three supports, A B C. Assume a single load, W, on one span only; the final position of the neutral axis and the tangent at B would be as shown in Fig. 4. For this case, $D_a = 0$, $D_c = 0$, and Equation (22) gives:

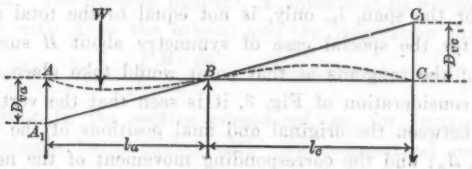

FIG. 4.

$$0 = \frac{D_{va}}{l_a} + \frac{D_{vc}}{l_c}; \text{ whence, } \frac{D_{va}}{l_a} = -\frac{D_{vc}}{l_c}.$$

This agrees with the result of considering the similar triangles, $AA_1 B$ and BCC_1, as D_{vc} would be negative.

FIG. 5.

SECTION 7.—GENERAL VALUES OF BENDING MOMENTS, SHEARS, AND REACTIONS, FOR ANY SPAN OF A CONTINUOUS BEAM.

Consider any span, AB, of a continuous beam, Fig. 5, and let:

M_a = the bending moment at A (from the theorem of three moments).

M_b = the bending moment at B (from the theorem of three moments).

M_s = the bending moment at X, due to the loading on l_a as a simple span.

M = the total bending moment at X.

S_L = the reaction at A from the span to the left of A = — shear to the left of A.

S_a = the reaction at A from the span, l_a = shear to the right of A

S_R = the reaction at B from the span to the right of B = shear to the right of B.

S_b = the reaction at B from the span, l_a = — shear to the left of B

R_{sa} = the reaction at A from the span, l_a, as a simple beam.

R_{sb} = the reaction at B from the span, l_a, as a simple beam.

$R_a = S_L + S_a$ = the total reaction at A.

$R_b = S_b + S_R$ = the total reaction at B.

To find the value of S_a, for the given span, write the equation for the value of the bending moment at $B = M_b$, considering all forces acting on the span, l_a:

$$M_b = M_a + S_a l_a - w_a \frac{l_a^2}{2} - W_a (l_a - z_a) \quad \ldots\ldots\ldots (24)$$

Solving for S_a:

$$S_a = \frac{M_b - M_a}{l_a} + \frac{w_a l_a}{2} + W_a \frac{l_a - z_a}{l_a} = \frac{M_b - M_a}{l_a} + R_{sa} \quad \ldots (25)$$

Note that if $M_a = M_b$, $S_a = R_{sa}$.

Similarly:

$$S_b = \frac{M_a - M_b}{l_a} + R_{sb} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Or, S_b = (the total loading on l_a) — S_a $\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$ (26a)

The values of M_a and M_b are first found from the theorem of three moments, and are generally negative. The sign must always be included in making substitutions in the foregoing formulas.

Having found the values of S_a and S_b for adjacent spans, the reactions are at once found by addition, noting that S_L = the S_b for the span on the left, and S_R = the S_a for that on the right.

The general value for M, at any point, X, can be stated in two ways:

First, $M = M_a + S_a\, x$ — (moment of loads on l_a to left of X about X).....(27)

Second, $M = \dfrac{M_a\,(l_a - x)}{l_a} + \dfrac{M_b\, x}{l_a} + M_s$.....(28)

This second form is seen to result at once from similar triangles in Fig. 4, and shows that M can be considered as composed of three distinct parts: (a) that due to M_a; (b) that due to M_b; and (c) that due to loads on l_a as a simple beam. The terms due to (a) and (b) can also be explained by noting that these end bending moments produce vertical couples; $+ M_a$ produces a force $+ \dfrac{M_a}{l_a}$ at B, and $- \dfrac{M_a}{l_a}$ at A, and similarly, M_b gives a force couple $+ \dfrac{M_b}{l_a}$ at A, and $- \dfrac{M_b}{l_a}$ at B. These forces produced as vertical couples to balance M_a and M_b also explain the form of Equations (25) and (26) for S_a and S_b.

SECTION 8.—DERIVATION OF THE USUAL RESTRICTED FORM OF THE THEOREM OF THREE MOMENTS.

For the usual practical case, the beam is straight, rests on the supports, may slope at an angle, B, with the horizontal, and E and I are assumed as constant throughout the entire length. For such a case, then:

$D_a = 0$, $D_c = 0$, $n = dx$ sec. B, and Equation (23) becomes:

$$0 = \frac{\displaystyle\int_0^{l_a} \frac{M\, x\, dx \text{ sec. } B}{EI}}{l_a} + \frac{\displaystyle\int_0^{l_c} \frac{M\, x\, dx \text{ sec. } B}{EI}}{l_c}$$

As sec. B, E, and I, are constant, they can be multiplied out, and

$$\int_0^{l_a} \frac{M\, x\, dx}{l_a} + \int_0^{l_c} \frac{M\, x\, dx}{l_c} = 0 \qquad \text{.....(29)}$$

To integrate $\displaystyle\int_0^{l_a} M\, x\, dx$, substitute for M the general value from Equation (28),

$$\int_0^{l_a} M\,x\,dx = \frac{M_a}{l_a}\int_0^{l_a}(l_a - x)\,x\,dx + \frac{M_b}{l_a}\int_0^{l_a} x^2\,dx + \int_0^{l_a} M_s\,x\,dx. \quad (30)$$

The first term becomes, $\frac{M_a}{l_a}\left[\frac{l_a\,x^2}{2} - \frac{x^3}{3}\right] = \frac{M_a\,l_a{}^2}{6}$;

the second term becomes, $\frac{M_b}{l_a} \times \frac{l_a{}^3}{3} = \frac{2\,M_b\,l_a{}^2}{6}$.

The third term in M_s consists of three parts: First, the bending moment in the segment, z_a, due to the concentrated load, W_a, that is, $\frac{W_a\,(l_a - z_a)}{l_a}\,x$; second, the bending moment in the segment, $l_a - z_a$, due to the concentrated load, W_a, that is, $\frac{W_a\,z_a}{l_a}\,(l_a - x)$; and third, the bending moment at any point due to the uniform load, w_a, that is, $\frac{w_a\,x}{2}\,(l_a - x)$.

Using these values, the third term then becomes:

$$\int_0^{l_a} M_s x\,dx = \frac{W_a}{l_a}\left[\int_0^{z_a}(l_a - z_a)\,x^2\,dx + z_a\int_{z_a}^{l_a}(l_a - x)\,x\,dx\right] +$$

$$\frac{w_a}{2}\int_0^{l_a}(l_a - x)\,x^2\,dx = \frac{W_a}{l_a}\left[(l_a - z_a)\,\frac{z_a{}^3}{3}\right.$$

$$\left. + z_a\left(l_a\frac{x^2}{2} - \frac{x^3}{3}\right)_{z_a}^{l_a}\right] + \frac{w_a}{2}\left[l_a\frac{x^3}{3} - \frac{x^4}{4}\right]_0^{l_a} = \frac{W_a}{l_a}\left[\frac{l_a\,z_a{}^3}{3}\right.$$

$$\left. - \frac{z_a{}^4}{3} + \frac{z_a\,l_a{}^3}{2} - \frac{z_a\,l_a{}^3}{3} - \frac{l_a\,z_a{}^3}{2} + \frac{z_a{}^4}{3}\right] + \frac{w_a\,l_a{}^4}{24}$$

$$\int_0^{l_a} M_s\,x\,dx = \frac{W_a\,z_a}{6}\,(l_a{}^2 - z_a{}^2) + \frac{w_a\,l_a{}^4}{24} \quad \ldots\ldots\ldots (31)$$

Substituting the foregoing values in Equation (30):

$$\int_0^{l_a} M\,x\,dx = \frac{M_a\,l_a{}^2 + 2\,M_b\,l_b{}^2 + W_a\,z_a\,(l_a{}^2 - z_a{}^2) + \frac{w_a\,l_a{}^4}{4}}{6} \quad \ldots (32)$$

By analogy, for the span, l_c;

$$\int_0^{l_c} M\,x\,dx = \frac{M_c\,l_c{}^2 + 2\,M_b\,l_c{}^2 + W_c\,z_c\,(l_c{}^2 - z_c{}^2) + \frac{w_c\,l_c{}^4}{4}}{6} \quad \ldots (34)$$

Substituting these values in Equation (29), eliminating the factor, 6, and transposing:

$$M_a\,l_a + 2\,M_b\,(l_a + l_c) + M_c\,l_c = -\,\Sigma\,W_a\,\frac{z_a}{l_a}\,(l_a{}^2 - z_a{}^2)$$

$$-\,\Sigma\,W_c\,\frac{z_c}{l_c}\,(l_c{}^2 - z_c{}^2) - \frac{w_a\,l_a{}^3}{4} - \frac{w_c\,l_c{}^3}{4} \quad \ldots\ldots (35)$$

The terms in W_a and W_c have the summation sign introduced in order to account for all such concentrated loads on the spans. Equation (35) is the usual restricted form of the theorem of three moments, and is used in general for all cases of continuous beams, even for swing-bridge trusses, where the neutral axis is not straight and the moment of inertia is not constant.

SECTION 9.—EFFECT OF SETTLEMENT OF SUPPORTS.

The foregoing form of the theorem assumes that the beam just rests on rigid supports. If the supports should settle, the values, D_a and D_c, would no longer be zero, but would be equal to the amount of such relative settlement. Assuming the beam to be straight, but having a slope, B, with the horizontal, Equation (23) becomes (as EI and sec. B are constant, n being equal to dx sec. B):

$$\frac{EI}{\text{sec. } B}\left[\frac{D_a}{l_a}+\frac{D_c}{l_c}\right]=\int_0^{l_a}\frac{M\,x\,dx}{l_a}+\int_0^{l_c}\frac{M\,x\,dx}{l_c} \quad \ldots.(36)$$

The second member of this equation is the same as that in Equation (29), which has been integrated in Equation (35). Thus, the only difference between Equation (35) and this case, is that the term, $\frac{6\,EI}{\text{sec. } B}\left[\frac{D_a}{l_a}+\frac{D_c}{l_c}\right]$, must be added, the factor, 6, having been multiplied out in getting Equation (35). The equation would then be:

$$M_a\,l_a+2\,M_b\,(l_a+l_c)+M_c\,l_c=-W_a\,\frac{z_a}{l_a}\,(l_a^2-z_a^2)$$

$$-W_c\,\frac{z_c}{l_c}\,(l_c^2-z_c^2)\;-\frac{w_a\,l_a^3}{4}-\frac{w_c\,l_c^3}{4}+\frac{6\,EI}{\text{sec. } B}\left[\frac{D_a}{l_a}+\frac{D_c}{l_c}\right]. \quad .(37)$$

This last term would be large, as it contains the multiplier, $E\,I$, and would be additive in effect if D_a and D_c were negative, that is, when the end supports settled downward with respect to the intermediate support.

All computations for bending moments, M, are made in foot-pounds or foot-kips, therefore the last term should be put in form for such computation by dividing by 12^2, as E and I are in inches, and D_a and D_c are in feet. Therefore, the last term of Equation (37) becomes:

$$\frac{EI}{24\text{ sec. } B}\left[\frac{D_a}{l_a}+\frac{D_c}{l_c}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(37a)$$

For the usual case of a horizontal beam, sec. $B = 1$.

SECTION 10.—DERIVATION OF THE COMPLETE GENERAL FORM OF THE THEOREM OF THREE MOMENTS.

The most general form of the theorem of three moments, applicable to any curved continuous beam with a variable moment of inertia and not originally resting on all supports, can be derived directly from the fundamental Equation (23). It is only necessary to obtain a general working form for the summations appearing in the second member of that equation, as follows:

Using the general value for M, as derived for Equation (18), there results:

$$\sum_A^B \frac{Mn\,x}{EI} = \sum_A^B \left[\frac{M_a}{l_a}(l_a - x) + \frac{M_b\,x}{l_a} + M_s\right]\frac{n\,x}{EI} \quad \ldots (38)$$

Let $n = dx$ sec. β, and assume E to be constant, then:

$$\sum_A^B \frac{Mn\,x}{EI} = \frac{1}{l_a E}\left[M_a \sum_A^B (l_a - x)\,x\,dx\,\frac{\text{sec. }\beta}{I} + M_b \sum_A^B x^2\,dx\,\frac{\text{sec. }\beta}{I} + l_a \sum_A^B M_s\,x\,dx\,\frac{\text{sec. }\beta}{I}\right] \ldots\ldots (39)$$

By analogy, for span, l_c:

$$\sum_C^B \frac{Mn\,x}{EI} = \frac{1}{l_c E}\left[M_c \sum_C^B (l_c - x)\,x\,dx\,\frac{\text{sec. }\beta}{I} + M_b \sum_C^B x^2\,dx\,\frac{\text{sec. }\beta}{I} + l_c \sum_C^B M_s\,x\,dx\,\frac{\text{sec. }\beta}{I}\right] \ldots\ldots (40)$$

By substituting the foregoing values in Equation (23), the following General Equation results:

$$E\left(\frac{D_a}{l_a} + \frac{D_c}{l_c}\right) = \frac{M_a}{l^2_a}\sum_A^B (l_a - x)\,x\,dx\,\frac{\text{sec. }\beta}{I} + M_b\left(\frac{\sum_A^B x^2\,dx\,\frac{\text{sec. }\beta}{I}}{l^2_a} + \frac{\sum_C^B x^2\,dx\,\frac{\text{sec. }\beta}{I}}{l^2_c}\right) + \frac{M_c}{l^2_c}\sum_C^B (l_c - x)\left(x\,dx\,\frac{\text{sec. }\beta}{I}\right) + \frac{\sum_A^B M_s\,x\,dx\,\frac{\text{sec. }\beta}{I}}{l_a} + \frac{\sum_C^B M_s\,x\,dx\,\frac{\text{sec. }\beta}{I}}{l_c} \quad \ldots (41)$$

This equation is the most general form of the theorem of three moments. Whenever the variables, sec. β and I, can be expressed as continuous functions of x, the summation sign can be replaced by the integration sign, and the mathematical integration can be made. Practically, it is generally found impossible to express these variables as continuous functions of x, and then make the integrations.

Usually, I is constant for short sections of the beam, in which case it is best to make successive summations for such sections, using the general form of the integration, with I constant, and making the limits correctly account for the variation in I for different sections. This method will now be illustrated by a practical example.

SECTION 11.—APPLICATION TO PLATE-GIRDER DRAW SPAN WITH VARIABLE MOMENT OF INERTIA.

As an example of the practical method of using the general Equation (41), and also in order to determine the effect of the variable moment of inertia, consider the following case of a plate-girder span continuous over three supports. This is the same girder as used by Johnson, Bryan, and Turneaure* to illustrate the use of a similar formula obtained by applying the principle of least work. It is used here in order to find how closely the results of the different methods agree.

Data for Girder.— $l = l_a = l_c = 60$ ft., that is, the total length $= 120$ ft. The girder is symmetrical about its center line.

The relative values of the moment of inertia, I, at the following distances from the outside ends, are:

0 to 12 ft., $I = 1$
12 to 36 ft., $I = 1.38$
36 to 48 ft., $I = 1.15$
48 to 60 ft., $I = 1.92$

The girder rests on all the supports, and has a straight horizontal neutral axis, therefore, $D_a = 0$, $D_c = 0$, sec. $\beta = 1$.

The end bending moments are zero, therefore, $M_a = 0$, $M_c = 0$.

Noting the fact of the constant, I, for the given sections, let x_1 and x_2 be the distances from the end of the girder to the beginning and the end, respectively, of a given section having a constant, I, and let $\frac{1}{I} = i$ for such section. Then, by substituting in the General Equation (41), there results, after multiplying through by l^2:

$$0 = M_b \left[\sum_A^B \int_{x_1}^{x_2} i\, x^2\, dx + \sum_C^B \int_{x_1}^{x_2} i\, x^2\, dx \right] + l \left(\sum_A^B i\, M_s x\, dx + \sum_C^B i\, M_s x\, dx \right) \ldots\ldots\ldots (42)$$

* "Modern Framed Structures," Vol. II, p. 39.

For the case here considered, with a fully loaded beam carrying a uniform load, w lb. per ft., $M_s = \frac{w}{2} x\,(l - x)$. Therefore,

$$\sum i\,M_s\,x\,dx = \frac{w}{2} \sum \int_{x_1}^{x_2} i\,x^2\,(l - x)\,dx$$

$$= \frac{w}{2} \sum \Big[\, i\,x^3 \Big(\frac{l}{3} - \frac{x}{4}\Big)\,\Big]_{x_1}^{x_2}$$

Then Equation (42) will give the following value for M_b:

$$M_b = -\frac{3\,wl}{2} \frac{\sum_0^l \Big[\, i\,x^3 \Big(\frac{l}{3} - \frac{x}{4}\Big)\,\Big]_{x_1}^{x_2}}{\sum_0^l \Big[\, i\,x^3 \Big]_{x_1}^{x_2}} \qquad \text{(43)}$$

The computation can best be made in the form shown by Table 1.

TABLE 1.—COMPUTATION FOR M_b.

6-ft. Sections.	(1)	(2)	(3)	(4)	(5)	(6)		(7)	(8)	
	x					$\Big[\, i\,x^3 \Big]_{x_1}^{x_2}$		$\frac{l}{3} - \frac{x}{4}$	$\Big[\, i\,x^3 \Big(\frac{l}{3} - \frac{x}{4}\Big)\,\Big]_{x_1}^{x_2}$	
	x_1	x_2	I	i	x^2					
1-2	0	12	1.0	1.0	x_2 1 730	Columns 4 × 5 1 730	.....	17	Columns 6 × 7 29 400	
					x_1 0	— 0	1 730	20	0	29 400
3-4-5-6	12	36	1.38	0.725	x_2 46 700	33 700	.....	11	371 000	
					x_1 1 730	— 1 200	32 500	17	— 21 000	350 000
7-8	36	48	1.15	0.87	x_2 110 600	96 000	.....	8	768 000	
					x_1 46 700	—40 400	55 600	11	— 445 000	323 000
9-10	48	60	1.92	0.52	x_2 216 000	112 400	.....	5	562 000	
					x_1 110 600	—57 400	55 000	8	— 460 000	102 000
						Σ = 144 800			Σ = 804 400	

Then, $$M_b = -\frac{3}{2}\,wl \times \frac{804\,400}{144\,800} = -8.34\,wl.$$

For the given case, $l = 60$ ft.:

Therefore, $M_b = -8.34 \times 60\ w = -500\ w$.

When I is assumed as constant, as in the usual form of the theorem, let $l_a = l_c = l$, and $w_a = w_c = w$, in Equation (35),

$$2\ M_b\ (l + l) = -2\left(\frac{wl^3}{4}\right), \text{ whence,}$$

$$M_b = -\frac{wl^2}{8} = \frac{-w \times 60^2}{8} = -450\ w.$$

The exact method, therefore, gives a value for M_b about 11% higher than the approximate method, using the constant, I. The method of least work* gave $M_b = -492\ w$, about 2% less than the value here found by the exact method.

To Derive the Maximum Limit for Error.—The error introduced by using the general form of the theorem of three moments in such cases of girders with variable I, carrying the uniform load, and symmetrical over three supports, can be shown to be about 15% for the limiting case where I is assumed to vary directly with M, that is, for a theoretically perfect design, which, of course, is a practically impossible case.

The reaction, R_a, can be found by locating the point of contraflexure where the bending moment changes sign, and noting that the end shears for the equivalent simple beam, between points of contraflexure or zero bending moment, can be found exactly as in simple beam analysis. For the foregoing case of two equal spans loaded with equal uniform loads, the tangent at the intermediate support, B, remains fixed and horizontal. Therefore, if x_0 = distance from A to the point of contraflexure:

$$[D_{va}]_0^l = \int_0^l \frac{M\,x\,dx}{EI} = \int_0^{x_0} \frac{M\,x\,dx}{EI} - \int_{x_0}^l \frac{M\,x\,dx}{EI} = 0.$$

Now let $\frac{M}{I} = K$, substitute, and cancel the constants, $\left(\frac{K}{E}\right)$,

$$\int_0^{x_0} x\,dx = \int_{x_0}^l x\,dx$$

$$\frac{x_0^2}{2} = \frac{l^2}{2} - \frac{x_0^2}{2}. \quad \text{Therefore, } x_0 = \frac{l}{\sqrt{2}} = 0.707\ l.$$

(Note that $x_0 = 0.75\ l$, when I is assumed as constant.)

Then, $R_a = \frac{wx_0}{2} = 0.354\ wl$; and, $M_b = R_a\ l - \frac{wl^2}{2} = 0.354\ wl^2 - 0.5\ wl^2 = -0.146\ wl^2$.

* As applied in "Modern Framed Structures," Vol. II, p. 40.

As shown before, the usual form of theorem, with I assumed as constant, gives for this case:

$$M_b = -\frac{wl^2}{8} = -0.125\,wl^2.$$

Therefore, the approximate method gives results which are too low by a maximum limit of 15% of the exact value, or 16.8% of the approximate value.

The general conclusion that the usual approximate formula will give M_b from 10 to 15% too low, when applied to girder spans with widely varying moments of inertia, seems to be quite justifiable, the effect of shear deflection being neglected.

Two cases of swing-bridge girders with variable I are solved by C. W. Hudson, M. Am. Soc. C. E., by the formulas derived from the method of deflections.* The first is a light single-track girder with two equal spans of 68 ft.; and the second is a heavy double-track girder with two equal spans of 78 ft. In the first case the center bending moment, M_b, is 15% greater, and in the second case 11% greater, by the exact method than by the approximate method. Mr. Hudson,† also computes the effect of shear deflection on the center bending moment, and finds, in the first case, a decrease of 2.6%, and in the second a decrease of 5%, as compared with the value obtained by neglecting shear distortion.

It is evident that the usual approximate assumption, neglecting the variable I, and shear deflection, will introduce errors which tend to compensate each other. Especially is this true in the case of framed trusses, where the effect of shear distortion is relatively much greater. It has been found elsewhere that the usual method of designing swing-bridge trusses by the ordinary restricted formula, assuming I as constant and neglecting shear deflection, is justifiable, because the method of deflections, when applied to the resulting design, gives reactions which agree very closely with those found by the usual approximate method using the restricted form of the theorem of three moments. For plate-girder draw spans, however, the ordinary design formulas have been shown to introduce errors as large as from 10 to 12% on the side of danger, when the effects of variable moments of inertia are neglected.

† *Loc. cit.*, pp. 54-55.

DISCUSSION

Mr. Ketchum.

MILO S. KETCHUM, M. AM. SOC. C. E. (by letter).—The writer wishes to call attention to the "method of area moments" for the solution of statically indeterminate structures. This method, due to Mohr, is much easier to derive and shorter to apply to the calculation of constrained beams than either the "theorem of three moments" or the "method of least work." The author is in error in referring to the method of three moments as being an exact one. It is subject to the same limitations as the methods of least work and area moments, and all methods, if correctly applied, will give identical results.

Before applying the method of area moments to the problem of the plate-girder draw span with variable moment of inertia, it will be necessary to discuss briefly the method. The statement of the method of area moments is:

"If A and B are two points in a beam, the deflection of B with respect to a tangent at A, is equal to the moment about B of the area of the portion of the equilibrium polygon between A and B, multiplied by $\frac{H}{EI}$, where E is the modulus of elasticity of the material, I is the moment of inertia of the section of the beam, and H is the pole distance of the force polygon that was used in drawing the equilibrium polygon."

The proof of this statement, together with applications, has been given by the writer.* If the equilibrium polygon is drawn with a force polygon having a unit pole, the equilibrium polygon becomes the true bending moment polygon, and the statement of the principle is simplified accordingly.

The application of the method of area moments to a simple beam with a constant moment of inertia, loaded with a concentrated load and with a uniform load, respectively, is shown in the following problems:†

Simple Beam.—Concentrated Load at Center of Beam.—The simple beam in (*a*), Fig. 6, is loaded with a load, P, at the center. The bending moment diagram is shown in (*b*), and the beam is loaded with the bending moment diagram in (*c*), Fig. 6.

To find the equation of the elastic curve, take moments of the forces to the left of a point at a distance, x, from the left support, and the deflection of the beam at any point in the beam, (*a*), Fig. 6, will be equal to the bending moment at the corresponding point in the beam, (*b*), Fig. 6, divided by EI, and

$$-EIy = \frac{PL^2x}{16} - \frac{Px^3}{12} \quad \ldots\ldots(1)$$

and

$$48\,EIy = P\,(4\,x^3 - 3\,L^2x) \quad \ldots\ldots(2)$$

* "Steel Mill Buildings," Chapter XIVa; and "Mine Structures," Chapter IV.

† Taken from "Steel Mill Buildings."

Mr. Ketchum.

The maximum deflection will occur when $x = \frac{1}{2} L$, in Equation (2), or it may be found by taking moments of forces to the left of $x = \frac{1}{2} L$, to be

$$\Delta = \frac{PL^3}{48\,EI} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Beam Uniformly Loaded.—The simple beam in (*a*), Fig. 7, is loaded with a uniform load of w per linear foot. The bending moment parabola is shown in (*b*), and the beam is loaded with the bending moment parabola in (*c*), Fig. 7. To find the equation of the elastic curve, take moments of forces to the left of a point at a distance, x, from the left support.

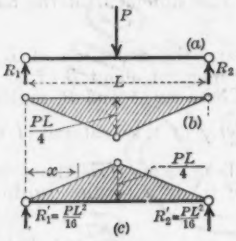

FIG. 6.

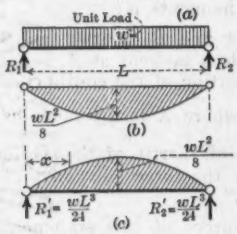

FIG. 7.

The equation of the bending moment parabola with the origin of co-ordinates at the left support is $y = \frac{1}{2} wLx - \frac{1}{2} wx^2$; the area of a segment of the parabola is

$$A = \frac{1}{4} wLx^2 - \frac{1}{6} wx^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

and the center of gravity measured back from x is

$$-X_1 = \frac{x\,(2\,L - x)}{6\,L - 4x} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Taking moments of forces to the left of a point, x, and reducing, we have

$$24\,EIy = w\,(-x^4 + 2\,Lx^3 - L^3x) \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The deflection is a maximum when $x = \frac{1}{2} L$, and may be found directly by taking moments, or may be found from Equation (6), and is

$$\Delta = \frac{5\,wL^4}{384\,EI} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Mr. Ketchum.

For a beam with a variable moment of inertia, the transformed beams, (*b*), Figs. 6 or 7, should be loaded with the bending moment divided by the moment of inertia, I, at each point, or with the bending moment divided by EI at each point, if both the modulus of elasticity and the moment of inertia are variable.

The reaction of the center pier of a draw span of two equal spans with a constant moment of inertia and modulus of elasticity, may be calculated as follows:

Draw Span with Constant Section.—If the total span be $2\,l = L$, in Fig. 6, the deflection of the beam with span, L, loaded with a uniform load, w pounds per linear foot, is

$$\Delta = \frac{5\,wL^4}{384\,EI} \qquad (7)$$

Now, if the center reaction, R_b, be considered as a load acting upward, it will be equal to a load, P, acting at the center of the span, which produces a deflection equal to the deflection of the simple beam, in Fig. 7, loaded with a load, w. The deflection of the beam loaded with a load, P, is

$$\Delta = \frac{PL^3}{48\,EI} \qquad (8)$$

Equating the values of Δ in Equations (7) and (8) gives the middle reaction

$$R_b = P = \frac{5}{8}\,wL \qquad (9)$$

With the foregoing preliminary statement, we may now take up the solution of the problem of the plate-girder draw span with variable moment of inertia, which was solved by the author in Section 11.

Plate-Girder Draw Span.—The span $l_a = l_c = 60$ ft.; the total length is $l = 120$ ft. The girder is symmetrical about its center line. The relative values of the moments of inertia, I, at the following distances from the outside ends are:

0 to 12 ft., $I = 1$
12 to 36 ft., $I = 1.38$
36 to 48 ft., $I = 1.15$
48 to 60 ft., $I = 1.92$

Solution.—Take a simple beam with a span of $l = 120$ ft., having the same cross-section as the draw span, and loaded with a uniform load of w pounds per linear foot, as in (*a*), Fig. 8. The bending moment diagram will be a parabola with a maximum ordinate at the center, $M = \frac{1}{8}\,wl^2 = 1\,800\,w$. To calculate the deflection in the beam due to the load, w, load the transformed beam in (*b*), Fig. 8, with $\frac{M}{I}$.

Mr. Ketchum.

The areas of the segments of the parabola in (*b*), Fig. 8, were calculated by Equation (4), and are as follows:

$$A_1 = 4\,032\ w \text{ (square-foot-pounds.)}$$
$$A_2 = 19\,618\ w \quad " \quad " \quad "$$
$$A_3 = 17\,030\ w \quad " \quad " \quad "$$
$$A_4 = 11\,100\ w \quad " \quad " \quad "$$

The centers of gravity of the segments of the parabola were calculated by Equation (5) as follows:

The center of gravity of A_1 about a is

$$x_1 = \frac{x\,(240 - x)}{720 - 4x} = \frac{12\,(240 - 12)}{720 - 48} = 4.07 \text{ ft.},$$

and the distance of the center of gravity of A_1 from the center of the beam, B, is 48 ft. + 4.07 ft. = 52.07 ft.

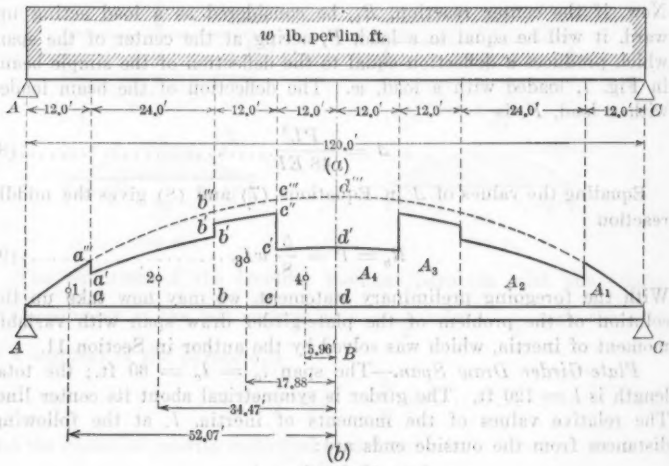

FIG. 8.

The center of gravity of the part of the dotted parabola about the point, b, is

$$\bar{x} = \frac{x\,(240 - x)}{720 - 4x} = \frac{36\,(240 - 36)}{720 - 144} = 12.75 \text{ ft.}$$

The center of gravity of the dotted A_2 about b will be

$$x_2 = \frac{(\text{Area } A_1 + \text{Area } A_2)\,12.75 \text{ ft.} - \text{Area } A_1 \times 28.07 \text{ ft.}}{\text{Area } A_2}$$
$$= \frac{31\,104\ w \times 12.75 \text{ ft.} - 4\,032\ w \times 28.07 \text{ ft.}}{27\,072\ w}$$
$$= 10.47 \text{ ft.}$$

and the distance of the center of gravity of A_1 from the center of the beam, B, is 48 ft. + 4.07 ft. = 52.07 ft. Mr. Ketchum.

The centers of gravity of A_3 and A_4 are calculated in the same manner.

The bending moment at the center of the beam, (b), Fig. 8, will be E times the deflection at the center of the beam, (a), Fig. 8.

$$M = E\,\Delta = R_1 \times 60 \text{ ft.} - A_1 \times 52.07 \text{ ft.} - A_2 \times 34.47 \text{ ft.} - A_3 \times 17.88 \text{ ft.} - A_4 \times 5.96 \text{ ft.}$$
$$= 51\,780\,w \times 60 \text{ ft.} - 4\,032\,w \times 52.07 \text{ ft.} - 19\,618\,w \times 34.47 \text{ ft.} - 17\,030\,w \times 17.88 \text{ ft.} - 11\,100\,w \times 5.96 \text{ ft.}$$
$$= 1\,850\,340\,w \text{ (cubic-foot-pounds)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Now load the same beam with a load of 1 lb., as in (a), Fig. 9. The bending moment diagram is a triangle with a center height of $M = \frac{Pl}{4} = 30$ ft-lb. The beam is loaded with the bending moment divided by the moment of inertia at each point.

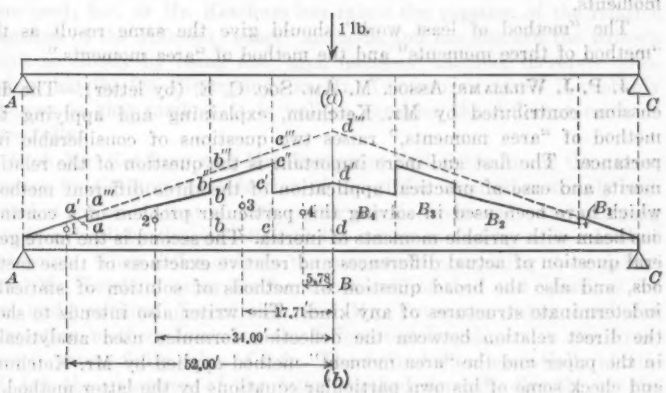

FIG. 9.

The areas of the different sections of the moment diagram are:

$B_1 = 36$ (square-foot-pounds.)
$B_2 = 208.7$ " " "
$B_3 = 219.1$ " " "
$B_4 = 168.7$ " " "

The centers of gravity are as shown in (b), Fig. 9. Then the bending moment at the center of the beam (b), Fig. 9, will be E times the deflection of the beam (a), Fig. 9, due to a center load of 1 lb.

Mr. Ketchum.

$$M = E\,\Delta' = R_1 \times 60 \text{ ft.} - B_1 \times 52 \text{ ft.} - B_2 \times 34.00 \text{ ft.} - B_3 \times 17.71 \text{ ft.} - B_4 \times 5.78 \text{ ft.}$$
$$= 632.5 \times 60 \text{ ft.} - 36 \times 52 \text{ ft.} - 208.7 \times 34.00 \text{ ft.} - 219.1 \times 17.71 \text{ ft.} - 168.7 \times 5.78 \text{ ft.}$$
$$= 24\,137 \text{ (cubic-foot-pounds)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Now the center reaction of the draw span will be equal to Equation (10) divided by Equation (11), and

$$R_2 = 1\,850\,340\ w \div 24\,127$$
$$= 76.67\ w.$$

The left reaction is

$$R_1 = \tfrac{1}{2}\ (120\ w - 76.67\ w)$$
$$= 21.665\ w.$$

The bending moment at the center support of the draw span is

$$M_b = 21.655\ w \times 60 \text{ ft.} - 60\ w \times 30 \text{ ft.}$$
$$= 500.1\ w \text{ (foot-pounds).}$$

This value checks the value calculated by the theorem of three moments.

The "method of least work" should give the same result as the "method of three moments" and the method of "area moments."

Mr. Williams.

J. P. J. WILLIAMS, Assoc. M. AM. SOC. C. E. (by letter).—The discussion contributed by Mr. Ketchum, explaining and applying the method of "area moments," raises two questions of considerable importance. The first and more important is the question of the relative merits and ease of practical application of the three different methods which have been used in solving this particular problem of a continuous beam with variable moments of inertia. The second is the more general question of actual differences and relative exactness of these methods, and also the broad question of methods of solution of statically indeterminate structures of any kind. The writer also intends to show the direct relation between the deflection formulas used analytically in the paper and the "area moment" method applied by Mr. Ketchum, and check some of his own particular equations by the latter method.

In order to determine the relative amount of labor required to solve the problem of the plate-girder draw span with variable moments of inertia, the writer has counted the number of "operations" required to make the solution for the center bending moment, M_b, by each of the three methods. By "operation" is meant, either a setting and reading of the slide-rule, or an addition or subtraction, also making allowance for cases of relatively easy additions or multiplications. The "area moment" method applied by Mr. Ketchum required 105 such operations, the tabular computation made by Mr. Turneaure, using a formula in terms of bending moments, required 78 operations, and the three moment method, using the writer's Equation (43) and

Mr. Williams.

Table 1, required only 41 operations. As the labor required to draw the diagrams for the "area moment" method is certainly as great as that of making the tables in the other methods, it is quite evident that, for this particular problem, the three moment method is far superior. It does not necessarily follow that, for other cases of different loading, or beams on more than three supports, the same method would still be best, but it is probable that it would, provided the mathematical integrations were handled rapidly.

The second question concerning the exactness of these three methods requires a clearer understanding of their essential differences. A careful reading of the first paragraph and the last three paragraphs of the paper will indicate that the term "exact method" used by the writer had reference only to the three moment method which included the effects of variable moments of inertia, settlement of supports, and slope of neutral curve. The principal object in view in Section 11 of the paper was the determination of the value of the error introduced in a particular case of a plate-girder draw span when the usual three moment formulas, neglecting effect of variable moments of inertia, were used; but, as Mr. Ketchum has raised the question of the relative exactness of the different "exact" methods, and has checked the writer's result so closely by using the "area moment" method, therefore indicating that the 2% discrepancy in Mr. Turneaure's result is probably inherent in that method, it is well to consider the different methods more fully.

Both Mr. Ketchum and Mr. Turneaure find the value of the center reaction by dividing the deflection of the girder assumed as simply supported at the ends (that is, with center reaction removed), and carrying the given load, by the deflection at the center caused by a unit load at that point. They differ only in the manner of computing these deflections, Mr. Ketchum using the "area moment" method and equations for area and positions of centroids, and Mr. Turneaure using a tabular summation method, assuming the differential length, dx, in the equations to have a finite value of 6 ft. The formulas are essentially identical, but the exactness of the latter method depends directly on the length assumed for dx, which, theoretically, should be very small. The 2% discrepancy between the result of this method and the results of the other two is probably due to this fact. The three moment method which the writer used is also essentially a deflection method, as it was based on the General Equation (41) derived by Equation (8) for vertical relative deflections of the ends with respect to a tangent to the neutral curve at the center. Mathematically, therefore, all three methods are based on the same theory of deflection due to bending, and, except for the practical inaccuracies in application, should give the same results. The vital differences in the working equations used are only differences in details of application.

Mr. Williams.

It should be emphasized, further, that all these methods give results which are inexact because of the neglect of shear deflection and of shear distortion of the assumed plane normal sections of the beam. Short, heavily-loaded girders with large concentrated loads are affected very materially by shear distortion, as has been shown in the writer's discussion* of "Faults in the Common Theory of Flexure"; and the common assumption of bending deflection only may be largely in error on the side of danger.

All statically indeterminate problems of any character can be solved by either of three general methods: (1) Method of Deflections or Deformations, (2) Method of Equal Work, and (3) Method of Least Work. All three methods give identical results when restricted to the same kinds of stress, but the first uses expressions for deflections or strains, the second equates internal work to external work, and the third applies the principle of minimum internal work.

For example, consider the very simple case of two elastic supports, a and b, subject only to the uniformly distributed direct stress caused by a load, W, carried in such a way that the total elastic strain of each support is the same.

Let W_a = portion of load, W, carried by a;

$W - W_a$ = portion of load, W, carried by b;

$$e_a = \frac{E_a A_a}{L_a} = \text{stiffness of support, } a, = \text{total force required}$$

to produce total strain of unity in a;

$$e_b = \frac{E_b A_b}{L_b} = \text{stiffness of support } b.$$

Then the total deflection or strain $= \dfrac{\text{stress}}{\text{stiffness}}$.

1.—Method of Deflections.—Equate deflection of a to deflection of b.

$$\frac{W_a}{e_a} = \frac{W - W_a}{e_b}; \text{ therefore } W_a = \frac{e_a}{e_a + e_b} W.$$

2.—Method of Equal Work.—Equate internal work to external work.

$$\frac{1}{2}\left[W_a \frac{W_a}{e_a} + W - W_a \frac{W - W_a}{e_b}\right] = \frac{1}{2} W \frac{W_a}{e_a}$$

$$\frac{W_a^2}{e_a} + \frac{(W - W_a)^2}{e_b} = \frac{W W_a}{e_a}$$

or $\dfrac{W_a}{e_a}(W - W_a) = \dfrac{(W - W_a)^2}{e_a}$; therefore $\dfrac{W_a}{e_a} = \dfrac{W - W_a}{e_b}$, as in 1.

* *Transactions*, Am. Soc. C. E., Vol. LXXV, pp. 932-953.

3.—Method of Least Work.—Write the expression for internal work or resilience, R, and place the first derivative with respect to W_a equal to zero, to get condition for minimum. Mr. Williams.

$$R = \frac{1}{2}\left[\frac{W_a^{\,2}}{e_a} + \frac{(W - W_a)^2}{e_b}\right]$$

$$\frac{dR}{dW_a} = \frac{1}{2}\left[\frac{2\,W_a}{e_a} - \frac{2\,(W - W_a)}{e_b}\right] = 0;\ \text{therefore}$$

$$\frac{W_a}{e_a} = \frac{W - W_a}{e_b},\ \text{as in 1.}$$

All three methods thus reduce to identical expressions, and it is possible to reduce even more complex problems, solved by the different methods, to the same working form. Usually, the method of deflection is the most direct and easiest of application. The vertical deflection of beams can be obtained in various ways: By the double integration of the fundamental equation, $M = EI\frac{d^2y}{dx^2}$, of the common theory of flexure; by the application of Equation (8) for $D_v = \sum_O^N \frac{Mn}{EI}x$; or by the semi-graphical method of area moments applied by Mr. Ketchum. They, also, are identical in result, if properly applied, and differ only in manner of procedure.

In order to show the relation between the last two methods, and also explain directly the "area moment" method in connection with that used in the paper, it is only necessary to note that $D_v = \sum_O^N \frac{Mn}{EI}x$ can be found by area moments. If values of $\frac{M}{EI}$ be plotted to scale as ordinates, and the lengths, n, be laid off on the X axis, then $\frac{Mn}{EI}$ will be an elementary area, and $\frac{Mn}{EI}x$ will be the moment of that area about the origin, O, the deflecting point. Then D_v = deflection of O with respect to a tangent to the neutral curve at $N = \sum_O^N \frac{Mn}{EI}x$ = total moment of area of diagram between limits O and N about O. Similarly, the change, A, in the angle between the tangents to the neutral curve at O and at N will be the area of the same diagram between limits O and N, because, by Equation (4), $A = \sum_O^N \frac{Mn}{EI} = \sum_O^N$ elementary areas = area between limits O and N. When E is constant, and M a continuous func-

Mr. Williams.

tion of x, n becomes dx for a horizontal beam, and if A_i = area of a diagram plotted with $\frac{M}{I}$ as ordinates and x_i = the distance of its centroid from the deflecting point as origin, then, for any given limits:

$$A = \frac{A_i}{E}, \text{ and } D_v = \frac{A_i x_i}{E}.$$

The last equation is the basis of the area moment method applied by Mr. Ketchum. When both E and I are constant, the ordinary bending moment diagram area can be used, because M is the ordinate and Mdx an elementary area.

Then
$$A = \frac{1}{EI}\int_O^N Mdx = \frac{A_m}{EI}$$

and
$$D_v = \frac{1}{EI}\int_O^N Mdx \,.\, x = \frac{A_m x_m}{EI}$$

in which A_m = area of bending moment diagram between limits O and N, and x_m = distance from centroid of A_m to origin O.

For example, the integration, $\int_0^{l_a} M\ dx\ x$, in Equation (30), can be more easily made by this method of area moments than by the analytic integration as given. Using areas of the bending moment diagram for M, Fig. 5, noting its component parts and that the origin is at A, the values of $A_m\ x_m$ will be:

For triangle due to M_a,

$$A_m x_m = \frac{M_a l_a}{2}\,\frac{l_a}{3} = \frac{M_a l^2{}_a}{6}$$

For triangle due to M_b,

$$A_m x_m = \frac{M_b l_a}{2}\,\frac{2\,l_a}{3} = \frac{2\,M_b\,l^2{}_a}{6}.$$

For triangle (not shown) due to bending moment caused by concentrated load, W_a, in simple beam, the area, A_m, would be:

$$A_m = \frac{W_a z_a}{l_a}(l_a - z_a)\,\frac{l_a}{2} = \frac{W_a z_a}{2}(l_a - z_a)$$

The distance from centroid to origin, A, is $x_m = \frac{l_a + z_a}{3}$.

Therefore, $A_m x_m = \frac{W_a z_a}{2}(l_a - z_a)\,\frac{l_a + z_a}{3} = \frac{W_a z_a}{6}(l^2{}_a - z^2{}_a)$, as in Equation (31).

For the parabolic bending moment diagram (not shown) due to uniform load, w_a, on a simple beam, the maximum center ordinate being $\frac{w_a l_a{}^2}{8}$, the area $A_m = \frac{2}{3}\,\frac{w_a l_a{}^2}{8}\,l_a = \frac{w_a\ l_a{}^3}{12}$, and $x_m = \frac{l_a}{2}$.

Mr. Williams.

Therefore, $$A_m x_m = \frac{w_a l_a^3}{12} \frac{l_a}{2} = \frac{w_a l_a^4}{24},$$

as in Equation (31).

The "equivalent beam" loaded with the bending moment diagram is a convenient method for finding, not only the deflection, y, but the slope, $\frac{dy}{dx}$, at any point of a given beam. As it will be of interest to note how this method is developed from the general equations already applied, consider the case of a simple beam, with constant E and I, and loaded uniformly with w pounds per foot, as in Fig. 2. The end reaction of the "equivalent beam" loaded with the parabolic bending moment diagram, as in Fig. 7 (c), is,

$$\frac{1}{2}\left[\frac{2}{3}\frac{wl^2}{8}\, l\right] = \frac{wl^3}{24} = \text{area between end and center.}$$

This area between end and center, however, when divided by EI, is the angle between the tangent at the end and the tangent at the center, when E and I are constant. As the tangent at the center is horizontal, the slope of the end tangent with the horizontal, therefore, is $\frac{wl^3}{24\,EI}$, as already obtained analytically in Equation (16). Thus slope of tangent at A equals reaction of "equivalent beam" divided by EI.

From Fig. 2, the slope at any point, X is:

$$\frac{dy}{dx} = (\text{slope of tangent at } A) - A_x$$

$$= \frac{\text{reaction of "equivalent beam"} - \text{area between } A \text{ and } X}{EI}$$

$$= \frac{\text{shear of "equivalent beam"}}{EI}.$$

Hence the slope, $\frac{dy}{dx}$, at any point, X, is equal to the shear at that point of the "equivalent beam" divided by EI. Using Equation (4) of Mr. Ketchum's discussion for the area of the segment of the parabola in Fig. 7 (c):

$$\text{Area between } A \text{ and } X = \frac{wlx^2}{2} - \frac{wx^3}{6} = \frac{wx^2}{24}(6\,l - 4\,x)$$

Therefore $$\frac{dy}{dx} = \frac{wl^3}{24\,EI} - \frac{wx^2}{24\,EI}(6\,l - 4\,x)$$

$$= -\frac{w}{24\,EI}[6\,lx^2 - 4\,x^3 - l^3],$$

which checks Equation (17), previously found by integration methods.

Mr. Williams.

The deflection, y, at any point, X, Fig. 2, is seen to have the value:

$$y = (\text{slope of tangent at } A)\ x - \text{deflection of } X \text{ with respect to tangent at } A$$

$$= \frac{\text{reaction of ``equivalent beam''}}{EI}\ x - \frac{\text{moment of area, } A \text{ to } X, \text{ about } X}{EI}$$

$$= \frac{\text{bending moment of ``equivalent beam''}}{EI}.$$

Using $x_1 =$ distance from centroid of area, A to X, from the point, X,

$$x_1 = \frac{x\,(2\,l - x)}{6\,l - 4x},$$

from Equation (5), given by Mr. Ketchum, there results:

$$y = \frac{wl^3}{24\,EI}\,x - \frac{wx^2}{24\,EI}\,(6\,l - 4\,x)\,\frac{x\,(2\,l - x)}{6\,l - 4\,x}$$

$$= \frac{-\,w}{24\,EI}\,[2\,lx^3 - x^4 - l^3x],$$

which checks the writer's Equation (18), or Equation (6), with opposite sign, as obtained by Mr. Ketchum.

This "equivalent beam" method of finding slope and deflection is perfectly general, and can be applied to beams with variable moments of inertia by a simple modification of the bending moment diagram, as already explained. The application made by Mr. Ketchum to the plate-girder draw span with variable moments of inertia, considered in the paper in Section 11, is a good illustration of this method of using an "equivalent beam," but, as already stated, it is much more laborious for this particular case than the three moment method giving identical results. Mr. Ketchum could have decreased by twelve the number of operations required for his solution by having used, instead of bending moment of "equivalent beam," simply the sum of the area moments about the end, as such sum gives the deflection of the end above the horizontal tangent at the center, which is equal to the center deflection desired for this particular symmetrical case.

CHARACTERISTICS OF CUP AND SCREW CURRENT METERS; PERFORMANCE OF THESE METERS IN TAIL-RACES AND LARGE MOUNTAIN STREAMS; STATISTICAL SYNTHESIS OF DISCHARGE CURVES.*

By B. F. Groat, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. G. Price, E. E. Haskell, Charles H. Miller, John C. Hoyt, C. W. Staniford, and B. F. Groat.

During the summer and autumn of 1911 the writer ran a number of efficiency tests on two of the 6 000-h.p. hydraulic turbine units recently installed in the power-house of the St. Lawrence River Power Company, at Massena, N. Y. On one of the units, two sets of tests were run, one prior, and one subsequent, to cutting off several feet of the draft-tubes. On the other unit, one set of tests was run after the draft-tubes had been shortened, as had been done in the case of the other turbine unit.

In all, about 40 000 instrumental readings, including gauge readings, were made. Of these, 7 000 were complete velocity observations by current meters, and 4 000 additional readings on a Pitot tube furnished about 100 complete velocity observations for comparison with simultaneous readings by the current meters.

Owing to the nature of the tail-races, which discharge into the Grasse River, a weir test was out of the question. Before beginning

*Presented at the meeting of February 5th, 1913.

the tests, therefore, it became necessary to decide between the current meter and Pitot tube as instruments for measuring the flow.

In favor of the current meter is its simplicity and the facility with which it may be used in tail-races. Against it is the fact that, notwithstanding the large number of observers who have experimented with it and the large number of records which have been made by it, there is still a great deal of well-founded skeptical discussion as to the accuracy of the instrument when the records are based solely on the still-water rating.

The Pitot tube has been not only a subject of adverse criticism but also an instrument about which much positive ignorance seems to exist. It would seem, however, that the recent demonstrations of the accuracy of Darcy and Bazin's experiments, 1865, by Messrs. William Monroe White,* L. F. Moody, Gardner S. Williams, John R. Freeman, and others, should sufficiently dispel all doubts as to the reliability of the instrument. On the other hand, where the velocity of the water is variable from moment to moment, a large number of readings must be taken and reduced to a mean square root in order to obtain sufficiently close approximations to the average in any one velocity determination.

After a final summary of advantages and disadvantages, it was decided to use both the screw and cup types of current meter, and to check their records, if necessary, with a Pitot tube.

E. E. Haskell, M. Am. Soc. C. E., Director of the College of Civil Engineering, Cornell University, made up one of his screw type meters especially for the series of tests to be undertaken, and a new Gurley-Price meter of the cup type (No. 600) was purchased from the makers at Troy. Master Mechanic D. J. Jones, of the Power Company, made up a Pitot tube, following as nearly as possible the description of Tube *N* given in Mr. White's paper, mentioned above.

The following are the general conclusions concerning current meters which have been drawn from the tests with the foregoing equipment:

1.—†When a cup meter is run in perturbed water it will register

* "The Pitot Tube; Its Formula," by William Monroe White, *Journal*, Association of Engineering Societies, Vol. XXVII, 1901, p. 35.

† In a discussion of a paper on current meter and weir discharge comparisons by Edward C. Murphy, Assoc. M. Am. Soc. C. E., *Transactions*, Am Soc. C. E., Vol. XLVII, 1902, p. 379, Charles H. Miller, M. Am. Soc. C. E., describes certain experiments on screw and cup meters in the following language:

"The Haskell meter was lowered from one side of the skiff and one of the Price meters

a larger number of revolutions per second than a perfect still-water rating would indicate.

2.—†When a screw meter is run in perturbed water it will register a smaller number of revolutions per second than a perfect still-water rating would indicate.

3.—†In the foregoing sense, a cup meter is affected relatively to a much greater extent than a screw meter. In the tail-races at Massena, as an average, the cup meter was affected to the extent of 6%, while the Haskell meter was affected mostly by less than 1 per cent. In boilers of considerable violence the cup meter may easily over-register by 25%, while the screw meter will under-register by not more than 3 or 4 per cent.

4.—Either type of meter when run in perturbed water will give uniform records in equal times, provided these times are sufficiently long, the flow of the water itself being subject to an established regimen.

5.—If both types of meter are used simultaneously in perturbed water, the disparity between the discrepant velocities thus determined by the still-water rating may be taken as a basis for correcting the discrepant velocities.

6.—The average corrections thus obtained for the Haskell meter when run with the Gurley-Price meter in the tail-races at Massena varied from 0.5 to 0.9 of 1%, while the corresponding corrections for the Gurley-Price meter were about six times larger. Comparisons with the Pitot tube furnished substantially the same corrections as those obtained by comparison of the meters.

7.—It would seem to follow that current-meter observations based on still-water ratings without further correction should be made with great caution. On the other hand, it seems certain that the correction

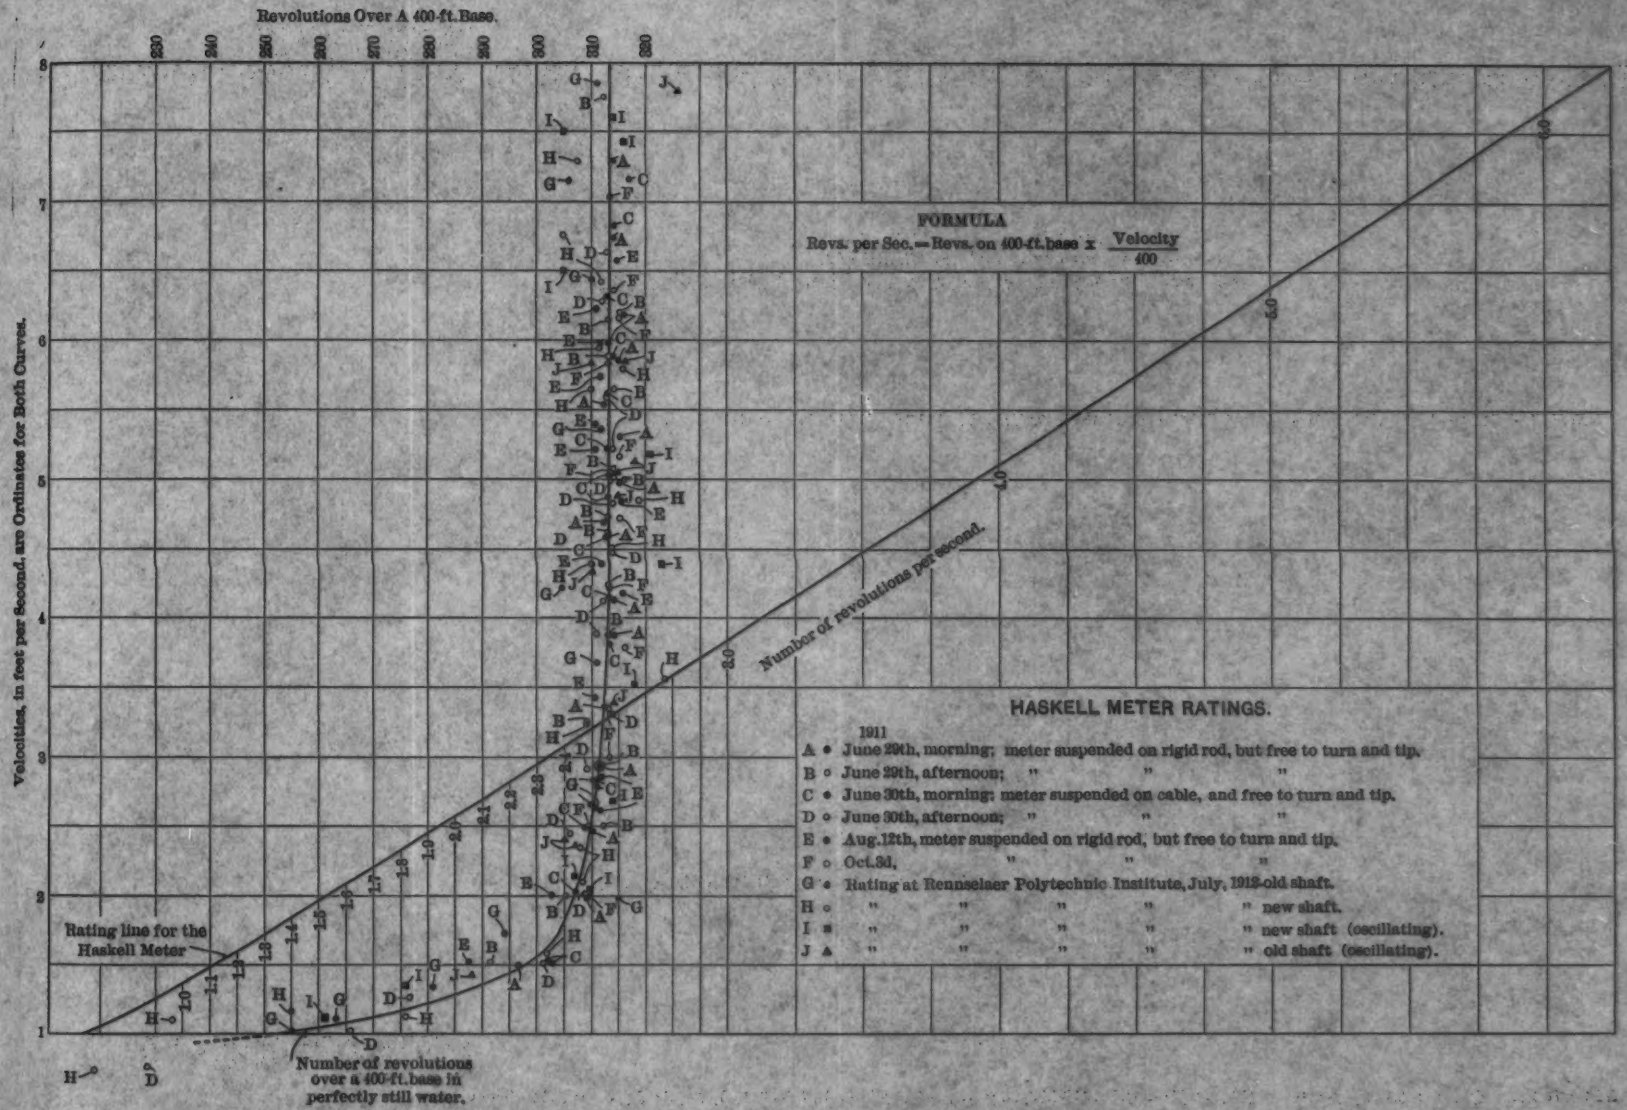
---

from the other side, both to the same depth (about 5 ft.). The registrations or revolutions of each, for periods of from 5 to 10 minutes, were noted; then, for similar periods of time, the skiff was caused to rock from one side to the other at short intervals, and the registrations recorded, the movement of the skiff giving to the meters a vertical motion of from 1 to 2 ft. Under this motion the revolutions of the Price meter increased, while those of the Haskell meter decreased, but in a less proportion than the increase of the Price meter, showing that the error due to instability of support is greater in the Price than in the Haskell meter. Lack of time prevented more extended observations, and in different velocities of current, which probably would have evolved some fixed difference due to the different construction of the meters in question."

Conclusions 1, 2, and 3, of the present paper seem to have been fairly stated by Mr. Miller, but as applied only to instability of support. They are here advanced as inherent characteristics of these different types of meter, and extended to apply, not only to cases of instability of support, but also to these current meters generally, however supported, in flowing water.

for a cup meter when run at a good meter station on an open river is not large, while the corresponding correction for a screw meter may be negligible.

Plate XXIII shows the results of a number of ratings of the Haskell meter. The general method was similar to that adopted by the United States Lake Survey, as described in the reports by F. C. Shenehon, M. Am. Soc. C. E.,* covering his current-meter observations. The meter was suspended either by cable or rod from a bowsprit at the head of a light skiff. The skiff, with an observer, was then towed back and forth over a 200-ft. base at a given velocity, one such double run constituting a velocity observation. The total time and total number of revolutions then stand for the transit of a 400-ft. base in perfectly still water.



The first four ratings, on June 29th and 30th, 1911, were made along the longitudinal center line of Lock No. 15 in the old Cornwall Canal, at Cornwall, Ont. Both lock gates were open, but the north miter leaf of the lower gate, opening into the St. Lawrence River, was not fully into its recess in the north wall. The meter was about 4 ft. below the surface of the water, and the depth in the lock was 9 or 10 ft. The water in the lock had a tendency to surge at times. Sometimes there was considerable velocity through the lock, and at other times very little.

The ratings of August 12th and October 3d, 1911, were made in a bay of the Grasse River, opposite the power-house of the St. Lawrence River Power Company, at Massena, N. Y. The meter was about 2.25 ft. below the surface of the water, and the average depth under the base line was about 7 ft., with a shallow spot near the east end about 5 ft. deep. There was very little current, but at times there were surges due to the operation of the power-house just across the river.

The ratings of July, 1912, were made under the direction of Professor Arthur M. Greene, Jr., at the rating station of Rensselaer Polytechnic Institute, Troy, N. Y., after the meter had been used extensively at Massena and in North Carolina and Tennessee. The meter had been overhauled twice at Cornell University before these ratings, but long after those at Massena. The meter was also provided with a new shaft. After running a complete set of tests at Troy, the new shaft was put in and another set of tests was made.

* As described in Reports, Chief of Engineers, U. S. Army, 1900 to 1904, inclusive.

GROAT ON
CUP AND SCREW CURRENT METERS.

The curve of revolutions over a 400-ft. base was plotted from the first four ratings in the Cornwall Canal. It will be seen from Plate XXIII, however, that the subsequent ratings do not materially alter the position of this line, up to velocities of 5 or 6 ft. per sec. If the correction were made, the number of revolutions, as shown by the line, would be increased only ¼% at 4 ft. per sec., and reduced only ¼% at about 8 ft. per sec. In fact, it may be seen that, out of about 100 double runs in the canal lock and Grasse River, not one plotted point differs by more than 1% from the line of revolutions as determined from the first four ratings for velocities of more than 1½ ft. per sec. For velocities of less than 1½ ft. per sec. the line of revolutions is so steep that errors of somewhat larger magnitude are to be expected. In the oscillating tests, the meter was oscillated parallel to the motion of the car, and covered an amplitude of 5¾ in. for every 8-ft. advance of the car. Transverse oscillations reduce the number of revolutions over a given base. The relations between velocity and revolutions over a 400-ft. base were then plotted, as shown on Plate XXIII, and from the resulting curve the rating line for still water was located and drawn, also as shown on that plate.

After having drawn the rate line, a reduction diagram, Plate XXIV, may be prepared, from which velocities may be read directly when referred to time and revolutions. This obviates either the necessity for reducing revolutions to revolutions per second, or of taking a fixed time for observing velocities, which is inexpedient where velocities are variant.

Plate XXV shows the Gurley-Price meter rating curves, obtained in a manner precisely similar to that used for the Haskell meter. In fact, the ratings were frequently made on the same day as for the Haskell meter.

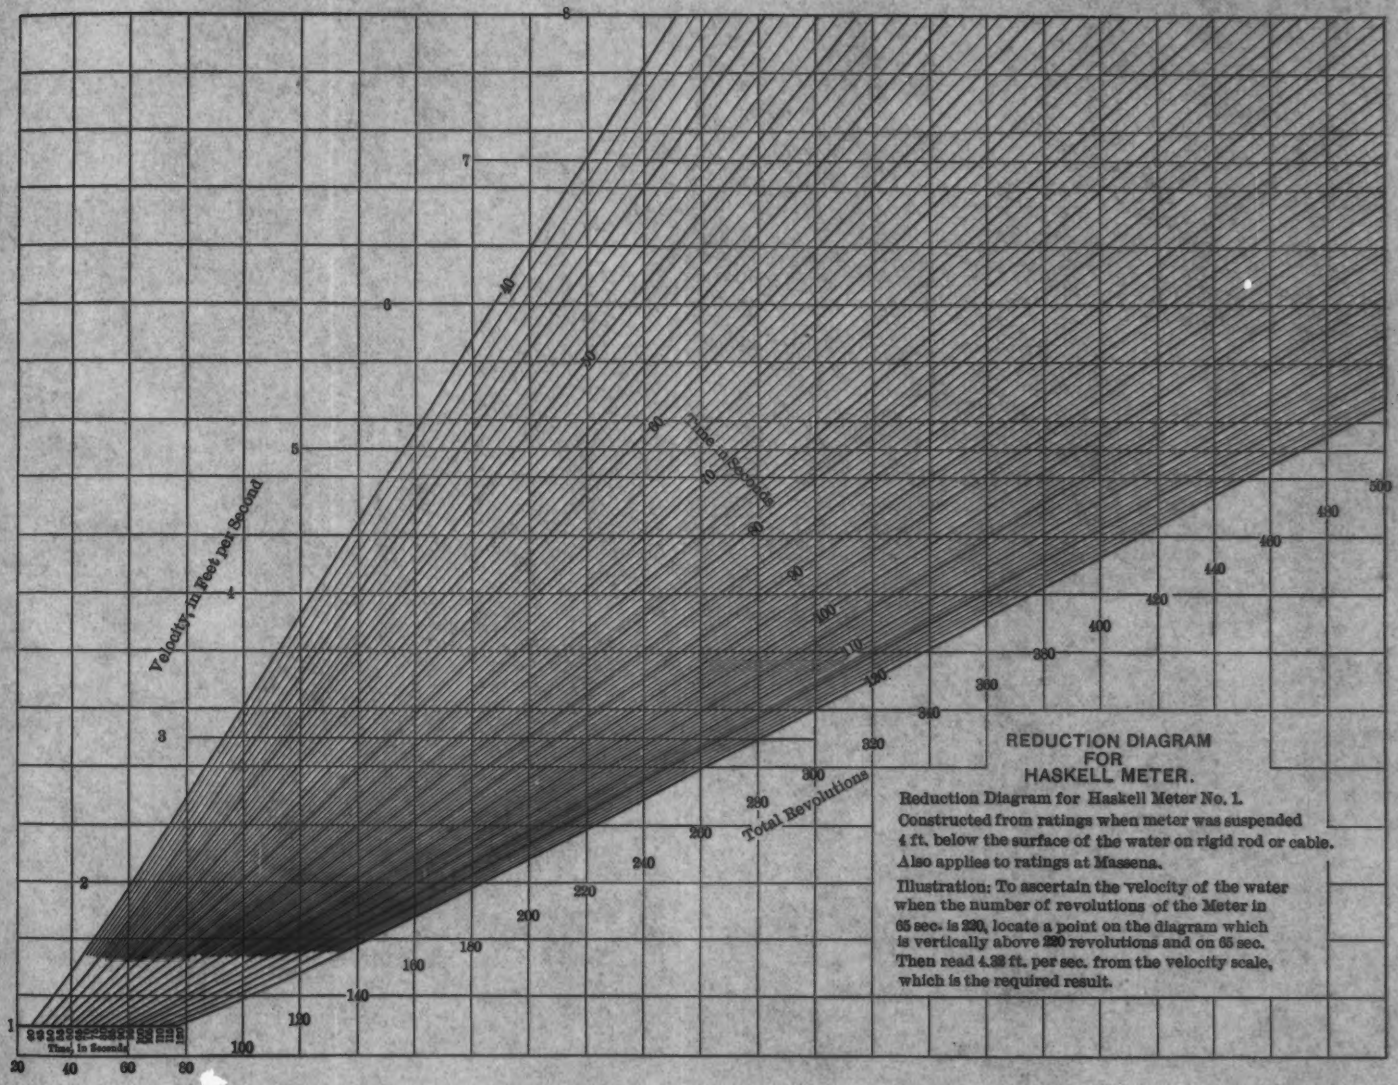
In order that there may be no misunderstanding concerning these ratings, it may be stated that the tests were severe, when considered as a whole. Some of the ratings were made at a depth of 4 ft., some at a depth of 2 ft. 3 in., some in windy weather, some in calm weather, and several different observers acted at different times.

Under all these diverse conditions, it may be seen that the Haskell meter, in the Massena and Cornwall ratings, never varied by more than 1% in any individual observation, and that rating lines drawn for different ratings would differ by only 0.2 or 0.3 of 1% at the greatest.

The Gurley-Price meter exhibits a much greater range of variations, 5 or 6% up to velocities of 5 ft. per sec., which were considerably in excess of the mean velocities in the tail-races where the meter was used.

It is not contended here that a satisfactory still-water rating under perfect conditions cannot be obtained with a meter of this type; it is intended, however, to show that varying conditions of water produce relatively larger variations in the records of the cup meter than in those of the screw meter.

On comparing the maker's rating curve with the several ratings in the canal and in the bay of Grasse River, it will be seen that the number of revolutions of the Gurley-Price meter over a 400-ft. base is generally higher in the canal and bay than in the maker's rating. Hence it is fair to suspect that a perfect still-water rating line of a cup meter is a line of minimum number of revolutions for such a meter, and that, when the water is disturbed in any degree, the number of revolutions over a fixed base will always be increased, other things being equal.*



Similarly, the contrary suspicion may be entertained, that a perfect still-water rating line of a screw meter is a line of maximum number of revolutions for such a meter, and that, when the water is disturbed in any degree, the number of revolutions over a fixed base will always be decreased, other things being equal.

Since, under similar circumstances, the deviations of the Gurley-Price meter are about six times as large as those of the Haskell meter, but in the contrary sense, it would seem fair to conclude that when the meters are run simultaneously in flowing water, one-seventh of any difference in the velocities thus determined from the still-water ratings should be attributed to a deviation of the Haskell meter, while six-sevenths should be attributed to a simultaneous deviation of the Gurley-Price meter.

Thus, if the difference between the velocities determined by the Haskell and Gurley-Price meters should be 0.42 ft. per sec., 0.06 ft. per sec. should be added to the record of the Haskell meter, while 0.36 ft. per sec. should be deducted from the corresponding record of the Gurley-Price meter. In strictness, this correction should be

* Certain interesting experiments by Professor L. F. Moody, in the rating station at Rensselaer Polytechnic Institute, seem to agree with the writer's experiments on this point and confirm the general conclusion.

PLATE XXIV.

GROAT ON
CUP AND SCREW CURRENT METERS.

applied to revolutions per second, but, as the number of revolutions is so nearly proportional to the velocity, and as the corrections are relatively small, no serious error results. The particular ratio here determined, of course, applies only to the two individual meters as used in the tail-races at Massena by the writer.

In order to establish more satisfactorily the principle mentioned above, the boat was rocked during several of the runs of a rating, imparting to the meter which was being rated an oscillation in an arc about 3 ft. long and about 2½ ft. in radius, and at right angles to the direction in which the meter was being drawn through the water. The result was that the Gurley meter was found to increase its number of revolutions by 15% while the Haskell meter reduced its number of revolutions by 2½%, practically the same ratio as that deduced above from the rating curves. The effect of longitudinal oscillations was tested also. The result of special tests of this character at Rensselaer Polytechnic Institute may be seen on Plate XXIII. Subsequently, other tests on a new Haskell meter showed that longitudinal oscillations of 22 in. in 6 ft. advance of car retarded the meter slightly, up to velocities of about 2 ft. per sec., above which the meter was accelerated, the error being less than 2% at 9 ft. per sec. The net result in perturbed water, however, seems to be slight retardation in all cases.

It is now desirable to show how these principles have been used to correct the current-meter records actually observed in the tail-races during the turbine tests referred to at the outset. In order to do this properly, it will be necessary to state another conclusion, based on the current-meter records, which the writer hopes to take up more fully in the future under another title. The conclusion is as follows:

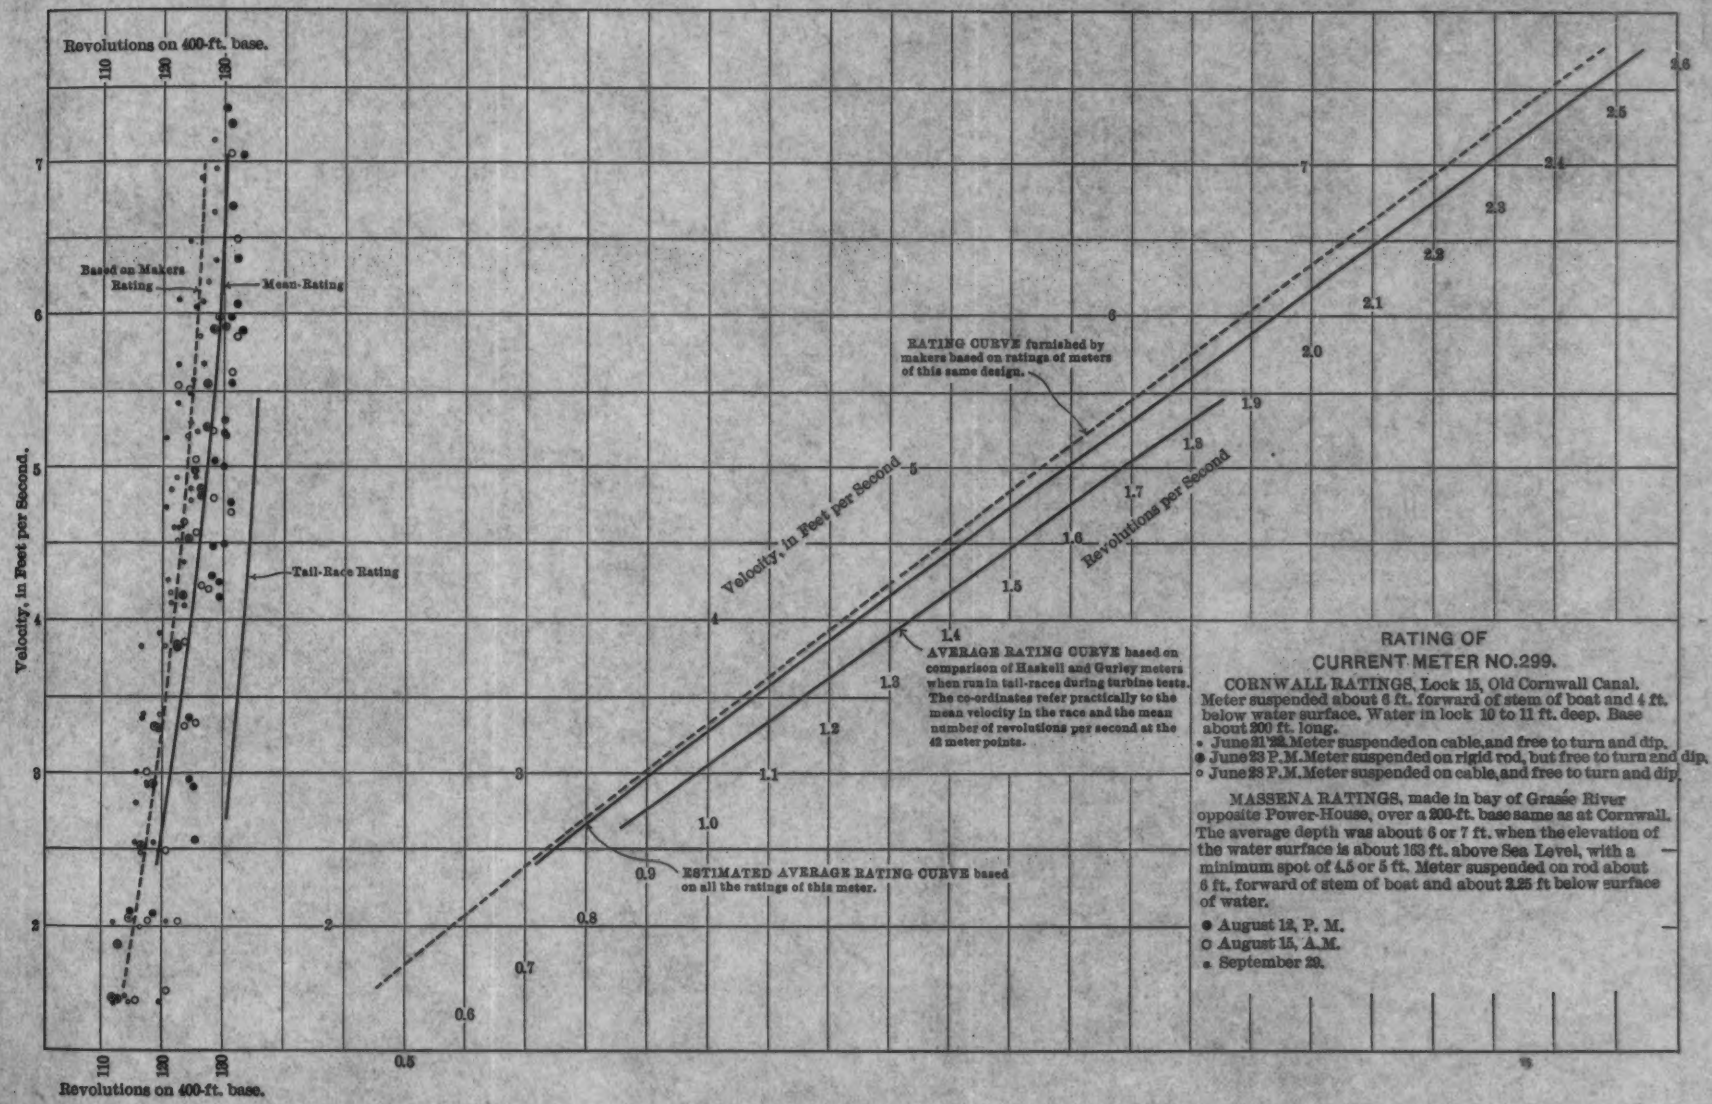
Under an established regimen, the distribution of the flow of water in a tail-race obstructed by stilling racks is fixed in character, the ratio of the average velocity at any given point to that at any other given point in the race being constant. This proposition applies over a considerable range in the total amount of discharge, but supposes the actual wetted cross-section of the race to remain the same.

The foregoing proposition was proven from a number of the turbine tests by computing and compiling the relative velocities at the 84 meter points in the races where velocity observations were taken. A turbine unit discharged through two tail-races, each about 15 ft.

wide, while the depth of the water varied from 15 to 16 ft. The meter section of each race was divided into six equal vertical, and seven equal horizontal, strips, and the meter points were the forty-two intersections of the median lines of the strips. The verticals were numbered 1 to 6 from west to east, while the depths were numbered 1 to 7 downward.

To demonstrate the truth of the principle of a fixed distribution of flow in tail-races, and also as a verification of Conclusion No. 4, Tables 1 to 4 are given:

TABLE 1.—GURLEY-PRICE METER IN WEST RACE, SHOWING CONSTANCY OF VELOCITIES TAKEN IN QUICK SUCCESSION. VELOCITIES WERE OBSERVED WITH A SINGLE STOP-WATCH PROVIDED WITH TWO SECOND HANDS.



Test of September 9th, at 0.82 gate.
The numbers are of revolutions per second.

	1	2	3	4	5	6	
1	1.32	1.40	1.12	0.88	0.90	0.94	6.62
	1.36	1.42	1.16	0.89	0.87	0.92	
2	1.23	1.44	1.40	1.23	1.20	1.16	7.70
	1.24	1.44	1.40	1.24	1.22	1.16	
3	1.35	1.44	1.62	1.42	1.34	1.31	8.45
	1.35	1.44	1.59	1.41	1.35	1.31	
4	1.37	1.44	1.43	1.30	1.31	1.37	8.21
	1.36	1.44	1·43	1.30	1.32	1.36	
5	1.53	1.47	1.52	1.40	1.26	1.38	8.57
	1.49	1.48	1.53	1.42	1.27	1.38	
6	1.70	1.72	1.80	1.72	1.51	1.66	10.09
	1.69	1.72	1.80	1.72	1.50	1.66	
7	1.60	1.81	1.84	1.78	1.78	1.86	10.64
	1.58	1.80	1.84	1.78	1.79	1.85	
Totals of lower set.	10.07	10.74	10.75	9.76	9.32	9.64	60.28

The register was started first and the observer noted the pointer as it clicked from revolution to revolution of the meter. By synchronizing with the rythm of the register, it was possible for the observer to start the stop-watch almost exactly at the moment the register clicked to zero. Similarly, the primary second hand could be stopped after any desired number of revolutions while the secondary hand could be stopped at, say, twice that number. Thus two or more velocities in immediate succession could be determined for each meter point in the tail-races.

In support of the principle of fixed distribution, it may be stated that the percentages corresponding to the figures of Tables 1 and 2 at the 84 meter points agree remarkably well with the corresponding ones of Tables 3 and 4 after applying certain necessary small corrections. Tables 1 and 2 each represent an individual set of double discharge measurements in one of the races, while Tables 3 and 4 have

Totals	16.00	17.40	17.53	16.31	15.68	17.06	99.98

The numbers are percentages of the sum of the velocities at the 42 meter points in the race. Thus, in Vertical 1, Depth 1, the velocity is 2.16% of the sum of all the velocities at the meter points.

been compiled as average percentages from a number of such sets of observations.

In verification of Conclusion No. 4, it may be seen that each pair of velocities determined at the same point by either meter consists practically of two equal velocities. This truth has been found to apply throughout the turbine tests.

Totals	17.12	16.55	16.21	16.33	16.57	17.22	100.00

The percentages of Tables 3 and 4 are computed by dividing the velocity at any meter point by the sum of the velocities at all the meter points.

Attention should be directed to the fact that while water discharged from a turbine will be much quieted by stilling racks, yet the latter themselves are sources of disturbance, and that the violent agitation caused by the turbines is merely supplanted by an entirely different type of disturbance produced by the racks. The effect of the racks is to render the flow parallel to the side-walls of the race, but the body of the water is full of small eddies and boilers of more or less violence. The parallelism of flow at each meter point was tested by a kind of inverted weather vane, which the writer understands was first used by John R. Freeman, M. Am. Soc. C. E. The indications of parallelism of flow by this vane were extremely satisfactory at all points.

The meter section was about 30 ft. down stream from the racks. The effect of the disturbance from the racks, however, was plainly indicated by the divergence of the velocity records, based on the still-water ratings, when the two meters were run in quick succession at any meter point. It is well to note here that the velocity was greater near the bottom of the race than at the top, and that the agitation

by the racks was greater near the top than at the bottom, where the flow was extremely steady and subject to little or no agitation. This is clearly shown by the records, and especially by the fact that the clicking of the register was almost absolutely uniform when the meters were near the bottom. It is also shown by the fact that there was always a greater disparity between the meter records near the surface than at the bottom.

To be precise, the corrections for the meters should be computed for each of the 84 meter points in the races. Practically, the corrections may be made for the average velocities in the seven horizontals, because the velocities along any horizontal do not vary widely.

An example of the computation of corrections for the Haskell and Gurley-Price meters is given in Table 5.

TABLE 5.—COMPUTATION OF VELOCITY CORRECTIONS.

Horizontal in which meter was run.	Velocities Based on the Still-Water Ratings.		Difference.	One seventh of difference + Haskell = true velocity.	Velocity excessive by Gurley. Percentage.	Velocity deficient by Haskell. Percentage.

$$\text{Average error of Gurley meter} = \frac{6}{7} \times \frac{2.16}{33.21} = 5.6 \text{ per cent.}$$

$$\text{Average error of Haskell meter} = \frac{1}{7} \times \frac{2.16}{33.21} = 0.93 \text{ " "}$$

The method given in Table 5 for computing the corrections for the velocities is based solely on the current-meter ratings and the rocking experiments in conjunction with the fundamental propositions before stated. It is desirable, therefore, to have independent means of checking the methods and the numerical results.

Accordingly, a Pitot tube was operated at the meter points, in Depths 2, 3, 5, 6, and 7, simultaneously with the Haskell meter. While the meter was recording in Vertical 3 the Pitot was recording in Vertical 2. After the record was taken, both the meter and Pitot were

advanced to the next succeeding verticals, so that the meter would then record in Vertical 4 while the Pitot was in Vertical 3. Depths 1 and 4 were omitted because the tail of the Pitot was out of water in Depth 1, and the construction of the piping of the Pitot did not conform with the staging for the observers in such a way as to admit of readings in Depth 4. This might have been remedied, but no great importance was attached to these facts.

The results of these tests are given in Table 6.

It should be noticed in Table 6 that the velocities given in Verticals 1 and 6 were not taken in quick succession. The meter and tube were traversed across each horizontal, beginning with the Pitot tube in Vertical 1 and the meter in Vertical 2, and ending with the Pitot tube in Vertical 5 and the meter in Vertical 6. After the five horizontals were traversed in this manner, the Pitot tube and meter were interchanged in relative position, and readings were taken at the five depths with the Pitot tube in Vertical 6 and the meter in Vertical 1. All other readings by the meter or Pitot tube were followed immediately by a reading of the other instrument.

The writer does not wish to make too much of these Pitot tube tests. The experimenters were not familiar with the instrument, as they had used it on only one other occasion. The dynamic and static columns were drawn up on a scale graduated to single tenths and half tenths of a foot and the differences in head were merely estimated to the nearest hundredth of a foot. This may seem crude, but when it is considered that the water columns are both vibrating, sometimes violently, that twenty or thirty readings are taken for each velocity, and that all percentage errors are nearly split in two by the process of extracting the square root of the head, it will be seen that the method is probably as accurate as need be for the purpose at hand. Indeed, the results seem to justify this conclusion.

Attention may be directed to three general facts shown by the summary of Table 6. The ratios for the verticals increase toward the right in the west race. They increase toward the left in the east race. The ratios for the horizontals increase upward in both races. On the whole, the tendency is for the ratio of the Pitot velocity to the meter velocity to increase upward, as it should, as it has been shown that the meter is retarded toward the surface.

It is not wholly clear to the writer, however, why the Pitot tube

velocity should be in the neighborhood of 1½% less than the meter velocity at the greater depths. It is not improbable that this would have been partly compensated for, had the observations in the east race been continued to Depths 5 and 6, but probably not entirely. In fact, there seems to be a reciprocal relation, as noted above, between the readings in the two races. This would follow naturally, owing to the symmetry of the flow in the races as to the central dividing wall, and the fact that the meters always rotate in the same direction. Thus, if there is an eddy clockwise at a certain position in either race, there should be a symmetrically located eddy counter-clockwise in the other race, and these might have opposite effects on the meter, the Pitot tube not being affected in the same way.

It is not impossible that the Haskell meter was running a trifle faster near the bottom of the race than the actual still-water ratings would indicate that it should. This would result from the fact that the rating boat was not a rigid support, nor was the water absolutely still during the ratings. This would necessitate shifting the rate line of the Haskell meter toward its ideal position of a maximum number of revolutions. This, in turn, would diminish all discharge records based on still-water ratings. On the other hand, to be consistent, it would follow that the rate line of the Gurley-Price meter would have to be shifted toward the maker's rate line, which would make for a larger correction to be added to velocities by the Haskell meter when based on still-water ratings, thus leaving true velocities in Table 5 practically unchanged. In corresponding manner, all the ratios of Tables 6 and 7 would be increased, while the meter velocities would be less in the same proportion, the effect of which would be to leave the corrected true velocities corresponding to the tables unaltered, they being in fact those of the Pitot tube. Thus, discharge estimates would not be affected materially in either case. The most reasonable explanation, however, is that the Pitot tube itself is variously affected by small amounts in different parts of the raceways.

The object, however, is not to speculate on such matters, but simply to check the computation of a small correction to the velocity, which correction may be in error by 50% and yet not affect the discharge measurements by the meter by more than three or four tenths of 1 per cent.

Interpolating a percentage for Depth 1, which was not observed in

the tests, equal to the mean given for Depth 2, 1.055, and another in Depth 4, taking an average between the means for Depths 3 and 5, practically 1.000, there may be arranged the figures in Table 7.

* Interpolated velocity ratio.

It follows from Table 7 that an approximate correction of 0.61% should be applied to discharges determined by the Haskell meter when used in these tail-races, and basing velocities on the still-water rating.

As a matter of fact, no direct use whatever was made of the still-water rating curves of the Gurley-Price meter, except to compute the corrections for the meters, which seem to be substantially verified by the Pitot tube tests. In reality, the Gurley-Price meter was rated relatively to the Haskell by comparisons of the simultaneous records taken by the meters in the two races during the numerous turbine tests.

While the Haskell meter runs in the west race, the Gurley-Price meter runs in the east race, and *vice versa*. If a pair of turbine tests be selected where the conditions are substantially the same, the Haskell meter being in the west race during one of the tests and in the east race during the other test, the total sum of the 84 velocities by the Haskell meter may be plotted to the total sum of the 84 numbers of revolutions per second by the Gurley-Price meter. If a number of such points be plotted, the curve drawn through them will represent the functional relation between the sum of the 84 velocities by the Haskell meter and the corresponding total sum of the numbers of revolutions per second by the Gurley-Price meter at the 84 meter points in the two races.

RELATIVE RATINGS OF GURLEY AND HASKELL METERS.

IN THE TAIL-RACES OF NO. 3 AND NO. 5 UNITS DURING THE TUBINE TESTS.

- In races of No. 5.
- In races of No. 3 after cutting off Draft-Tubes.
- In races of No. 3 before cutting off Draft-Tubes.

METHOD OF COMPARISON The sum of the numbers of revolutions of the Gurley meter at the 42 meter points in either race during any test, is reduced to correspond to the same area as the corresponding sum of the velocities by the Haskell meter by multiplying the number of revolutions of the Gurley meter by the inverse ratio of the areas of the two races. A pair of tests at the same gate is selected where the Haskell meter was in opposite races in the two cases. The half sum of the number of revolutions by the Gurley meter is then plotted to the half sum of velocities by the Haskell meter as indicated by the three classes of dots above. Curves may then be drawn as shown to distinguish the three cases.

As the two races are so nearly alike, it may be accepted that, on the average, half the total sum of the 84 velocities will correspond to half the total number of revolutions per second at the 84 meter points, as a functional relation between the total sum of the velocities at the 42 meter points and the corresponding total sum of the revolutions per second at these points for either race taken separately.

Plate XXVI is such a relative rating curve, compiled from selected turbine tests, and may be used to reduce the records of the Gurley-Price meter to what they would have been by the Haskell meter. Thus, if in any tests on Unit No. 5 the Gurley-Price meter makes a total sum of revolutions per second of 50, then, by this curve, the Haskell meter would have made a record indicating a sum of 149.3 ft. per sec.

It was not found necessary to have any regard for the individual velocity by the meter at any point, except as a part of the total sum. A system of constants and ratios was devised, so that, to obtain the mean velocity in a raceway during any tests, it was merely necessary to multiply the sum of the velocities at the 42 meter points by a factor obtained from a curve. This, however, is a matter which the writer hopes to take up more in detail at another time, and therefore, he will confine himself here to the performance of the meters in the tail-races.

With this relative rating curve and the percentages of Tables 3 and 4, it would be quite possible to determine the absolute rating curve of either meter at each of the 84 meter points; but this is hardly necessary. It will suffice here, as a matter of interest, simply to conclude this paper by determining what the average absolute rating curve of the Gurley-Price meter was in the turbine tests. This may be done by dividing the numerical value of the abscissas and ordinates of Plate XXVI by 42 and plotting the resulting pairs of reduced coordinates to the corresponding reference lines in Plate XXV.

It may there be seen that the number of revolutions per second by the Gurley-Price meter in the tail-races was, on the average, about 6% greater than the still-water rating would indicate. In other words, if the writer had relied on this meter alone, without any other guide than the still-water rating curve, his discharge results would undoubtedly have been 6% too high.

These conclusions are not to be taken as casting any reflections on the Gurley-Price meter, which according to the writer's experience, is an admirably constructed instrument. In fact, the results could not have been obtained without it. The rating of the meter was perfectly definite at each of the 84 meter points in the races, but could not be determined directly by the still-water rating, which, in reality, is the only thing at fault. The still-water rating should never be applied without regard to the probable deviations of the speed of revolution due to disturbances in the water. An excellent check on the meters is to rate them where operated with a Pitot tube.

ADDENDA.

Since the foregoing was written, the writer has had a very instructive experience with several types of meter used simultaneously on a complicated network of mountain streams. The results of oscillating the meters have confirmed the general conclusion that in all cases, relatively, cups are accelerated considerably, while screws are retarded slightly, in turbulent water. The errors of the cup meter, based on still-water ratings, were from 3 to 6 times greater than those of the screw, and in the contrary sense.

Design of Meters.—The principal desideratum of a current meter is that it should give the resolved component of velocity in a direction fixed relatively to the meter. The fact that a cup over-registers in turbulent water while a screw under-registers, gives a basis of design which may be used to produce a meter possessing this characteristic more or less rigidly. If the blades of a screw are "cupped" to the proper extent, and in the right sense, the effect may thus be toward neutralizing the retardation which the screw would otherwise suffer.

There are other ways of producing such a meter. Professors Greene and Moody, of Rensselaer Polytechnic Institute, have conducted a series of experiments there which resulted in the production of a meter practically giving only the resolved components of velocity.

A conclusion to be drawn from these experiences is that a tail, or rudder, is a useless appendage to a meter used in stream gauging. The meter should be held rigidly in the stream or conduit, giving only the component of velocity perpendicular to the cross-section. A cup meter would give better results in turbulent water if it had no tail, but was simply allowed to run at the end of a vertical rod like an inverted cup anemometer.

The recording device for a meter designed to be held rigidly in the current should register positively for down-stream current and negatively for up-stream current. There are cases where the current beneath the surface is up-stream; and the old forms of meter make no distinction, as they should.

Accuracy of Velocity Determinations by Current Meters.—Under given conditions, the current meter is a very accurate instrument. To prove this, it is only necessary to take a series of observations at a given meter point, or better, at a given set of meter points, when conditions at the gauging section are constant. Repetitions of these observations will give results checking within 1 per cent.

It is not even necessary to take observations under constant conditions, as is shown by the writer's plottings of the sums of the metered velocities at selected sets of meter points at various gauging stations. These curves are drawn through the plottings of points the co-ordinates of which are the elevation of the water surface at the given gauging station and the sum of the velocities at a selected number (25 to 100) of meter points in the cross-section. In shallow streams the meter points should be at mid-depth.

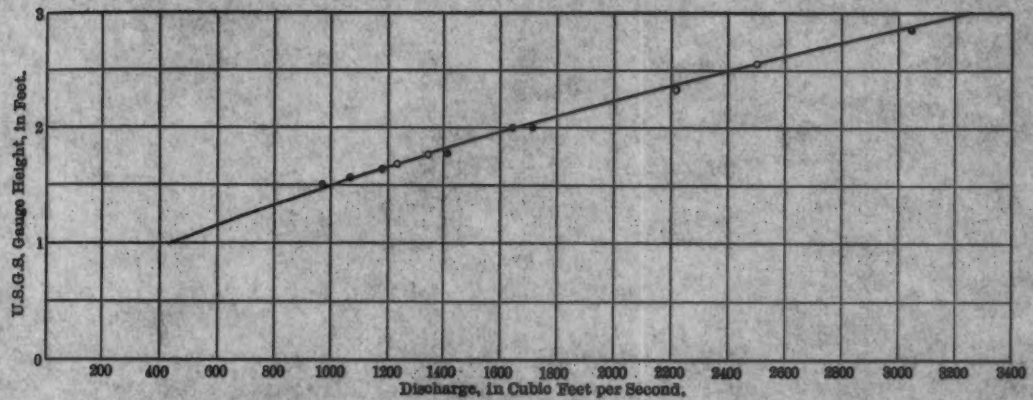
Even in the case of shallow, turbulent, stony streams, such plotted points all lie within 1% of the finally determined curve, thus showing that the performance of the meter, be it of screw or cup type, is uniform and reliable.

The main sources of error are in the application of the still-water rating, the determination of the section area, and the determination of the distribution of flow through the cross-section. The errors due to an erroneous determination of the distribution of velocities are frequently styled the "errors due to the method of calculation."

Distribution Factor.—If the discharge and section area are determined accurately for any one gauging, the mean velocity in the section may be divided by the sum of the velocities at a selected set of meter points. This ratio may be called the distribution factor for the corresponding stage of the water. In this way, corresponding values of the distribution factor and stage of the river may be determined and plotted, the co-ordinates being the elevation of the water surface and corresponding value of the distribution factor. If the work has been good, the points will plot as close to a smooth curve as the plotting of points representing the sums of velocities at the selected set of meter points.

Section Area.—The section area, next to the error in applying the still-water rating, is probably the most uncertain element of a discharge determination, where the stream is shallow and stony. Nevertheless, it has been ascertained that the surface profile of such streams at reasonably good stations is a function of the stage of the water, in many cases being simply a horizontal line. By taking a minutely accurate profile of the bottom of such a stream along the cross-section, and a number of surface profiles at various stages, the section area may be plotted to the corresponding elevation of water surface. This is another element for the accurate determination of a discharge curve.

Statistical Synthesis of a Discharge Curve by Means of its Generating Elements.—According to the definitions given above, there are three principal generating elements of a discharge curve, all of which may be exhibited as curves plotted to the elevation of the water surface at the cross-section. These generating elements are, respectively, the sum of the velocities at a selected set of meter points, the distribution factor, and the area of cross-section.



If, for any given stage of water, the corresponding values taken from the curve of sums of velocities and the curve of distribution factors be multiplied together, the result is the mean velocity in the section for that stage. The product of this mean velocity and the section area taken from the area curve for the same stage is the discharge for that stage. In this way the discharges of the stream may be computed for all stages and plotted as a finally determined discharge curve.

The method is as strictly statistical as though the laws of probability had been applied formally, and the result is practically as satisfactory and infinitely easier to obtain. Moreover, errors are immediately detected and located.

Good work on the mountain streams of North Carolina and Tennessee has shown that individual discharge determinations based on the foregoing processes will plot within 1 or 2%, as extreme errors, of the final discharge curve.

Distribution of Flow.—The distribution of flow is determined in the ordinary manner by vertical velocity curves. It is best, however, to be systematic. A good system is to determine the ratio of the mid-depth velocity to the mean velocity in each vertical for the whole range

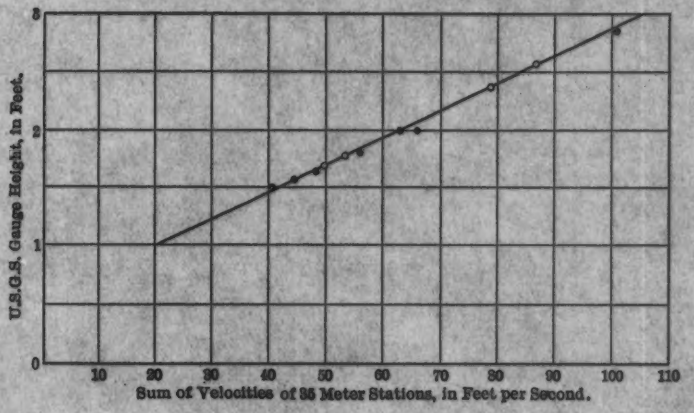
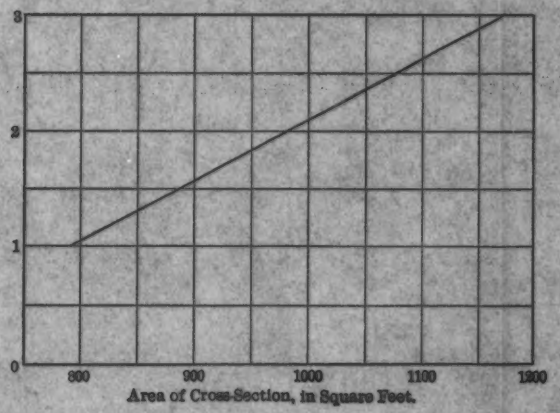
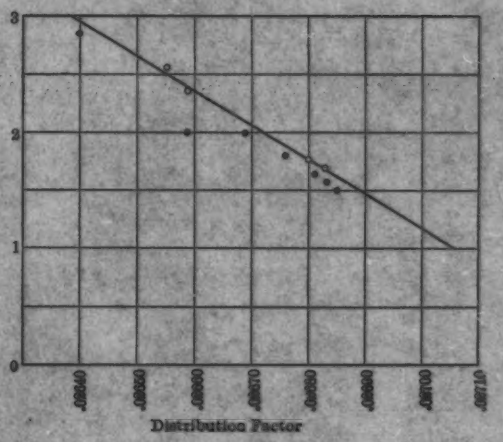
CUP AND SCREW CURRENT METERS.





DISCHARGE CURVE FOR TUCKASEGEE RIVER AT BRYSON, N. C.



- • Observations with Gurley Meter
- ○ Observations with Haskell Meter

The discharge curve has been computed from the elementary curves obtained from observations with the Haskell Meter.

The points spotted on the discharge curve indicate the individual discharge obtained from each gauging.

of stages of the river. The writer has used an average value of these ratios for each stage of the river, by which the mean mid-depth velocity for the corresponding stage is to be divided, in order to obtain the mean velocity in the section before computing a discharge. In practice, a curve may be drawn giving the mean value of the ratio for each stage of the river. The determination of this ratio is a different thing from a gauging for discharge.

Discharge Gauging.—As described above, the writer prefers to take gaugings of shallow rivers at mid-depth at equidistant stations along the cross-section. The individual discharge is then computed by dividing the sum of the products of the corrected mid-depth velocities and their corresponding areas by the average value of the before-mentioned ratio for the proper stage. The discharges at the ends of the section, below obstructions in the stream and around and through piers of bridges, should be treated separately under the title "end discharges" or "additional discharges." This additional discharge may be plotted as a function of the stage of the river. Such a plotting shows whether the calculation has been made on a consistent basis by forming a well-determined curve. Otherwise, the computer has varied his method of attack inconsistently.

Error in Using Average Ratios.—Undoubtedly, an error is made in using an average ratio of any sort, unless that average be determined properly. Thus a time average and a space average of a quantity are two entirely different things. It is important, therefore, to use the correct form of averages. However, if the values of the ratio of mid-depth velocity to mean velocity in thirty or forty verticals at a station of fairly uniform depth and velocity all lie between 1.10 and 1.18 as extremes, with an arithmetical average of about 1.14, no serious error can result in using such an average value. In fact, in this particular case, a detailed computation and one based on the average value of 1.14 differed by only one-seventh of 1 per cent.

Room for Research.—In the writer's opinion, it would pay scientific investigators to develop a meter which under all conditions would give the resolved component of velocity in a given direction, rather than to attempt to determine any functional relation between the deviations of cup and screw meters from their still-water ratings. In the foregoing studies of the results at Massena it was thought sufficiently accurate to consider the error of the cup meter about six

times the error, in the contrary sense, of the screw meter. This ratio is undoubtedly a variable, but no serious error can result by assuming it to be constant where the extremes observed would make less than 1% difference in the discharge, as was the case in the turbine tests at Massena.

Practical Application of the Methods.—Table 8 exhibits the results of a number of discharge determinations at a station where the turbulence of flow is at a minimum. In fact, the disparity between the records of the Haskell and Gurley meters is less in these observations than for those at any of the other stations operated in North Carolina and Tennessee. The average ratio of mid-depth velocity to mean velocity in the vertical, for 45 vertical velocity curves, is 1.055. The curve has not been drawn.

TABLE 8.—RESULTS OF A NUMBER OF DISCHARGE OBSERVATIONS TAKEN AT THE STATION AT THE WAGON BRIDGE, BRYSON, N. C.

Meter.	Gauge height.	*Sum of velocities in 35 verticals.	Section area.	Distribution factor.	Discharge.	Mean velocity.
Gurley	1.50	40.59	885.0	0.02685	965	1.090
Gurley	1.57	44.31	898.3	0.02684	1 068	1.189
Gurley	1.64	48.19	911.7	0.02681	1 179	1.292
Haskell	1.69	49.83	921.2	0.02683	1 230	1.337
Haskell	1.77	53.28	936.4	0.02680	1 338	1.429
Gurley	1.80	55.97	942.1	0.02676	1 410	1.498
Gurley	2.00	65.73	980.2	0.02659	1 718	1.748
Gurley	2.00	62.94	980.2	0.02669	1 646	1.680
Haskell	2.37	78.96	1 050.7	0.02659	2 208	2.100
Haskell	2.56	86.66	1 087.3	0.02655	2 502	2.301
Gurley	2.85	100.73	1 144.3	0.02640	3 044	2.660

*The velocities are here based solely on the still-water ratings of the meters.

Plate XXVII shows the plottings of the main elements of the discharge observations of Table 8, according to the statistical methods described herein. The discharge curve is determined by the three elementary curves, as already explained. The elementary curves are plotted from the records of the Haskell meter.

DISCUSSION

W. G. PRICE, M. AM. SOC. C. E. (by letter).—This paper gives the results obtained from a very large number of observations, and should be of much value. Before accepting these results as perfectly reliable, the writer would be pleased to know if the meters, in both the rating and stream tests, were suspended in precisely the same way and by supports of the same size? Mr. Price.

Were weights used in both cases; and were they always the same distance from the wheel?

Was the skiff so far from the wheel that it did not push the water ahead of itself a trifle and thus reduce the rate of revolution of the wheel? In some cases, a steamer ascending the Upper Mississippi will check slightly the flow of the water some hundreds of feet ahead of itself.

The writer has had an extensive experience with current meters during a period of seventeen years, beginning with 1879, during which time he measured the flow in the Mississippi, Missouri, and Ohio Rivers, and their large and small tributaries, many times, and in many places. The following propositions are the result of his experience:

The thread of a perturbed current, of course, is longer than that of a steady current. A meter of the cup type, without a vane, measures the thread of the horizontal current perturbations, but when provided with a vane, it measures a trifle more than the thread of the horizontal perturbed current. This is due to the effect on the vane of the perturbed current which swings the wheel transversely to the current. If a cup meter with no vane is fixed on a vertical rod, the current perturbations moving up and down in the vertical plane will decrease the revolutions of the wheel and thus offset the increase due to the horizontal perturbations. This action is due to the fact that the top and bottom faces of the meter wheel present a propeller-shaped surface to the water, and when vertical currents strike the wheel they tend to turn it in the opposite direction from that produced by the water flowing against the cups. For this reason the vane should not be used in streams shallow enough to permit of it being omitted, if there are perturbed currents. Larger streams, when the gauging station is carefully selected, are not perturbed to such an extent as to cause a serious error in meter measurements.

A meter of the propeller type will measure less than the thread of the perturbed current, because of the inability of the vane to keep the face of the wheel at all times precisely normal to the current. A current striking a propeller wheel sidewise does not increase its revolutions, as is the case with the cup meter. Each type of meter, in

Mr. Price. clear, straight, running water, will give the same accurate results, provided it has been accurately rated and is supported in the stream in precisely the same way as when rated, or by a method which does not produce an increase or decrease of current at the meter wheel.

When a weight is attached to the supporting rod under the meter, it reduces the discharge area and increases the velocity of the water in its vicinity, and thus increases the rate of revolution of the meter wheel. If the weight is placed 6 in. below the meter, the wheel, in each type, will run much faster than when the weight is 12 in. below the meter. A difference in the location of the weight, or the use of the weight in one case and not in the other, will produce all the difference, noted by the author for the Price meter, between ratings and stream measurements.

The propeller type of meter is often made to run more slowly between rating and stream measurements by a slight quantity of grit blowing into the bearings, or being carried in by the water. This type of meter is often made to run slow by a particle of dead grass or leaf (found moving in most streams) catching on the propeller. The propeller type of meter does not free itself from such débris, as does the cup meter.

When meters are rated in still water, it is necessary to wait 10 min. or more after each passage of the meter for the water to become still again. If the wind is blowing against the surface of the water, variable and sometimes rotary currents will be produced, which will make the rating inaccurate. The surface currents will run in one direction and the under current in the opposite direction. For this reason, the meter should be rated at a depth of more than 2½ ft., and in water more than 5 ft. deep.

A rating taken in running water is likely to be the most accurate, because the running water carries away the disturbing currents produced by the movement of the meter.

When a cup meter is accurately rated in still water and in ordinarily steady running water, the two ratings will be the same within a small fraction of 1%, and the rating curve can be drawn through all the plotted points obtained by the rating, so that no point will vary in revolutions as much as 1% from the curve.

The writer has used a Morse paper tape register and electric device to start and stop the register, or mark the paper tape, at the instant of passing the cross-wires suspended over the 200-ft. base, so that the fractions of revolutions of the cup meter wheel were determined at the beginning and end of the run; and such a rating in still water, with almost no wind, located all the plotted points within a very small fraction of 1% of the number of revolutions from the rating curve as drawn.

Mr. Price.

The ratings of both the Haskell and Price meters given on Plates XXIII and XXV are inaccurate, as the plotted points indicating the number of revolutions vary entirely too much. The errors in the Price ratings are apparently much greater than in the Haskell ratings.

Mr. Groat has conducted a series of observations in one tail-race where the currents were quite divergent, and the writer submits that the result of his experiment, treating as it does of one special condition, cannot be taken, either directly or by inference, to apply to general conditions of measurement of the flow of streams.

Under such peculiar conditions, where there are cross-currents, as in the Massena experiment, it is possible that the propeller type, owing to its peculiar construction, is less affected by such currents than the cup type; but if the propeller type were better for the measurement of streams where accurate measurements are impossible, owing to cross-currents, this fact would not indicate that such meters are better for general use.

A perfect still-water rating, of course, is what is required when the instrument is to be used in the measurement of straight, flowing streams. The usual rating in running water is made only to secure the same result as would be obtained by a perfect still-water rating. The small variations of the current from a straight line, as seen at the gauging section in most streams, makes only a negligible error in meter measurements.

A meter measures approximately the length of the curved thread of the current; therefore, if the thread is very divergent, inaccurate results will be obtained with any meter.

A gauging section having a perturbed current which would cause an error of 6% would give evidence to the eye by the boiling of the water, and would make the experienced observer hunt for a better section. However, better sections cannot possibly always be found.

A gauging section which has an up-stream current should never be used, and one which has very divergent currents cannot give accurate results with any method of measurement.

The first meter used by the writer had a cup wheel which revolved in a horizontal plane. It was designed by Gen. Ellis, and had been used by him in the Connecticut River. This meter did good work in water which was absolutely free from grit. Floating organic matter, such as leaves and grass, did not often affect it, as the turning of the wheel caused such débris to free itself. When the attempt was made to use it in the muddy water of the rising Ohio in 1882, it gave very inaccurate results, owing to grit getting into the bearings, which made its rate variable. The writer was then furnished with two very finely constructed meters, designed by Clemens Herschel, M. Am. Soc. C. E., and made by Buff and Berger especially for this work. Each was of

Mr. Price. the propeller type, with horizontal shaft, having agate bearings, and each was provided with a vane to hold the meter in line with the current in both the vertical and horizontal planes. They were as perfect instruments of the propeller type as the writer has seen.

These meters were tested by rating them in clear water, and gave good results. They were then rated in a bayou of roily water, an overflow from the Ohio, and the results were very inaccurate, owing to grit getting into the bearings, and leaves and other débris catching on the wheel and continuing to revolve with it. They were tested in the turbid Ohio River with no better results.

It was absolutely necessary to have a meter which would do accurate work, if the great Ohio flood of 1882, which was then on its way, was to be accurately measured. In designing and constructing what is called the Price meter, on this occasion, the cup type of wheel was adopted, for three reasons: The friction of the bearings is so small that this wheel can measure sufficiently low velocities, which is not the case with the propeller type; the revolving wheel will clear itself of débris; and, by using a vertical shaft, with inverted cup bearings filled with air and oil which will stay in by capillary attraction, no water with its load of grit can enter. The friction of the bearings thus becomes a constant quantity. The well-known and successful operation of these meters is due to these three features, which the writer believes cannot be secured by any other design.

The propeller type of meter, designed by Mr. Herschel, was in service before the Price meter, but has had quite a limited use, while several thousand Price meters have gone into service. This test of time, under all kinds of conditions, indicates that the cup meter is the most efficient for general purposes.

The writer believes that with an accurately rated cup meter of the type having no vane—which is much the better design for shallow, perturbed streams—more accurate results could have been secured at Massena.

Mr. Haskell. E. E. HASKELL, M. AM. SOC. C. E. (by letter).—The writer has been greatly interested in the results set forth in Mr. Groat's paper, for he has never had occasion to use current meters under just such conditions.

The current meter was designed originally to measure velocities in open channels. It has developed into two distinct types: those having screw wheels and those having cup wheels. The first current meter, "Woltman's Mill", more than 100 years old, was of the screw wheel type. This meter has undergone various changes in form and in the mounting of its wheel, and, on the whole, has proved to be very accurate and reliable. The origin of the cup wheel meter is not as definite. It has undergone various changes, and the cups have been of various forms, namely, cones, hemispheres, and combinations of cones and

hemispheres. Although a great deal of good work has been done with meters of this type, they have not shown themselves to be anywhere near as reliable as those of the screw wheel type. In the writer's judgment, this is due to the fact that they do not always present the same area and form of wheel to the current pressure. The tilting of the meter, even through small angles, changes these, and consequently changes the rating curve or equation. In current meters of the screw wheel type, such tilting through small angles makes but a slight change in the area and form of wheel presented to the current pressure, and, accordingly, they follow much more closely their rating curve or equation. Mr. Haskell.

In the last paragraph on page 836, the author states, as follows:

"A conclusion to be drawn from these experiences is that a tail, or rudder, is a useless appendage to a meter used in stream gauging."

The writer's experience will not allow him to accept this conclusion. In a large river, the difficulty of holding the axis of the meter perpendicular to the cross-section becomes so great that it is out of the question. In large streams it is necessary to measure both factors, velocity and direction, and reduce to obtain the velocity normal to the cross-section. In small streams or tail-races it is possible to hold the meter rigidly in place; but, when thus held, if the direction of the current makes an angle with the horizontal, that is, strikes the wheel of the cup meter either on the top or bottom of the cups, it will over-register as readily as if running in "eddies" or "boils". The amount of this over-registration depends on the angle which the direction of the current makes with the horizontal, and can only be determined by some check method.

It is not at all clear to the writer why a still-water rating of a current meter should not give an entirely satisfactory result. In all cases where the elements of the current in the open channel are reasonably parallel, the meter is working under almost the same conditions as when drawn through still water. In one case the meter is free and the water moving, and in the other the meter is free and moving, and the water still.

The following test of a direction current meter was made after it had been rated in still water. It was made in a large tidal channel, free from "eddies" or "boils", where the elements of the current were parallel. Each comparison was made by running the meter for 10 min., and in this time running ten large cylindrical can-floats, alternating on each side of the meter. The determined velocities are in feet per second, as follows:

Float....	1.04	1.29	1.55	1.94	2.56	2.65	2.76	2.80	3.08
Meter....	1.05	1.28	1.55	1.96	2.59	2.64	2.74	2.82	3.11

Mr. Haskell. The greatest uncertainty in the results obtained with cup wheel meters is caused by using such meters from an unstable support, like a boat, particularly if the weather conditions are such as to give the boat any rocking or pitching motion.

The author is deserving of much credit for his work and his paper. Well planned and well executed work cannot help but make for engineering progress.

Mr. Miller. CHARLES H. MILLER, M. AM. SOC. C. E. (by letter).—Although the writer has made scarcely any current meter observations during the past twelve years, and hence has not kept up fully with the progress in such work, he is much pleased at the opportunity to read such a clear presentation of a series of observations, evidently made with much painstaking care; and is gratified to note such a complete verification, stated, however, in a much clearer manner, of a positive difference between a cup meter and a screw meter when running in perturbed water; which difference the writer noted just a short time before leaving the Government service, and has never had opportunity to investigate further.

Although the difference was then cited as being due to instability of support, in other words, the rocking of the skiff, this rocking was done for the purpose, not only of causing conditions actually to be found in the river on account of "boils" and "eddies", but to show the effects that might be expected should the skiff or support be moved otherwise than in a straight and even course, while taking a rating in still water. That the writer was familiar with this source of error a number of years ago may be noted by referring to a letter* written by him, in which, in speaking about the rating of meters in skiffs, it is stated that "a rating should never be taken in a skiff which is being pulled with the oars," and that "the observers should be cautioned about keeping the same positions and not swinging their bodies from one side to the other while the observation is being made." This same passage was noted by the late William Starling, M. Am. Soc. C. E., and referred to in his paper entitled "The Discharge of the Mississippi River."†

Mr. Starling's paper treats in general of the many difficulties attending the taking of discharge observations on the Lower Mississippi River, and explains the reasons for some of the apparently discrepant results published in those days, he having had access, at the time, to the large mass of data gathered by the writer and others then engaged in wrestling with the problem of determining the extent of, or in eliminating, errors. It must be remembered that the possibility of error is very great when measuring the discharge of a river in which a favorable cross-section has a width of approximately ½ mile, with a

* *Engineering News*, January 24th, 1895, p. 58.
† *Transactions*, Am. Soc. C. E., Vol. XXXIV, p. 347.

maximum depth of 105 ft. at times, where velocities of 9 ft. per sec. or greater are found, and a total discharge of 1 750 000 cu. ft. per sec. may be obtained. Under such conditions, it is impossible to anchor the boat or equipment, and it must be held on one spot, as nearly as possible, by means of the rudder and the propelling power, counterbalancing the current and wind forces. Careful observations were made to determine how much movement actually took place. In fact, a large portion of the time in the field was devoted to checking the accuracy of the observations. It may be noted that the meters then used were of the cup variety. Some checks, however, were made by a system of double floats. Mr. Miller.

As noting some of the improvements that were being made from time to time, attention is called to the fact that, at a time as recent as 1891, the meter rating was considered as following a straight line, and the proper straight-line equation was calculated by the method of least squares, often, however, not until some time after the field observations had been made. About the date just mentioned it became customary to plot the rating observations and draw the curve conforming as nearly as possible thereto, from which a rating table was taken directly. Other tables were made to cover all necessary computations in the discharge work, and each station observation was calculated while the boat or steamer was moving to the next station, so that the total discharge was known a few minutes after the last velocity observation had been made. For instance, during the morning of May 4th, 1892, at Arkansas City, Ark., the discharge was computed at 1 733 676 sec-ft. as compared with 1 532 875 sec-ft. for the day before. Another observation, made during the afternoon, gave 1 741 526 sec-ft., showing that some marked change had taken place during that time. On the following day it had dropped back to 1 589 172 sec-ft., or to about the general average at that time. Under the old methods, the observations were not computed until some time, often weeks, after the field observations had been made.

As illustrating the fact that every method that could be thought of at the time was used to eliminate errors, it will suffice to say that, in the case of a large and persistent difference in the discharge, as found at two stations 90 miles apart, new meters were purchased, later they were interchanged, frequent ratings were made, and finally the observers exchanged places with each other; all this was done without finding a satisfactory reason for the difference. This was in 1892. During the high water of 1893 these same stations were again occupied, and further efforts were put forth to get accurate results. Mr. Starling, in the paper previously cited, has this to say regarding this work:

"In 1893, the discharges at Arkansas City and Wilson's Point agree fairly well; and when checked by the results of the flanking observations, they present a very coherent mass of data, affording the

Mr. Miller. most trustworthy measurement of the extreme high-water discharge ever obtained on the Mississippi."

Too much stress cannot be placed on the fact that it is just as important to avoid errors in rating meters as in taking the actual discharge observations; and the writer is strongly of the opinion, based on long experience in the field, that by far the larger part of the error is due to the fact that ratings are usually made under physical conditions which are widely variant from those under which the discharge observations are made. For instance, if the observations are to be made from a steamer, then the ratings should be made from the same or a similar steamer, and in dead water, if possible, although they can be made accurately in moving water, provided the movement is smooth, generally uniform, and slow enough to permit the taking of slow velocities in the down-stream direction. Care must be exercised in keeping the meter below the influence of the "drag" occasioned by the steamer hull moving through the water.

Necessarily, the official reports, on account of limited space, as a rule, can contain but a brief explanation of methods and results; and, naturally, these reports incline toward the better showings, failing in general to recognize the fact that the publication of actual failures will often hasten the time of the final solution of the problem.

It may be of interest to know that the first forms of meters were of the wind-mill, screw, or propeller type; that is, the vanes turned, in a plane which was perpendicular to the direction of the current. These were used on South American rivers in 1871.

To eliminate the tail or rudder appears to be a move in the right direction, but a vertical rod could hardly be used with success in gauging a stream as large as the Mississippi, and it would no doubt be possible to work out a design which could be mounted concentrically on the cable which is now used to lower the meter, with its attendant lead weight, to depths of 60 ft. or more, affixing the tail or rudder to the lead weight, and placing the latter so far below the meter that it would not influence its running.

Mr. Hoyt. JOHN C. HOYT, M. AM. SOC. C. E.—Although more than fifty devices for measuring the velocity of water have been patented, the only meters which have had general use are the Price, Haskell, Fteley, and Ellis, or modifications of these.

Each of the various meters has first been devised to meet the requirement of some special condition, and may or may not be applicable to other conditions. Therefore, a current meter should never be used for other conditions than those for which it is designed or has been found to be applicable.

In 1888 the United States Geological Survey began gauging streams of all sizes and in all sections of the country. These streams pre-

sented an infinite variety of combinations of range in depth, width, and velocity, were often remote from railroad or other regular transportation facilities, and were consequently difficult and expensive to gauge. No adequate instruments or methods had been developed for work of this varied nature. Furthermore, elaborate equipment and methods were out of the question on account of the limited funds. It was necessary to devise or adapt a current meter which could be readily carried in the field and operated by one man, either from a bridge, boat, cable and car, or by wading. Mr. Hoyt.

To fulfill these requirements it was essential: (*a*) that the meter should be simple and light in construction, with no delicate parts which easily get out of order; (*b*) that it should be simple in operation, including its preparation for use under any conditions, and its dismantling, cleaning, and boxing after use; (*c*) that it should offer a small area of resistance to the action of the water; (*d*) that it should have a simple and effective device for indicating the number of revolutions of the wheel; and (*e*) that it should be adaptable for use under all conditions.

After experimenting with various types, the engineers of the Survey developed a meter combining certain essential features of the Price acoustic and the large Price electric meter. This is known as the small Price electric meter, and is now in general use in the Survey work. Modifications in its construction have been made from time to time, until now it represents the ideas of many engineers based on results of more than twenty years of experience in stream gauging.

The limitation of the Price meter pointed out in this paper, namely, that it may be affected by cross-currents, has always been recognized by its designers and users. Therefore, special care has been taken to restrict its use to work where the conditions are such that errors from this cause will not affect the final estimates of discharge. These requisite conditions are: (*a*) a fairly smooth bed; (*b*) a measurable and steady velocity of current; and (*c*) a stationary stage during the measurement. The velocity of the current should vary gradually throughout the section, which should show no marked eddies, cross-currents, or boils, and its mean should not be less than 0.5 ft. per sec. at low stages. After visiting hundreds of gauging stations, on streams of varied character, in all sections of the United States, the speaker is convinced that only the exceptional station is not or cannot be located in accordance with these requirements. This statement is made in order to correct any impression which may be drawn from Mr. Groat's paper, that the Geological Survey records, based on measurements with the small Price meter, generally involve large errors. More than two hundred engineers have been engaged in the stream gauging work of the Survey for various periods during the last twenty years, and, as far as known, no valid criticism of the methods used

Mr. Hoyt. has ever been made which was not fully appreciated by the Survey engineers; and they have made combined effort to correct, as far as possible, each defect in the work as soon as it is discovered. The instruments and methods have been subject to continual change, and old have been supplanted by new whenever the new have been proved the better. Constructive criticism of the work is, and has always been, welcomely received and acted upon, and this opportunity is taken to appeal to engineers who are interested in the use of stream flow records for more constructive criticism and for co-operation in raising this branch of hydraulics to the high plane for which all who are engaged in it are striving.

A few points in Mr. Groat's paper may be referred to briefly:

1.—The paper calls attention to the recognized fact that the differential meter is affected by cross-currents.

2.—It is believed by the speaker that the methods used in carrying on the work from which the conclusions in the paper were drawn, and the magnitude of the results obtained, are both open to question.

3.—Unfortunately, the methods are described only in a general way, and various factors which might affect the results materially are not adequately presented. Furthermore, sufficient data for making any exhaustive study of the results are not given. Therefore, any detailed discussion of the work is impossible.

4.—The large Price meter used in the work is of a type which has not been used for several years by engineers who are most familiar with stream gauging. In the work of the Geological Survey, it was abandoned several years ago, when fifty meters of this style, all practically new, were condemned and replaced by the small Price meter, which was found to give more satisfactory results.

5.—The reader is left in great doubt and uncertainty in regard to the standards used in the comparisons. Though the Haskell meter used may not be seriously affected by cross-currents, there are no experimental data, as far as known to the speaker, which show that this meter gives results any more accurate under the adverse conditions stated than does the Price meter.

6.—The results obtained with an unrated Pitot tube do not appear to be sufficiently conclusive for any final deductions. The Pitot tube itself has had no extended use in open channels, its behavior has not been fully investigated, and, in the limited experiments which have been made with it, many questions have come up which leave an uncertainty as to its action. It has been demonstrated that its rating does not hold near the sides of a canal, and it has also been shown that it will not measure the true velocity when the opening is not in line with the current.

7.—The paper points out a well-known defect in the Price meter,

but gives no remedy, and offers no substitute which can be used under a wide variety of conditions. Mr. Hoyt.

8.—The assumption that the differences shown by the so-called still-water ratings of the meters apply when the meters were used in the canal is questionable. The amount of difference between the Price and Haskell meters, when rated under the conditions mentioned, will depend on the amount of disturbance introduced into the rating; as the Price meter will record, not only the horizontal motion, but also the vertical motion and the cross-currents.

9.—The experience of the Geological Survey shows that accurate ratings of the current meter cannot be made from boats, owing to the errors introduced in connection with obtaining the various factors entering into the rating. Changes in the methods of rating by the United States Geological Survey, the Bureau of Standards, and the Rensselaer Polytechnic Institute have changed the results of ratings about 3 per cent.

10.—The speaker is unable to see why one familiar with current-meter work would have attempted to use the Price current meter under the conditions found at Massena. Engineers of the Geological Survey have frequently refused to co-operate in work where similar conditions existed.

11.—The statistical synthesis method, as understood by the speaker, does not take into account the relative distribution of velocities and areas in various parts of the cross-section. The mean velocity in a cross-section, as defined by the Geological Survey, is obtained by dividing the discharge by the area, which will not give the same results as taking the mean of the velocities at various points in the cross-section. For example, a certain stream may have 50% of its flow in 10% of its cross-section. Furthermore, this method of computation has no apparent advantage over that ordinarily used, and has the disadvantage of being much more complicated, even if the results are of equal value.

12.—The question of the distribution of velocity in the vertical has been investigated most thoroughly by the engineers of the Geological Survey, who have found the mid-depth method to be the least desirable. The mean of the velocities at two-tenths and eight-tenths of the depth gives (without a coefficient) the velocity in the vertical, under all conditions of natural flow; and, next in value, the six-tenths depth method has been found to be the most satisfactory.

The only method yet devised for rating a current meter is by drawing it through still water. A close study indicates that no material error is introduced in the results obtained with this instrument on account of the method of rating. Large numbers of comparative measurements have been made with the Price current meter, calibrated weirs,

Mr. Hoyt. and measuring tanks, all of which show that the meter, when properly used, will give results accurate within 1 or 2 per cent.

It has also been found that measurements at different points on a stream, where the conditions of measurement are entirely different, give results which agree closely. Many measurements have been made on two tributary streams and then on the main stream below, and the results check within the limits of accuracy necessary in work of this type.

Mr. Staniford. C. W. STANIFORD, M. AM. SOC. C. E.—The speaker would like to ask Mr. Groat or Mr. Hoyt whether any of the current meters mentioned—the Haskell, the Price, the Ellis, or perhaps the admirable German instruments—after being rated in fresh water (still water, of course), have been used in salt water; and what percentage of accuracy can be obtained with such meters in salt water?

If such instruments have been rectified against corrosion, and against short-circuiting, can they be relied on when used in salt water?

Mr. Groat. B. F. GROAT, ASSOC. M. AM. SOC. C. E. (by letter).—If one will examine the papers and discussions concerning current meters published since the original study was made by Frederic P. Stearns, Past-President, Am. Soc. C. E., in 1879,* it will be found that there is much uncertainty among engineers concerning the reliability of these instruments, with which, up to the present time, there does not seem to have been any generally satisfactory and generally adopted practice. These facts are in sharp contrast to those connected with the use of other engineering instruments, such as the transit and level. No method can be deemed generally satisfactory until it meets the general approval of practitioners. So long as there is lack of agreement between various classes of current-meter observers, not only as to the general method of procedure, but also as to the reliability of various types of instruments, there can be no such thing as a satisfactory current-meter practice.

When it becomes generally realized that current meters obey their still-water ratings only when the conditions of flow are ideal, and that cup meters are affected in one sense and screw meters in the contrary sense, it will be apparent that there is a real reason for the diversity of opinion concerning the reliability of current-meter work.

The writer, therefore, was inspired by the hope that this paper might reopen the discussion and possibly put in motion an effort to improve the current meter.

Appended to the paper there is a brief description of a new system of taking discharge observations and a new method of constructing the discharge curve. This system and method have been applied most

* *Transactions*, Am. Soc. C. E., Vol. XII, 1883, p. 301.

successfully in a number of cases, and are worthy of the attention of those contemplating a series of gaugings at one or more stations. Mr. Groat.

The method of synthesizing a discharge curve is not an invention of the writer which he is trying to introduce, but is a well-established method used by physicists and practicing engineers in determining various kinds of relations between observed magnitudes. It consists simply in separating a given investigation into its elementary parts and drawing a curve for each, the final relations being derived from the elementary curves or relations. The fact that the sum of the velocities at a given set of meter points at a gauging station forms such an elementary relation, when plotted as a function of the gauge height, leads to the term "statistical."

The main advantage of the statistical method is that the entire series of gaugings, extending over a long series of years, may be connected into a consistent whole. The peculiar characteristics of a station may be studied from the elementary curves. If any change or break occurs in one or more of the elementary curves, a corresponding change or break has taken place in one or more of the physical characteristics or hidden conditions of the station. This is especially true of the sum of the velocities at a given set of meter points, because the sum forms a fixed relation between velocity and stage. The sum is chosen because, in taking a number of velocities, the accidental variations and errors in the velocities eliminate themselves. That is why, even at turbulent stations, a smooth curve can be drawn through the plotted values of the sum, with errors well within 1 or 2%, as extremes. It is not likely that changes in the hidden conditions at a station would be detected by any other method. They would be set down simply as unaccountable variations.

Another very important advantage of the statistical method is that it affords at once the most independent and most easily secured check on the velocity readings. Indeed, the sum of the velocities must plot on a definite curve, and this enables one to check the meter work at any newly observed stage with that at any other stage within 10 min. after all the velocities for the former have been recorded.

The writer is glad to know that his Conclusion 1, concerning cup meters, is generally recognized. Under certain nearly ideal conditions, such meters will give good results, but, the moment the conditions are changed in the slightest degree, the still-water rating becomes more or less inapplicable, with a resulting constant or systematic error.

Nevertheless, it would be perfectly safe to use a cup meter in turbulent water if, where used, it were rated with a Pitot tube. The fact that the meter runs with fidelity under such circumstances is another of the conclusions drawn in the paper, and one should not lose sight of this good quality. It may also be remarked that this is a

Mr. Groat. fact which does not seem to have been generally recognized. Cup meters will undoubtedly have their uses, but improvements in the means for obtaining their ratings—not still-water ratings, but actual ratings at the time and place of use—are imperative. It will do to talk about refined ratings when probable errors are reduced to values of less than from 3 to 5 per cent.

After reading the discussions one can scarcely shake off the idea that the niceties demanded for the conditions under which cup meters must be rated are altogether out of proportion to the degree of accuracy attainable with these meters in stream gauging. If a cup meter cannot be rated accurately from a boat when operated carefully, owing to changes in rating due to the slight irregularities of motion, what must be the effect on such a meter when subjected to the far greater irregularity of the motion of the water at a fairly good gauging station, to say nothing of the errors to be expected at a really turbulent station.

The writer believes that Mr. Miller made an important discovery in current-meter engineering when he noticed that cups over-register considerably and screws under-register slightly in agitated water. In due time this fact will impress itself on engineers generally, and lead to a meter which obeys its still-water rating more closely than any hitherto made.

The Haskell meter is so nearly correct under a wide range of conditions that it would seem to require only slight modification, as suggested in the paper, to render it almost independent of conditions. It would be a delightful task, for some one who has the time and means, to develop such a meter. Meantime, it cannot be too strongly urged on hydraulic engineers that a screw current meter is the most reliable kind for measuring the velocities of flowing water when using the still-water rating.

It may be well to define the terms "cup" and "screw," as the writer does not wish to apply the general propositions stated to every kind of instrument which may chance to be called a cup meter or a screw meter: A cup meter is one in which the rotating element operates on the principle of the Robinson cup anemometer, though the shape of the cups need not be limited to that of the hemisphere. A screw is a rotating element the surface of which would be generated by a straight line perpendicular to, rotating uniformly about, and moving uniformly along, the axis of rotation.

One would also hesitate to apply the propositions to meters having large or badly designed frames which would be likely to interfere with the action of the water on the runner. Although the frame of the cup meter is at the rear of the runner, it has decided and different effects on the rating of the instrument when turned somewhat to the right and then an equal angle to the left of the line of motion.

Mr. Groat.

The writer is more than pleased to have Mr. Price's open-minded discussion. The cup meter is very ingenious, and the means which Mr. Price has adopted to protect the bearings and secure uniformity of friction have probably been the cause of the continuance of this meter in the Government service.

Mr. Price may be assured that the meter was suspended in precisely the same manner during the turbine tests as in the ratings. This applies also to the stream tests. No weights were used in any case, and the meter wheel was about 7 ft. in advance of the stem of the rating boat. The reaction of the boat on the screw must have been slight indeed, as the ratings from a car at the Rensselaer Polytechnic Institute do not differ materially from those by the boat.

Fig. 1 shows the rating boat, and below it the rod used to support the meter. The hooks on this rod may be adjusted so that any desired series of depths may be secured. From the staging on which the observer stood a $\frac{5}{8}$-in. rod extended across the tail-race at a fixed elevation. The meter was attached to one end of a $\frac{3}{4}$-in. rod, about 2 ft. long, the other end of which was screwed into the supporting rod. There were seven hooks on the supporting rod during the turbine tests, any one of which could be hooked over the $\frac{5}{8}$-in. rod on the staging, thus immersing the meter to the corresponding depth. Six rope clips were attached to the $\frac{5}{8}$-in. rod at the verticals in which the meters were to be operated. The rope clips served as stops at which to hold the meter rod, when taking observations in the verticals.

Fig. 2 is a rough sketch of the Pitot tube and supporting rod. The Pitot tube (to the right) is a copy of "Tube *N*," as described in Mr. White's monograph, referred to in the paper. The supporting rod (to the left) was designed to be operated from the staging in the tail-race, in the same manner as the supporting rod for the meters. On Fig. 2 is shown one of the hooks to engage the $\frac{5}{8}$-in. rod on the staging, and also the eyes on both the Pitot tube and meter supporting rods to which a guy wire was attached near their lower ends, thus holding the rods and preventing bending.

Mr. Price states that the meter of the propeller type does not free itself from such débris as dead grass and leaves. This is too broad a statement, for there is at least one meter of that type which does free itself, and that is the Haskell. This meter has been used by the writer many times in streams carrying much dead grass, leaves, twigs, sand, and mud. On no occasion did it catch the slightest particle or give any evidence of being affected thereby.

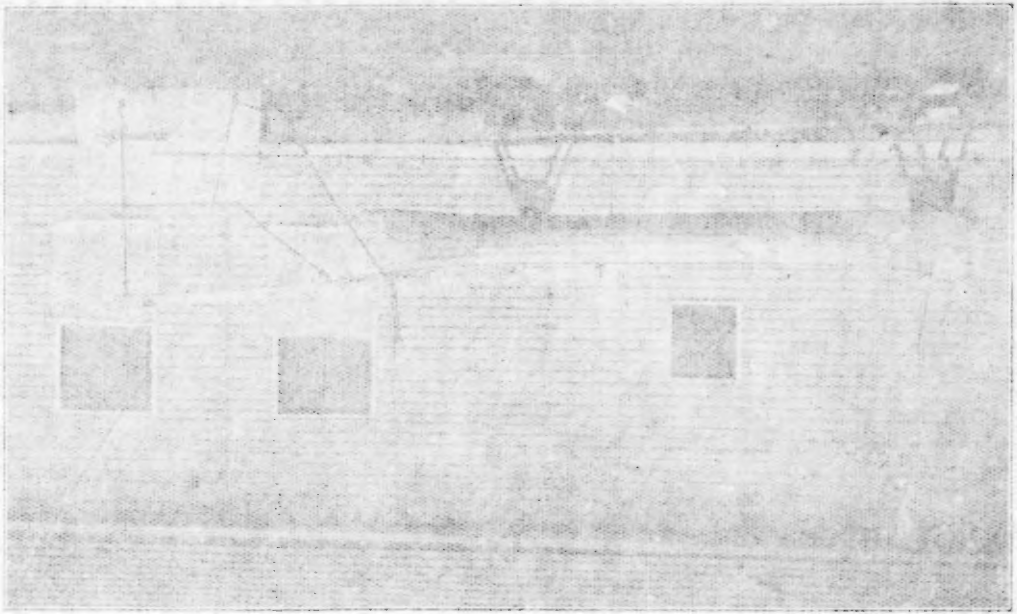
This is due to the effective shape of the runner, which Dean Haskell has undoubtedly designed expressly for the purpose. The up-stream end of the wheel is brought down to a moderately pointed or conical nose which sheds all débris carried by the water.

The question of friction in a current meter is very interesting. Throwing out the case of low velocities, the necessity seems to be,

Mr. Groat.

not so much for a small amount of friction as for constancy of amount. If the resisting torque is large but constant, a rating should be fixed just as exactly as in the case where the friction is small and constant. Notice, too, that there is a resisting torque caused by the hydraulic skin friction on a screw, which can be made as large as desired by lengthening the vanes along the axis. In this respect, the screw is just as much a differential meter as the cup meter.

The retarding skin friction has a much longer lever arm than the bearing friction, and has a much larger resisting torque, so that the bearing friction of a screw meter offers a resistance of secondary importance. Further, the resisting skin friction is a fixed function of the velocity, varying approximately as the square thereof. Hence it is clear that the principal portion of the resisting torque is fixed for each velocity and cannot be changed. It follows that, if the meter is kept in only fair condition, the rating is not affected seriously by moderate changes in bearing friction. The truth of this was tested in the experiments at Massena by taking part of a rating while the bearing was dirty and stiff, then completing the rating after the meter had been cleaned and oiled. Let the reader select from ratings *E* and *F* of the Haskell meter, Plate XXIII, the points taken before cleaning and oiling the meter. The Haskell meter is not sensitive to moderate changes of bearing friction.



Mr. Price thinks the ratings (Plate XXIII) of the Haskell meter are inaccurate. If any one will take the pains to examine the percentage errors of the various ratings and the wide range of conditions under which these ratings were made, he will feel compelled to admit that the performance of this meter was very consistent throughout. Ratings of this kind are of more practical value than those obtained under restricted conditions, because the former afford an indication of the degree of accuracy to be expected of the meter when in actual service, while the latter do not.

No doubt the rating line could be adjusted to the observations somewhat better. This rating line was located from a few of the earlier ratings, the later ones being plotted on the diagram subsequently. The change, if made, would be trifling, excepting for low velocities, which were not used.

The idea must not be entertained that the conditions in the Massena tail-races were bad. On the contrary, they were much better than those usually encountered in stream gauging. The flow of the water was parallel to the side-walls, and the meters might as well have been fixed rigidly to the rods, as far as concerned any tendency to swing. The errors of the meters were caused by small eddies and boils such as would certainly have to be dealt with at most gauging stations. The conditions of flow were carefully studied at each of the 84 meter points by using an inverted weather vane. An instrument

FIG. 1.—RATING BOAT, WITH ROD USED TO SUPPORT CURRENT METER.

was invented and used to ascertain the quantity of air in the water at each meter point. This quantity was found to be negligible. Mr. Groat.

Mr. Price states that a gauging station which has an up-stream current should never be used, and one which has divergent currents cannot give accurate results with any method of measurement. It

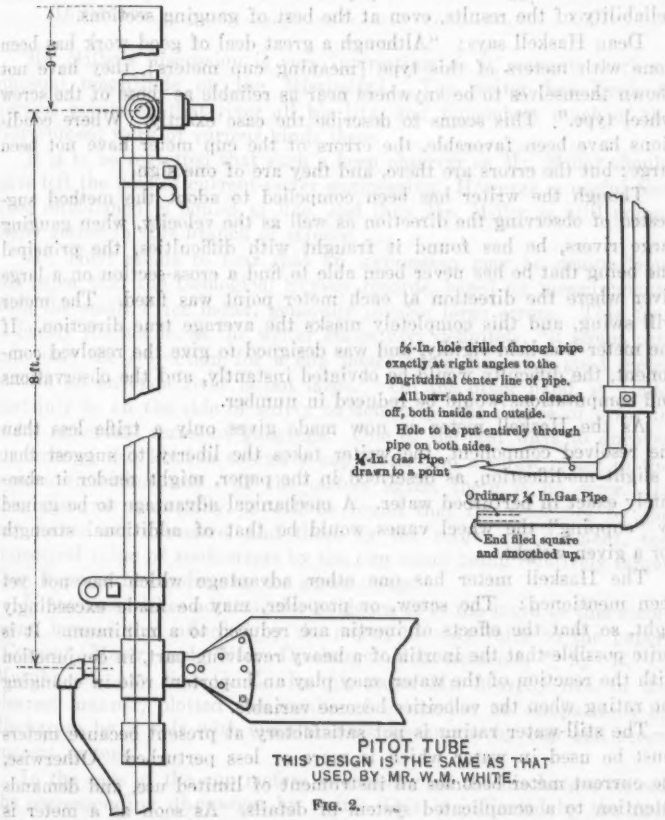


FIG. 2.

may be that gauging stations with negative velocities should not be used, but do our current meters give any indication which would lead one to discard such a station when encountered? If the meter is 4 or 5 ft. under water, it cannot be seen; but it goes on recording the velocity just the same, even if the current is directed up stream,

Mr. Groat. and the unsuspecting observer records a considerable positive velocity at the point, whereas it should have been recorded as negative.

As to the matter of divergent currents, the writer believes most fully that the problem may now be solved by using a screw meter held rigidly at right angles to the direction of flow. When the screw is modified, as suggested in the paper, it will increase still further the reliability of the results, even at the best of gauging sections.

Dean Haskell says: "Although a great deal of good work has been done with meters of this type [meaning cup meters], they have not shown themselves to be anywhere near as reliable as those of the screw wheel type." This seems to describe the case exactly. Where conditions have been favorable, the errors of the cup meter have not been large; but the errors are there, and they are of one sign.

Though the writer has been compelled to adopt the method suggested of observing the direction as well as the velocity, when gauging large rivers, he has found it fraught with difficulties, the principal one being that he has never been able to find a cross-section on a large river where the direction at each meter point was fixed. The meter will swing, and this completely masks the average true direction. If the meter was held rigidly, and was designed to give the resolved component, the difficulty would be obviated instantly, and the observations and computations would be reduced in number.

As the Haskell meter as now made gives only a trifle less than the resolved component, the writer takes the liberty to suggest that a slight modification, as described in the paper, might render it absolutely exact in perturbed water. A mechanical advantage to be gained by "cupping" the wheel vanes would be that of additional strength for a given weight.

The Haskell meter has one other advantage which has not yet been mentioned: The screw, or propeller, may be made exceedingly light, so that the effects of inertia are reduced to a minimum. It is quite possible that the inertia of a heavy revolving part, in conjunction with the reaction of the water, may play an important rôle in changing the rating when the velocities become variable.

The still-water rating is not satisfactory at present because meters must be used in water which is more or less perturbed. Otherwise, the current meter becomes an instrument of limited use, and demands attention to a complicated system of details. As soon as a meter is produced which will resolve the momentary velocities at a meter point, the still-water rating will apply, even in perturbed water. Dean Haskell is to be congratulated on the fact that his meter almost does this very thing, so that probably only slight modification will be necessary to secure the desired result.

Mr. Groat.

The float and meter comparisons are interesting. Applying the statistical method of summing the velocities in each case, the resulting comparison follows:

Sum of velocities by float	19.67
Sum of velocities by meter	19.74
Difference	0.07

Mr. Miller's discussion is very interesting, as it recounts work of unusual magnitude on the Mississippi. The writer has lived at various points on that river all his life, and remembers much of the Government work of various kinds there.

It is to be regretted that such a keen observer as Mr. Miller should have left the field of current-meter engineering. However, a useful fact once established is bound to live, and thus Mr. Miller is still potentially active in this branch of science.

Mr. Hoyt seems to fear that an impression may be drawn from the paper that the Geological Survey records, based on measurements with the small Price meter, generally involve large errors. This fear is hardly justifiable, as the writer states very definitely, "it seems certain that the correction for a cup meter when run at a good meter station on an open river is not large." On the other hand, it would certainly be on the side of safety to determine the degree of error in every important series of gaugings. One of the best ways to uncover an error of this kind is to run a cup meter and a screw meter in the section simultaneously. If the meters agree, there is no error. If they disagree materially, it will be found that the velocities by the cup meter are excessive, and those by the screw are deficient, the numerical value of such errors by the cup meter being relatively larger than those corresponding by the screw meter.

If any one wishes adminicular evidence as to the truth of this statement, beyond that afforded by the paper, he may refer to the paper, "Current Meter and Weir Discharge Measurements,"* by E. C. Murphy, M. Am. Soc. C. E. In this paper Mr. Murphy has, in the clearest manner, plotted the results of a number of comparisons of discharges by a weir with simultaneous discharges by cup and screw current meters.

In the case of the cup meters, practically all the discharges exceed the corresponding discharges by weir. This is indicated by the fact that practically all the points for the cup meters plot below the axis of abscissas in Fig. 2 of that paper.

In the case of the screw meter, the discharges are generally deficient, as the points generally plot above the axis of abscissas. Moreover, this

Transactions, Am. Soc. C. E., Vol. XLVII, p. 376.

Mr. Groat. is the more accurate meter, because the points average much closer to the axis, being in fact within 0.07% of it.

Mr. Hoyt concludes his discussion with several numbered paragraphs. They may be taken up in the same order:

1.—The paper does much more than call attention to the recognized fact that the cup meter is affected by cross-currents. It calls attention to the fact that the effect is productive of errors all on the side of excessive velocity, and that the screw meter is affected in the contrary sense, but to a relatively smaller extent. Though this was discovered by Mr. Miller years ago, it does not seem to have been recognized by anybody else since that time; but it is undoubtedly of the greatest importance to those who wish to improve the present methods of stream gauging.

Before carrying out any experiments at Massena, the writer was of the opinion that screw meters, like cup meters, would always show excessive discharges. This, he thought, would be the case because of the swinging of the meter and the consequent measurement of the thread of a sinuous, rather than of a straight, current. This, however, is incorrect. To prove it, attach a screw meter to the rating boat or rating car. Draw the meter over its course in the usual manner and count the revolutions. Then repeat the process, having all conditions the same as before, except that the meter is oscillated transversely to the direction of motion during its transit of the course. If the rating boat is used, the oscillation may be effected by rocking the boat. In the case of the car, some mechanical device may be used.

Theoretically, the number of revolutions in the latter case should exceed those in the former case. Practically, the reverse is the case. The side-wash of the current has somewhat more than annulled the effect of increasing the length of the course.

2 and 3.—It is true that the methods used by the writer in making his discharge measurements were described only in a general way. Otherwise, the paper would have become so voluminous that the main facts would have been obscured. It must be remembered that the conclusions of the paper are not derived from a study of current meters *per se*, but are inductions from observations on the behavior of meters while testing turbines.

4.—The large Price meter was adopted as one type of meter to be used in the Massena tests, because the same type had been used by other engineers in the same tail-races several years before, and a comparison was desired. The results of the turbine tests would have been the same had the small Price, or any other cup meter been used instead of the large Price meter, because means were taken to correct the errors due to deviations from the still-water ratings.

5.—The standard adopted by the writer when comparing the cup and screw meters was the true velocity of the water. This appears when

discussing Table 5, where it is shown that the cups over-register, on the average, by 5.6%, and the screw under-registers, on the average, by 0.93 per cent. Mr. Groat.

When the Pitot tube and Haskell meter were compared, the Pitot tube was supposed to indicate, on the average, the true velocity. The result of this comparison was that the Haskell meter under-registered by about 0.6 per cent.

Thus there were two different methods of determining the discharge: (*a*) by cup and screw meters corrected through the medium of the boat-rocking tests, and (*b*) by Pitot tube and screw meter comparisons by which corrections were determined to be applied to the metered discharges.

It is worthy of note that these two methods of correcting the discharge, when applied to any given turbine test, give rise to a discrepancy of scarcely 0.3 of 1 per cent.

It is not claimed that rocking the boat is the best means for ascertaining the relative errors of cup and screw meters. It is claimed that the nature of the case is such that extreme accuracy in this respect is not necessary. This is because the errors to be determined are not relatively large.

If it is feared that this paper is too daring in its conclusions to be credible, it may be well to search for independent verification. Such material may be found in Mr. Murphy's extremely valuable paper, "Current Meter and Weir Discharge Measurements," previously quoted.

Though Mr. Murphy gives an interpretation of the results of his experiments, yet he expressly states that he has "avoided in this paper a detailed comparison of results by different meters." Hence it will be permissible to analyze the results for the purpose of such a comparison.

The best method of eliminating accidental errors in comparing such a series of observations is the "statistical" method. In the case at hand, this method is particularly facile because comparable results may be obtained by the simple operation of summation.

In order the better to understand the conditions under which the tests by Mr. Murphy were conducted, it may be stated that they were made in the canal of the Hydraulic Laboratory at Cornell University. The discharge in each test was measured by weir and by two current meters. The two current meters were observed simultaneously in the same discharge section, one starting on the south side and progressing north while the other started on the north side progressing south.

There were twenty-five experiments, each made in the manner described. Ten of these were comparisons between the weir, Haskell meter No. 3, and small Price meter No. 363. Nine were comparisons between the weir, small Price meter No. 351, and small Price

Mr. Groat.

meter No. 363. Six were comparisons between the weir, Haskell meter No. 3, and small Price meter No. 351. Moreover, from these experiments may be selected sixteen in which the Haskell meter is compared with the weir, fifteen for Meter No. 351, and nineteen for Meter No. 363.

There are, therefore, six sets of experiments which may be compared statistically. In each case the aggregate discharge by the weir may be compared with the corresponding aggregate, or aggregates, by the meter, or meters, as the case may be. Table 9 gives the comparisons in tabular form.

TABLE 9.—STATISTICAL SUMMARY OF TWENTY-FIVE EXPERIMENTS BY E. C. MURPHY, M. AM. SOC. C. E., IN WHICH THE DISCHARGE OF A CANAL IS MEASURED SIMULTANEOUSLY BY A WEIR AND TWO CURRENT METERS, THE LATTER OPERATED IN THE SAME DISCHARGE SECTION.

Compiled from Table 1, *Transactions*, Am. Soc. C. E., Vol. XLVII, p. 373.

No. of experiments.	Sum of all the discharges in all experiments, as shown by weir, in cubic feet per second.	Sums of the Discharges in All the Experiments, as Shown by the Various Meters.								
		Screw Type.			Cup Type.					
		Haskell Meter.			Price Meter No. 351.			Price Meter No. 363.		
		Sum, in cubic feet per second.	Error, in cubic feet per second.	Error. Percentage.	Sum, in cubic feet per second.	Error, in cubic feet per second.	Error. Percentage.	Sum, in cubic feet per second.	Error, in cubic feet per second.	Error. Percentage.
16	3 474.78	3 473.99	− 0.79	− 0.02	.....	.....	.....	.....	.....	.....
15	3 373.67	.....	.....	.....	3 439.03	+ 65.36	+ 1.94	.....	.....	.....
19	4 186.17	.....	.....	.....	.....	.....	.....	4 238.23	+ 52.06	+ 1.24
10	2 143.64	2 147.39	+ 3.75	+ 0.18	.....	.....	.....	2 164.22	+ 20.58	+ 0.96
6	1 331.14	1 326.60	− 4.54	− 0.34	1 368.26	+ 37.12	+ 2.79	.....	.....	.....
9	2 042.53	.....	.....	.....	2 070.77	+ 28.24	+ 1.39	2 074.01	+ 31.48	+ 1.54

The function of such a summary of aggregates is to eliminate in large measure the unavoidable accidental errors arising during the observations. Thus the remaining errors are each composed of two parts, namely, a large part, which is the net average constant error of the observations, and a small part, which is the net residual of the unequated accidental errors. From the approximate uniformity of the errors of the table, it may be concluded that accidental errors have been practically eliminated, and the computed errors for the sets of observations of greatest weight (the first three sets in the table) are the constant errors due to the meters, or due to deviations from their still-water ratings. Thus the constant error of the Haskell meter is − 0.02%, that of the small Price No. 351 is + 1.94%, and that

of the small Price No. 363 is + 1.24 per cent. It may be inferred from the plottings by Mr. Murphy, on page 376 of his paper, that the average constant error of No. 351 should exceed that of No. 363. The reason for this is that the discharge by either of the meters shows an increasing excess over the discharge by the weir with decreasing velocities, and there are relatively more observations of low velocity by Meter No. 351 than by No. 363. Had the reverse been the case, it might have been expected that the constant error of No. 363 would exceed that of No. 351. Mr. Groat.

It will be seen that the error of the Haskell meter for the ten comparisons with weir and small Price meter No. 363, is + 0.18 per cent. This error, though insignificant, would have been negative had it not been for three experiments, Nos. 1-2, 3-4, and 5-6, in which this meter, for some unaccountable reason, gave discharges 4 or 5% greater than the weir. These three observations are plainly discordant, as may be seen by referring to the plottings for the Haskell meter in Fig. 2 of Mr. Murphy's paper. Had the meter run in these three experiments according to the same law as in all the other experiments, the errors for these three experiments would have been about nil. Thus the excess in discharge by the Haskell meter in the three experiments in question is about 25 cu. ft. per sec., as may be seen by consulting Table No. 1 of Mr. Murphy's paper. The aggregate for the weir from the writer's comparison, Table 9, is 3 474.78, and that for the meter would become 3 473.99 — 25.0 = 3 448.99. Thus the deficiency in the aggregate for the Haskell meter would be 3 474.78 — 3 448.99 = 25.79. In other words, it is more than probable that the discharges by the Haskell meter are deficient by the slight percentage of 25.8 ÷ 3 475 = 0.75. However, it will not do to correct or reject observations simply because they are discordant.

It follows from the results shown in Table 9 that the cup meters in all cases gave excessive discharges and the Haskell meter gave relatively much smaller errors, the discharges being slightly deficient on the average. Therefore, the following general conclusions may be drawn from the results contained in Mr. Murphy's valuable paper:

(*a*) When a cup meter is run in moderately perturbed* water, it will register a larger number of revolutions per second than a perfect still-water rating would indicate.

(*b*) When a screw meter is run in moderately perturbed water, it will register a smaller number of revolutions per second than a perfect still-water rating would indicate.

(*c*) In the foregoing sense, a cup meter is affected relatively to a much greater extent than a screw meter.

* At the bottom of page 374 of Mr. Murphy's paper it is stated that there was a slight agitation of the water during the experiments.

Mr. Groat.

(*d*) Either type of meter, when run in moderately perturbed water, will give uniform records in equal times, provided these times are sufficiently long, the flow of the water itself being subject to an established regimen.

(*e*) If both types of meter are used simultaneously in moderately perturbed water, the disparity between the discrepant velocities thus determined by the still-water rating may be taken as a basis for correcting the discrepant velocities.

(*f*) If the discharge by the weir be considered correct, the average error of the Haskell meter in Mr. Murphy's experiments was 0.02% on the side of deficiency, with a probability of its being slightly larger, and the average error of the cup meters was in the neighborhood of 1½% on the side of excessive discharge.

(*g*) It would seem to follow that current-meter observations based on still-water ratings, without further correction, should be made with great caution. On the other hand, it seems certain that the correction for a cup meter when run at a good meter station on an open river is not large, and the corresponding correction for a screw meter may be negligible.

6.—It cannot be said that the Pitot tube used at Massena was an unrated instrument. It is an exact copy of one which was investigated as "Tube *N*" by Mr. White in the paper already referred to. It has a coefficient equal to unity.

In speaking of the accuracy of Pitot tubes, two distinct reactions must be kept in mind. One is the impulse of the moving water on the dynamic orifice, the other is the reaction of the static pressure and the moving water on the static orifice. If the static orifice is properly designed, the motion of the water, or the dynamic reaction, will have no effect on it; but the motion of the water will exert either suction or a positive pressure on an improperly designed static opening. It is this latter difficulty which has caused most of the uncertainty as to Pitot tubes.

Mr. White's experiments showed, in the most convincing manner, that the coefficients of all dynamic orifices of circular section, be they cylindrical, diverging, or converging, are exactly equal to unity. This was accomplished by towing a boat through the water with a number of different types of circular dynamic orifices attached somewhat in advance of the stem. The water stood at exactly the same level in all the risers, and the total head raised was equal to the sum of the velocity head and static head in each case.

7.—Although the paper does not essay to offer at once a complete remedy for the erratic behavior of current meters in perturbed water, it does point out the interesting fact that a close estimate of the true velocity may be made by using a screw meter of good design. If still

greater accuracy is desired, both cup and screw meters may be used, the records being corrected by the observed relative deviations produced in some such manner as the rocking tests described briefly in the paper; or, even better still, the screw meter may be rated by a properly constructed and properly manipulated Pitot tube, under the exact conditions and at the exact point, or points, where the meter is to be used. Mr. Groat.

8.—The writer has oscillated a number of meters of different types, both longitudinally (up and down stream) and transversely (athwart stream and vertically). In all cases the cups were affected by increments several times as large as the decrements of the screws. This was for violent, as well as moderate, vibrations. It is true that the ratio is a variable, values ranging from 3 to 6 having been noted; but, when the error between the cup and screw is not more than 7%, the application of the extreme ratios leads to corrections for the screw meter of only 1¾ and 1 per cent. Thus, an error of 100% in the true value of the ratio makes a difference in the final discharge of only ¾% for the case cited.

This method, of course, is only a practical way of getting an approximate result, but the approximation is shown to be close.

9.—A current meter which cannot be rated with sufficient accuracy from a boat will show even greater discrepancies when run at the average gauging station. The United States Lake Survey has done a great work on the Niagara and St. Lawrence Rivers, and its ratings were frequently made from a boat. The writer knows that screw meters were used extensively on this important work, but does not know whether cup meters were also used. If the boat ratings had been unsatisfactory, it is certain that that fact would have led to a condemnation of such ratings. Possibly, if cup meters had been used, the boat ratings would have proven unsatisfactory. Of course, a rating made under laboratory conditions will plot almost exactly on a smooth curve; but a rating of a screw meter of good design will be nearly as good, if made from a boat.

It is presumed by the writer that the changes in the method of rating referred to by Mr. Hoyt were such as might be made by placing the weight too close to the wheel, or by running it near the sides, or bottom, of the tank. These are abnormal ratings, of a character which does not affect the question at hand.

10.—It has already been explained that the large Price meter was selected for the tests at Massena for the sake of comparison with the results of a former test in the same tail-races with a meter of this particular type. The writer is of the opinion that the results would have been substantially the same, even if the small Price meter had been substituted for the larger pattern. It must be emphasized that the conditions of discharge for much the greater portion of the

Mr. Groat. gauging section at Massena were as good as those most frequently encountered at a good gauging station. The reliability of these tests cannot be questioned on this account.

The cup meter ran with great fidelity at any given point in the race. Its rating there, relatively to that of the Haskell meter or Pitot tube, was perfectly definite, a fact which does not seem to have been known heretofore. The trouble was not with the cup meter, but with the application of the still-water rating to the case. A raceway of uniform section can certainly be gauged within 1% of the true discharge. This statement is made because any given condition of discharge can be exactly reproduced at the observer's pleasure. This is one of the facts demonstrated at Massena.

11.—The distribution factor used in the statistical method is essentially a form factor. Its value depends on the shape of the solid constructed out of the components of velocity which are normal to the cross-section when these components are erected at their points of application. To every shape a particular value of the distribution factor attaches, but it is not true, conversely, that to every value of the distribution factor a particular shape must attach. It is only necessary that shapes be equivalent as to discharge in order that two or more shapes may have the same value for their distribution factors. Hence it is not at all improbable that such changes of distribution actually take place at gauging sections without changing the discharge curve or rating table.

The mean velocity in the cross-section is the quotient obtained by dividing the total discharge by the area of the cross-section. The statistical method relies on this definition. In the turbine tests at Massena, the value of the distribution factor was ascertained by drawing the familiar contours of equal velocity over the cross-section of the race. The volume under these contours was computed, and, when expressed in proper units, was numerically equal to the discharge. This discharge was then divided by the area in order to ascertain the mean velocity.

By definition, the distribution factor is the ratio of the above determined mean velocity to the sum of the velocities recorded at the 42 meter points in the race. By actually computing this ratio, in the foregoing manner, for several of the turbine tests where the conditions were substantially the same, it was found that the value of the ratio—that is, of the distribution factor—was constant for given conditions. Consequently, it follows that the mean velocity in the tail-race may be ascertained simply by multiplying the sum of the observed velocities by the proper value of the distribution factor.

Though a somewhat different procedure was adopted in the Southern work, it was clearly proven that the distribution factor is a definite function of the gauge height, or stage of the river, which,

when once reduced to a curve, may thereafter be used as the quickest possible means of ascertaining the mean velocity in the gauging section. This is accomplished simply by multiplying the sum of the velocities at a given set of meter points by the corresponding value of the distribution factor, as read from its locus. Mr. Groat.

In short, it has been demonstrated by these experiments that, in current-meter work, and discharge gauging in general, one may deal with aggregates of velocity area, and discharge, instead of individual values, with a gain in accuracy, time, labor, and satisfaction, to be realized in no other way.

Take, for example, the case of an observer who has just hurried to a gauging station to measure a discharge at a particular stage of the stream. He drops his meter at two or three dozen permanently established meter points (supposing the river is, say, 250 ft. wide), adds up all his velocities, compares the sum with his statistical velocity curve, finds the sum correct, and then multiplies it by a factor taken from a curve, the product being the discharge. The whole work may be done within an hour or two. Moreover, the observer knows his work is correct, because his velocity observations are checked.

12.—It is very certain that the Geological Survey has done excellent work in studying velocity curves and in formulating therefrom a few simple laws which govern the discharge of rivers. Much of this work is due to Mr. Hoyt with whose name is linked some of the most valuable hydraulic investigations.

For the most part, the writer's studies have been connected with shallow turbulent rivers, as he is frequently compelled to examine streams of this class with regard to the character of their flow. It may be of interest to know that he has arrived at two conclusions connected therewith. They are:

(*a*) A shallow turbulent stream may be gauged satisfactorily with a screw meter, or, better still, with a cup and a screw meter simultaneously.

(*b*) The proper point in a shallow turbulent section at which to take the meter readings is at mid-depth, otherwise the meter is too near the surface or too near the bottom to admit of accuracy.

Like Mr. Hoyt, the writer has summed up the measured discharges of two or more tributaries to find a good check on the discharge of the main stream. This does not prove, however, as a necessary conclusion, that the work at any of the stations is correct, as all may be, and sometimes are, affected by the same constant error.

In reply to Mr. Staniford: The writer has had only a limited experience with the current meter in salt water, in the form of a ship's log. This instrument was of the screw type, the runner being very

Mr. Groat. similar to that of the Haskell meter. With care, such an instrument will give distances, and, therefore, velocities, well within 2%, even when the sea is agitated, assuming, of course, that there is no current or surface drift.

The Haskell meter was designed by Dean Haskell when he was working in salt water, and is adapted for use in both salt and fresh water. These meters have been used in coast harbors by officers of the U. S. Engineer Corps, and the Coast and Geodetic Survey; these officers would undoubtedly be able to state how fresh- and salt-water ratings compare.

Paper No. 1260

HYDROLOGY OF THE PANAMA CANAL.*

By Caleb Mills Saville, M. Am. Soc. C. E.†

With Discussion by Henry L. Abbot and W. E. Fuller.

A most critical and interesting period in the history of the discharge from the Chagres River Basin has just been completed, and, on account of the wide-spread interest in the Panama Canal, it seems pertinent just now to put on record certain data bearing on the hydrology and other natural phenomena of this basin. In comparatively close sequence have followed the year of minimum run-off, the year of least dry-season run-off, and the year of maximum discharge, and these and other facts relating to the water supply of the lake seem to be of especial interest at this time. In a way, this paper may be considered as an extension of the records set forth previously by A. P. Davis, M. Am. Soc. C. E.,‡ in his reports,§ and by Gen. H. L. Abbot, Engineer Corps, U. S. A. (Retired), in his several monographs on this subject. Especial attention is directed to "Problems of the Panama Canal," by the latter author, in which may be found valuable compilations of former records, some of which are not available elsewhere. These and the deductions therefrom are the careful work of a trained hydraulician, and represent painstaking investigation.

* Presented at the meeting of March 5th, 1913.

† Formerly Assistant Engineer in Charge of Third Division, Office of Chief Engineer, Isthmian Canal Commission.

‡ Chief Engineer, U. S. Reclamation Service.

§ "Hydrology of the American Isthmus," and "Hydrology of Nicaragua." (U. S. Pub. Doc.)

The data and records used in the preparation of this paper were taken from the hydrographic and meteorological files of the Isthmian Canal Commission by the kind permission of Col. George W. Goethals, Corps of Engineers, U. S. A.; M. Am. Soc. C. E., Chairman and Chief Engineer of the Isthmian Canal Commission.

Introduction.

As is generally known, the Isthmian Canal is being constructed across the Isthmus of Panama from the Caribbean Sea to the Gulf of Panama, and its location is approximately in the center of a strip of land, 10 miles wide, the use and control of which was granted in perpetuity to the United States by the Republic of Panama. This strip of land, called the "Canal Zone," stretches in a generally northwest and southeast direction, and is approximately contained between Longitude 79° 30′ and 80° 00′ west and Latitude 8° 55′ and 9° 25′ north.

Topography.

Most of that portion of the Isthmus of Panama which lies in the immediate vicinity of the Canal Zone is of little elevation above sea level, and the higher portions are either a series of more or less parallel ridges of nearly uniform height, or isolated dome-shaped hills, seemingly dropped haphazard. Along the Caribbean Coast there are many stretches of fresh swamp land, such as the Mindi Marshes southwest of Colon and reaching inland 6 or 7 miles. On both sides of the Isthmus there are also extensive salt-water shallows, mostly covered with low-growing mangroves. On the other hand, there are many bold bluffs of hard trap rock which rise abruptly from the sea, and ridges of these run back into the higher hills inland. The harbor of Porto Bello is nearly surrounded by such a barrier, and at Limon Bay, the harbor of Colon, the opposite condition appears.

On the Pacific side similar shore conditions are to be found, except that, for miles along the coast in each direction, there are no harbors which can compare with those on the Atlantic side. The main drainage of the Isthmus, of course, is dependent on the cordillera, or continental divide. About 4 miles southeast of Panama City the divide approaches within 7 miles of the Pacific shore, and for the entire distance along the southerly boundary of the Chagres Basin it is nowhere much more than 11 miles from this ocean.

The Chagres River is the largest in the Republic of Panama on the Atlantic side of the Isthmus. It has a drainage area above Gatun of 1 320 sq. miles, and between this station and the mouth of the river there are probably about 25 sq. miles of additional drainage. The Chagres discharges into the Caribbean Sea about 5 miles southwest of Toro Point, which is the northernmost limit of Canal Zone land on the westerly side of Limon Bay. Going up stream from its mouth, the course of the river is generally southeastward to Gamboa, which is about half way across the Isthmus and 35 miles from the mouth of the river. Up to this point, the rise has been very slight, the elevation of the river bed at Gamboa being only 42 ft. above sea level. The course has thus far meandered through comparatively level and oftentimes swampy bottom lands, which vary in width, to the low hills on each side. The widest stretch of this country is found in the Gatun and Trinidad marshes, lying between Gatun and Ahorca Lagarto, a swampy area about 7 miles long and from 2 to 4 miles wide, with many low, isolated hillocks scattered here and there, rising slightly above swamp level. Near Gamboa the river makes an abrupt turn almost at right angles, and the course is now generally northeastward. Its character also changes at this point, and instead of the sluggish river running through a comparatively level flood plain, with a slope of about 1¼ ft. per mile, there is now a stream, for the most part swiftly running, between banks which are the slopes of the higher hills. The Zone line is passed 40 miles above the mouth and about 5 miles above Gamboa, and the remainder of the course is in the Republic of Panama. At Alhajuela, 11 miles above Gamboa, 38½ miles above Gatun, and 46 miles above the river mouth, the bed of the stream is about 92 ft. above sea level. Twenty-four distinct rapids have been passed, and the rise has been about 50 ft. since leaving Gamboa, the average slope being about 4.6 ft. per mile between these stations. This point is approximately at proposed high-water level in Gatun Lake at its final elevation.

The climate of the Canal Zone, in a general way, has the characteristics stated by Dr. W. F. R. Phillips as belonging to the tropics:

"Unusually mild, equable, moist, warm; average temperature, 80° F.; rainfall frequent and heavy over water and over windward land exposure; nights unusually clear; afternoons cloudy; no general storms; seasons, rainy and dry, but this division only a relative one."

In regard to climatic changes and the length of time necessary for a complete cycle of fluctuation and evidence of periodicity, Willis J. Moore,* quoting Brückner, states that such a period is completed in an average of 35 years, with possible extremes of 15 years in individual cycles. Dr. W. J. S. Lockyer came to the same conclusion, using different premises from Brückner. The late George W. Rafter, M. Am. Soc. C. E.,† quoting Mr. A. R. Binnie, states that "dependence can be placed on any good record of thirty-five years' duration to give a mean rainfall correct within 2 per cent. of the truth." Mr. Rafter further states that:

"for records from twenty years to thirty-five years in length, the error may be expected to vary from 3.25 per cent. down to 2 per cent., and that for the shorter periods, of five, ten, and fifteen years, the probable extreme deviation from the mean would be 15 per cent., 8.25 per cent., and 4.75 per cent., respectively."

Station Instrumental Equipment.

Three first-class meteorological stations are in operation in the Canal Zone: Ancon, on the Pacific Coast; Culebra, in the interior on the continental divide; and Cristobal, on the Atlantic Coast. Each of these stations is equipped with the following instruments:

Standard.—Mercurial barometer, hygrometer, anemoscope, anemometer, sunshine recorder, automatic rain gauge, maximum, minimum, and standard thermometers.

Self-recording.—Thermograph, hygrograph, barograph, and meteorograph, the latter recording sunshine, rainfall, and direction and velocity of the wind.

The meteorological instruments are all of standard types, similar to those in use by the United States Weather Bureau. The Culebra station is also equipped with a maximum solar thermometer for recording the direct sun temperature, and the two coast stations have water thermographs for recording automatically the temperature of the sea water. Besides the regular meteorological stations, three wind-movement stations are maintained, at Pedro Miguel, Gamboa, and Gatun. These stations are equipped with anemometer, anemoscope, and meteorograph for recording the direction and velocity of the wind.

* "Descriptive Meteorology."
† "Water Supply and Irrigation Paper No. 80."

Twenty-five rainfall stations are maintained in the Canal Zone, and rainfall records are also received from Chepo, Chorrera, and Bocas del Toro, R. P., and from three other stations outside the Zone and at the head-waters of representative streams.

Evaporation stations are maintained at Ancon, Rio Grande, and Brazos Brook Reservoirs, and at three selected locations on Gatun Lake, and seismological stations at Ancon and Gatun. Continuous tidal records are kept at Balboa and Cristobal.

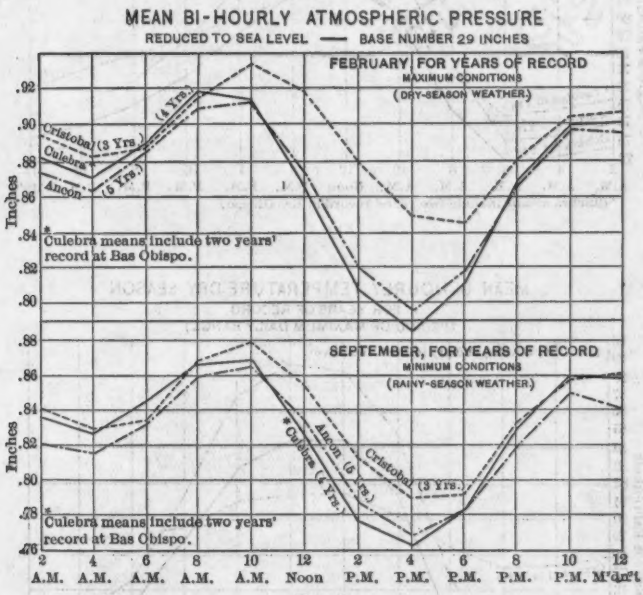

FIG. 1.

For purposes of comparison, Table 1 shows meteorological data from the three first-class stations in the Canal Zone and from Government weather reports of stations in the United States and the Philippine Islands.

EVAPORATION.

Evaporation is the name of the process by which aqueous vapor is taken up from a water surface and returned to the atmosphere. By condensation this vapor is changed back into water, and by precipita-

* Mean of bi-hourly values.
Rainfall records cover 13 years at Ancon, 20 years at Culebra, and 40 years at Cristobal.
Humidity, temperature, and wind records cover 5 years at Ancon, 4 years at Culebra, and 3 years at Cristobal.
Culebra records include 2 years at Bas Obispo.

tion the water is again returned to the earth, completing the so-called "meteorological cycle." The prevailing winds, constantly blowing over large bodies of water, keep the saturated vapor always moving on, and dry air behind it flows in, taking up in turn its load of moisture which it carries to land. When the elevation of the land is only a little above water level, there is formed a vast blanket of air thoroughly saturated and ready for any disturbance to cause it to drop its burden in the form of rain. As the air moves away from the water surface, it meets with more and more obstructions, in the form of hills and ridges, and by them is deflected upward into the colder areas. There, becoming condensed, the vapor falls to earth in the form of rain. In the regions of steadily prevailing winds like the trades, the windward slope of the mountain ranges is the one of more copious rainfall.

The laws of evaporation are probably very complex, and although much study and investigation have been given to the phenomena, no satisfactory conclusions have been reached as yet which are applicable to all conditions. The principal factors influencing evaporation are wind, temperature, and vapor pressure. In a region like the Canal Zone, where atmospheric temperature and pressure are exceedingly uniform, the effect of the wind is of paramount importance in causing variation in the rate of evaporation. The diagram, Fig. 5, shows the relation between these factors for the years of record at the Brazos Brook station. The parallelism of the evaporation and wind velocity curves is especially noticeable, as is also the inverse relationship of these curves and the lines of monthly rainfall. The air temperature curve, which is that of the monthly mean, although very uniform, still indicates a certain parallelism with the evaporation curve, while the opposite is shown in the curve of vapor pressure. The diagram, Fig. 8, shows graphically the number of days on which the evaporation at Rio Grande Reservoir and at Brazos Brook Reservoir have exceeded a stated quantity. From these curves it appears that the mean daily evaporation for dry-season conditions is about $\frac{1}{8}$ in. per day, and that this rate is only exceeded for about 80 days. This rate means a lowering of the lake by about 1.7 ft. during the entire dry season, with no allowance for increase by rainfall on the surface. The high rates are recorded for short periods—$\frac{1}{3}$ in. and more for 40 days, and $\frac{1}{4}$ in. per

day for about 10 days. The average evaporation for the 8 rainy months is about 0.11 in. per day, and during this period the rate is exceeded on only about 120 days.

Regarding the loss of water from the lake by trees growing in the shallow portions, it has been found by experience that all standing timber now growing on lands which are to be submerged will be killed by the water after 2 or 3 years, and a large area, approximately that

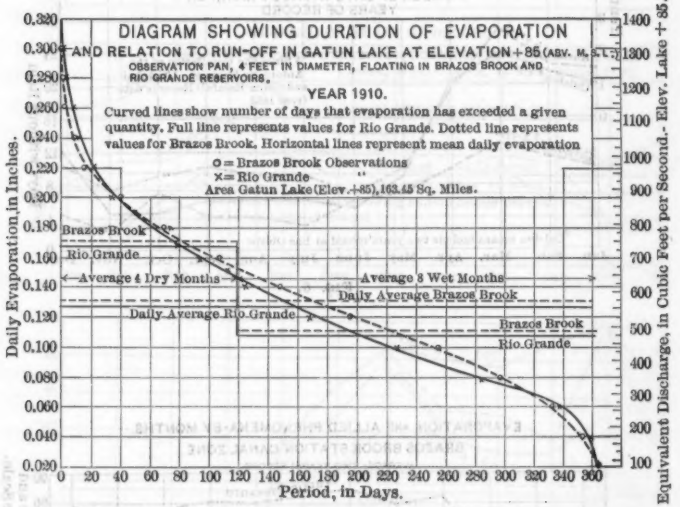

FIG. 8.

of the lake itself, will then be relieved of what must be a very large draft necessary for the support of this vegetation. Attention was first called to this gain to Gatun Lake by Lieut.-Col. H. F. Hodges, M. Am. Soc. C. E., Assistant Chief Engineer, Isthmian Canal Commission.*

The diagram, Fig. 9, shows the monthly evaporation values for Brazos Brook and Rio Grande Reservoirs, and in Table 3 may be found the monthly values for all stations. Evaporation measurements were begun on the Isthmus in 1907, and have been continued since.

* Tank floating in lake; 4 ft. diameter. † Insulated tank, protected from direct rays of

The best values are being obtained from copper pans, 4 ft. in diameter, floating in Rio Grande and Brazos Brook Reservoirs and in Gatun Lake. At these stations the evidence is being made to approximate as nearly as possible the conditions of an extensive water surface fairly exposed to all atmospheric conditions. Fig. 11 (from Annual Report, I. C. C., 1910-11) shows the evaporation apparatus at Rio Grande Reservoir, which is similar to those in use at Brazos Brook and Gatun.

In order to obtain some data regarding the relative quantities evaporated by day and by night, series of readings were taken at different stations, and the results appear in Table 5. It has seemed desirable to obtain some information as to the relative evaporation that will take place in various parts of the lake due to the differing conditions which will exist along the shore. In order to investigate this matter, three 4-ft. floating pans were placed in Gatun Lake in such locations as seemed to cover the various conditions to be anticipated. Pan No. 1 was placed in an exposed location about 1 000 ft. south of the dam and an equal distance from each shore or other obstruction.

sun; 10 in. diameter. ‡ Concrete tank, 12½ ft. diameter, 5 ft. deep.

This exposure was intended to represent ordinary conditions on the open lake. Pan No. 2 was placed among the trees of what had been a considerable forest, but which was now partly submerged by the rising waters of the lake. It is located about 500 ft. in from the edge of the forest, several trees being felled in order that the records might not be affected by rain dropping from the leaves. Pan No. 3 was placed in the center of an area of tall water grass, about ½ acre in extent. Such a growth as this will be very frequent along the shallow portions of the shore. In the last two exposures it appears that the action of the wind is a very great factor in determining the quantity of evaporation. It also demonstrates that the action of the shore growth will be that of a wind-break, and that the evaporation figures based on data collected from exposed locations are on the safe side, that is, probably they will give too great an evaporation. Table 4 shows the results obtained since the installation of the pans.

The equipments at Rio Grande, Brazos Brook, and Gatun consist of the following measuring instruments:

A copper pan, 4 ft. in diameter and 10 in. deep, floating in the

water, for evaporation; an anemometer, for wind movement directly over the evaporation pan; a rain gauge, for rainfall; a thermometer, for water temperatures, and maximum and minimum thermometers, exposed in an instrument shelter of the regular type located on the shore close by, for recording the air temperatures.

The evaporation pan is set in a light wooden frame, properly buoyed, which serves to keep the top of the pan above the surface of the water in the lake, as well as to prevent occasional waves from splashing over into the pan. The pan rests with its bottom and sides submerged in the water, thus insuring that the temperature of the water within the pan at all times will be very close to that of the water at the surface. The float is located at a considerable distance from shore, for the purpose of getting an exposure which represents actual average conditions.

A sharp-pointed, copper-wire index is set in the center of the pan and inside a perforated copper cylinder still-box which serves to reduce the wave motion of the surrounding water, and thus permits more accurate readings of the daily evaporation. The index point is 4 in. below the top of the pan, and it follows that the usual height of the water in the pan is also approximately 4 in. below the top. This arrangement is necessary to prevent the overflow of the pan during heavy rains.

* 11 months, 1908; Cristobal, 6 months, 1911.
Readings taken at 8.00 A. M. and 8.00 P. M. daily.
Mean of all observations, 59% day and 41% night.

The pan is set by bringing the surface of the water exactly to the level of the point of the copper index. When the evaporation measurements are made, 24 hours later, if there has been no rainfall, the surface of the water in the pan will be found below the index point. The quantity of water necessary to raise the water surface to the level of the index point is carefully measured and poured into the pan. This quantity of water, expressed in thousandths of an inch over the surface of the evaporation pan, equals the evaporation for the previous 24 hours. When the rainfall during the day has exceeded the evaporation, the surface of the water in the pan will be found above the point of the copper index. The excess water must be removed from the pan and measured. In this case the difference between the rainfall and the quantity of water removed from the pan, expressed in thousandths of an inch, equals the evaporation for the previous 24 hours. When rain occurs during the day, but is less than the evaporation, the sum of the rainfall and the quantity of water poured into the pan, expressed in thousandths of an inch, equals the evaporation. The water poured into or removed from the evaporation pan is measured in a copper measuring tube having exactly $\frac{1}{100}$ of the cross-section

area of the evaporation pan. Depths are measured with the regular rainfall measuring stick, graduated to inches and tenths; $\frac{1}{10}$ in. in the measuring tube represents $\frac{1}{1000}$ in. over the surface of the evaporation pan.

Table 5 shows the quantities of evaporation, by day and by night, that have been recorded at the several stations on the Canal Zone, together with the relative percentages. The mean of the entire series is 59% by day and 41% by night.

Besides the direct loss due to the run-off by evaporation from water surfaces, a large percentage of the rainfall is still unaccounted for, which is aptly called "retention" by Professor D. W. Mead,* M. Am. Soc. C. E.; part of this is used by vegetation and transpired by the leaves, part is retained in the ground and returned to the stream at periods of low rainfall, and a portion is permanently lost to the watershed either by deep percolation or, as is sometimes the case, by meeting a permeable stratum which conducts it to another basin. This latter cause, however, is usually relatively unimportant, but should not be overlooked in the examination of a water supply. In the Gatun Lake Basin, due to the practically impervious argillaceous sandstone and other rocks of similar character which appear to underlie the entire lake area, permanent loss of water to the basin is probably too small for any consideration, and is neglected hereafter in this paper. The following shows the portion of the rainfall unaccounted for in certain northern streams:

Rivers.	Portion of rainfall unaccounted for.
Hudson, N. Y.	52 per cent.
Sudbury, Mass.	49 " "
Croton, N. Y.	46 " "
Wisconsin, Wis.	65 " "
Chippewa, "	50 " "
Rock, "	21 " "

In his treatise on water supply engineering, the late J. T. Fanning, M. Am. Soc. C. E., has given values from investigations at Emdrup, Denmark, from which the following is deduced:

* "Flow of Streams and the Factors that Modify It," *Bulletin No. 425*, Univ. of Wisconsin.

	Mean evaporation.	Ratio to water evaporation.
Water surfaces, mean evaporation (annual)	27.9 in.	1.00
Short grass	30.1 "	1.08
Long grass	44.0 "	1.58
From Bradmore's "Hydrology."		
Lancashire, England, Lat. 53° 30′ N., from earth	25.7 "	....
Cumberland, England, Lat. 54° 34′ N., from earth	29.2 "	....

Investigations by Risler concerning the quantity of water required for different crops* are tabulated below, and give the daily consumption of water for various crops:

Lucerne grass	from 0.134	to 0.267 in.
Meadow "	" 0.122	" 0.287 "
Oats	" 0.140	" 0.193 "
Indian corn	" 0.110	" 1.570 "
Clover	" 0.140	" .... "
Vineyard	" 0.035	" 0.031 "
Wheat	" 0.106	" 0.110 "
Rye	" 0.091	" .... "
Potatoes	" 0.038	" 0.055 "
Oak trees	" 0.038	" 0.030 "
Fir trees	" 0.020	" 0.043 "

Mr. Tweeddale states as his opinion that cereals and grasses, from seed time to harvest, will take up, respectively, from 15 to 37 in.

In his report on water supply, Mr. C. C. Vermeule has used the following factors for the water required by various crops in one growing month:

Crop.	Inches.
Forest (oak and chestnut)	1.2
Wheat, rye, oats, etc	3.5
Indian corn	4.5
Potatoes, etc	1.2
Long grass	6.0

* Quoted by W. Tweeddale, Kansas State Board of Agriculture, December 31st, 1889.

Crop.	Inches.
Short grass	5.0
Orchards	3.0
Fallow lands, etc	4.0

In investigation work at Pomona, Cal.,* the following duty has been required of the water used on various crops for the average year (1906-09):

Citrus fruits (oranges and lemons)	2.94 ft.
Deciduous fruits and miscellaneous crops	2.58 "
Alfalfa	4.6 "

Although these figures do not show the quantity of water that similar crops would use were they entirely dependent on natural supply, they do indicate the relative quantities that such crops demand for the best conditions, and the quantity they might use if it were available. The depth of water used on a 21½-acre apple orchard in Wenatchee, Wash.,† was found to be 23 in. during the year, the trees being 7 years old and producing heavily. Mr. Samuel Fortier‡ states that the results of experiments have shown that, where water is applied to the surface of orchard soils, the evaporation is very great as long as the top layer remains moist. Even in light irrigation, the loss in 48 hours after the water is put on may amount to from 10 to 20% of the volume applied. Mr. W. W. McLaughlin,§ in discussing the irrigation of grain, states that it is always safe to assume that the ranker the growth of straw the greater will be the quantity of water required. He also says that the total depth of water applied to grain crops on the older lands will vary from 1 to 8 ft., depending on the porosity of the soil and the climate of the place, average depths of 2 and 3 ft. representing the quantities required, respectively, in cool and warm climates. Field peas‖ in an average irrigation season of 42 days are shown to have required about 4.7 in., or about 0.112 in. per day.

The foregoing figures, though not exact, and applying to crops and conditions elsewhere and under different climatic conditions, are nevertheless instructive in obtaining some idea of the quantity of water which must be required by the rank and lush vegetation of this

tropical country. With all its heavy precipitation, were it not for the steep hillsides, and consequent quick discharge of the waters, it is doubtful if the ratio of run-off to rainfall might not even be less here than in countries where the rainfall is smaller but the vegetation less luxuriant.

E. Oppokov* states that marshes are a detriment to the drainage area of a water supply system. It is ordinarily thought that such areas are valuable for the storage of water in the rainy season, and that during the dry period they allow of a gradual discharge, which increases the stream flow. Having studied the features of the Dnieper and adjoining rivers, Mr. Oppokov believes that his investigations prove there is intensified evaporation from marsh areas in periods of drought, which not infrequently results in the total drying out of the marsh. These areas then act as a great sponge for the absorption of subsequent precipitation and seepage waters from the uplands, and cause decreased returns of the waters to the rivers, the run-off being actually lessened thereby.

In the case of the Gatun Lake water-shed, there will probably be an increase in run-off when the swamp areas are eliminated by submergence. Under present conditions, these areas annually absorb large quantities of the rainfall to make up for the depletion caused by evaporation and plant necessity. After submergence, the trees and other vegetation will die off, and the ground will become saturated once for all. Subsequent rainfall will then be available for lake purposes. Such conditions will be especially appreciated during periods of light rainfall, when the demands of vegetation are greatest.

The fact that a considerable rainfall may occur with little run-off from a basin overgrown with vegetation, and that the daily evaporation from a water surface is relatively small in comparison with the precipitation, is an indication that the available run-off will be increased. For river regulation and the prevention of floods, this condition might present an aspect entirely different from what it has when applied to the conservation of the water. The well-sustained run-off from the area above Alhajuela is due, not only to its large rainfall, but probably also to the absence of swamps with their shallow storage, and the presence of an extensive limestone formation. This latter undoubtedly allows the deep storage of large quantities of water during the rainy season,

* *Russ. Jour. Expr.*, Landau, 1910, pp. 369-372.

which, as the dry season proceeds, is given off for the benefit of river discharge. The swamp and the limestone storage, although both classed as underground, to distinguish them from surface water, are nevertheless entirely distinct in their tendencies. The former is shallow and readily affected by the agencies producing evaporation, including plant demands; the latter, deep and far removed from the surface losses, is all available for stream flow, if it can but find an outlet.

An excellent example of this latter condition is found in a limestone cliff overhanging the Chagres River above Alhajuela. Here is a nearly perpendicular wall, more than 100 ft. above the river surface, and having a length of more than 500 ft. This whole surface, more or less covered with moss and clinging vegetation, is constantly and copiously dripping with water during the entire year. The contour surveys and explorations have shown that there are no extensive swamp areas in the Chagres River Basin above Elevation + 60, and it seems fair to presume that, when the lake has reached its final elevation, hydrographic conditions similar to those now observed for the area above Alhajuela will obtain elsewhere, modified by local conditions of rainfall.

The geological and topographical investigations which have been made in the lake area and its drainage basin seem to give assurance of exceedingly favorable conditions for the collection of the water supply and its conservation. The lower part of the Chagres Basin, as has been stated, is underlaid by argillaceous sandstone, and this is the principal constituent in the ridges bordering the lake. Nearly the entire bottom of the lake, up to about Elevation + 30, is covered with a deposit of alluvium, which is also practically impervious. This cover, about 51 miles in extent, and of varying thicknesses up to several hundred feet, presents an additional safeguard against bottom seepage, and at the place where, if needed at all, it will be of most service, namely, in the deepest parts of the lake. Above this impervious covering is found the residual deposit overlying the impervious argillaceous sandstone from which it was derived. The characteristics of this surface layer are its more or less claylike nature at the extreme surface, and its sandy and less cohesive structure as it approaches the solid rock. The nature of this argillaceous sandstone is to crumble and break down to a fine clay where mostly exposed to the weather, the

particles becoming larger and more firm with distance from the surface. The result of this quality is that there is an extensive layer of more or less open structure overlying the impervious rock, capable of storing large quantities of water, and well protected from surface evaporation. From this layer comes the well-sustained flow that appears in many streams during periods when there is little or no rain. This formation also gives additional storage capacity to the lake, so that demands on it will be honored in excess of visible storage. Such condition has been found in the case of the Rio Grande Reservoir, and will be commented on later. What this storage may be is unknown at present, and can only be determined after the lake is filled. This quantity should not be considered in calculations affecting the water supply, but should be left as an asset to be applied to any losses which may have been overlooked or under-estimated.

Rainfall.

The cause of rainfall is to be found in the operation of certain general principles of physics, but is influenced more or less by local conditions. Rainfall is due to the precipitation of the water vapor in the atmosphere which has been derived primarily from the ocean by the process of evaporation. No matter how far this vapor may be driven by the winds, in the course of time the water returns again to the ocean. Evaporation takes place from the surface of every body of water, from the ground, and from vegetation. Whenever for any cause the moisture-laden air is cooled, condensation and consequent precipitation take place.

According to Curtis, three different processes are primarily concerned in the production of rain, acting either singly or in combination. These factors are:

1.—Convective currents;
2.—Hills and mountains which cause deflection of atmospheric currents; and
3.—Cyclonic circulation.
